There are interesting observations that one can make regarding this reconstruction. One is that, generally speaking, the brain appears smoother in it than in the phantom. This is because the FBP algorithm that we use was designed to perform efficaciously on real data and it does some smoothing to counteract the effect of noise. Consequently, small variations due to inhomogeneity are also smoothed. The most noticeable features in the reconstruction that are not present in the phantom are the streaks that seem to emanate from straight interfaces between the skull and the brain. (Similar features are observable in the real reconstruction shown in Fig. 15.) Their presence can be explained by considering Radon's formula (1), which expresses the distribution of the linear attenuation coefficient in terms of its line integrals. Consider an ℓ and a θ such that $m(\ell, \theta)$ is the integral along a line that is very near to a straight edge between the skull and the brain. Due to the fact that attenuation is much larger for bone than for brain, numerical estimation of the partial derivative $m_1(\ell, \theta)$ from the discretely sampled projection data is likely to be inaccurate, introducing errors into the calculated reconstruction. Phantoms that lack such anatomical features should not be used for algorithm evaluation, since the resulting reconstructions do not indicate the errors that will occur in a real application in which the object to be reconstructed is likely to have such straight interfaces. This is illustrated in Fig. 21.

The reconstructions shown in Figs. 20 and 21 are from “perfect” data; i.e., from line integrals based on the geometrical description of the phantoms. When data are collected by an actual CT scanner there are many physical reasons why the data so obtained can only provide approximations to such line integrals. In testing reconstruction algorithms we should use realistic projection data, which is what was done for the remaining two-dimensional reconstructions in this chapter. The exact method of simulated data collection (using SNARK09 [12, 37]) is described in Section 5.8 of [23], here we just give an outline. The data were collected for the head phantom shown in Fig. 20a according to the standard geometry. For

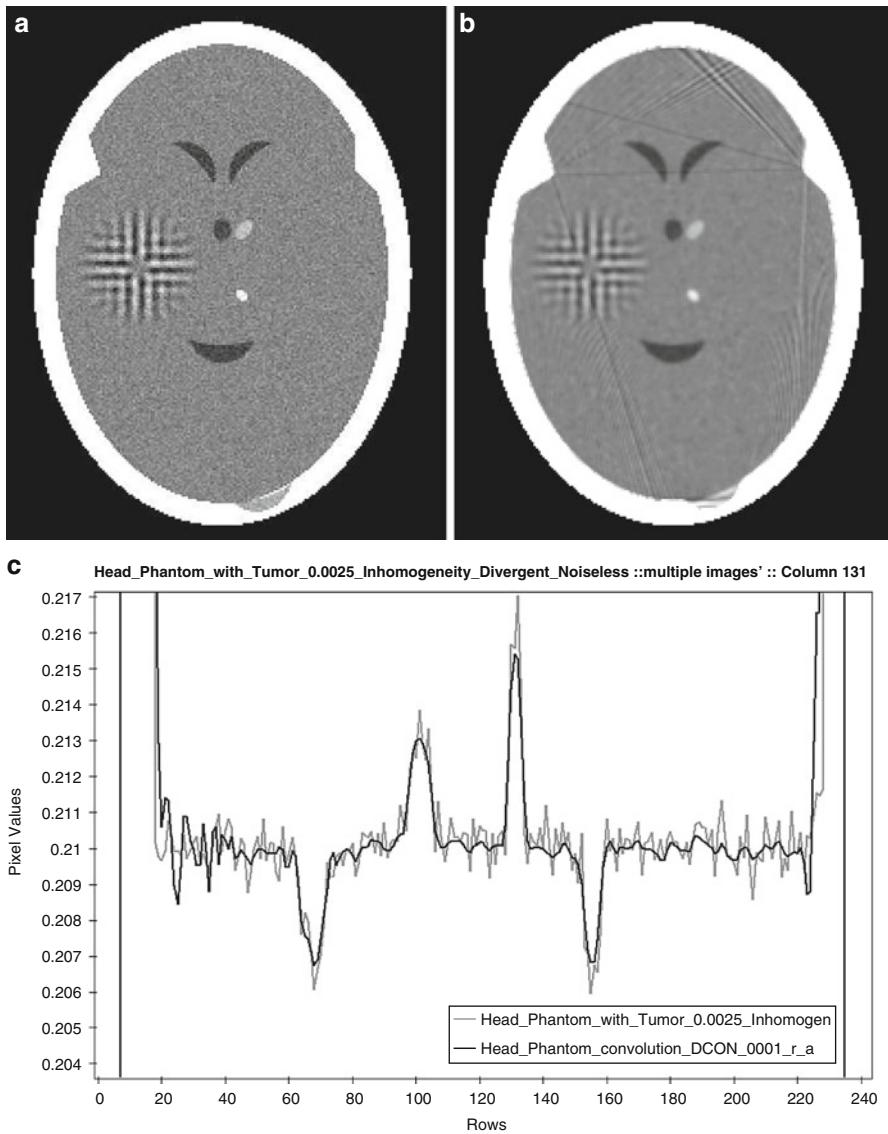

Fig. 20 (a) Head phantom (the same as Fig. 18a). (b) Its reconstruction from “perfect” data collected for the standard geometry. (c) Line plots of the 131st column of the phantom (*light*) and the reconstruction (*dark*) (reproduced from [23])

photon statistics we chose an average of million X-ray photons originating in the direction of each detector during the scanning of the head. A realistic spectrum of the polychromatic X-ray source was also simulated. The focal spot of the X-ray source was assumed to be a point, but the detectors were assumed to have width of

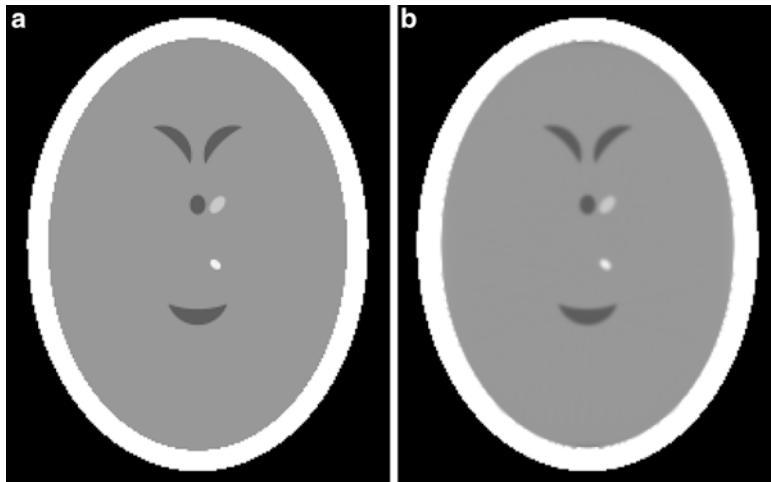

Fig. 21 (a) A simple head phantom without straight edges between bone and brain. (b) Its reconstruction from “perfect” data collected for the standard geometry. In this reconstruction there are no false features of the kind that emanate from the straight edges in Fig. 20b (reproduced from [23])

0.10668 cm (i.e., there are no gaps between the detectors). It was assumed that the number of scattered photons that are counted during the measurements is 5 % of the number of unscattered photons that are counted. The data so obtained was corrected for beam-hardening, to provide us with an estimate of the monochromatic projection data. The outcome of this correction is what we refer to as the *standard projection data*. For the experiments involving statistical evaluation, the same assumptions were made except that the phantom was randomly selected from the previously described ensemble; for an example, see Fig. 19a. Our illustrations are restricted to demonstrating the effects of various choices that can be made in ART and the comparison of ART with FBP.

We start with the variant of ART described by (23) and (24). We choose $x^{(0)}$ to represent a uniform picture, with the estimated (based on the standard projection data) average value of the phantom assigned to every pixel. (The estimation of the average value from projection data is described in Section 6.4 of [23].)

We first show that the order of equations in the system (the data access ordering discussed in the previous section) can have a significant effect on the practical performance of the algorithm, especially on the early iterates. With data collection such as the geometry depicted in Fig. 9, it is tempting to use the *sequential ordering*: access the data in the order $g(-N\lambda, 0), g((-N+1)\lambda, 0), \dots, g(N\lambda, 0), g(-N\lambda, \Delta), g((-N+1)\lambda, \Delta), \dots, g(N\lambda, \Delta), \dots, \dots, g(-N\lambda, (M-1)\Delta), g((-N+1)\lambda, (M-1)\Delta), \dots, g(N\lambda, (M-1)\Delta)$, where $g(\sigma, \beta)$ denotes here the measured value of what is mathematically defined in (5). However, this sequential ordering is inferior to what is referred to as the *efficient ordering* in which

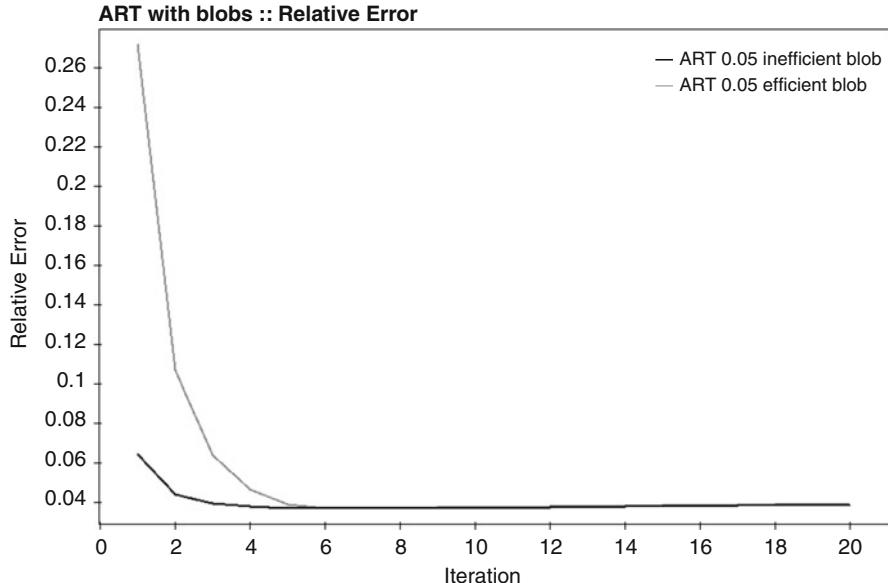

Fig. 22 Values of the picture distance measure r for ART reconstructions from the standard projection data with sequential ordering (*light*) and efficient ordering (*dark*), plotted at multiples of I iterations (reproduced from [23])

the order of projection directions $m\Delta$ and, for each view, the order of lines within the view is chosen so as to minimize the number of commonly intersected pixels by a line and the lines selected recently. This can be made mathematically precise by considering the decomposition into a product of prime numbers of M and of $2N + 1$ [27]. SNARK09 [12,37] calculates the efficient order, but this is only useful if both M and of $2N + 1$ decompose into several prime numbers, as is the case for our standard geometry for which $M = 720 = 2 \times 2 \times 2 \times 2 \times 3 \times 3 \times 5$ and $2N + 1 = 345 = 3 \times 5 \times 23$. While the sequential ordering produces the sequences $m = 0, 1, 2, 3, 4, \dots$ and $n = 0, 1, 2, 3, 4, \dots$, the efficient ordering produces the sequences $m = 0, 360, 180, 540, 90, \dots$ and $n = 0, 115, 230, 23, 138, \dots$. These changes in data access ordering (keeping all other choices the same) translate into faster initial convergence of ART, as is illustrated in Fig. 22 by plotting the picture distance measure r of (33) against the number of times the algorithm cycled through all the data (all I equations). To produce this illustration we used blob basis functions and $\lambda^{(k)} = 0.05$, for all k . While it is clearly demonstrated that initially r gets reduced much faster with the efficient ordering, for the standard projection data it does not seem to matter much, since both orderings need about five cycles through the data to obtain a near-minimal value of r . In other applications in which the number of projection directions is much larger (e.g., in the order of 10,000 as is often the case in electron microscopy), one cycle through the data using the efficient ordering yields about as good a reconstruction as one is likely to get, but the

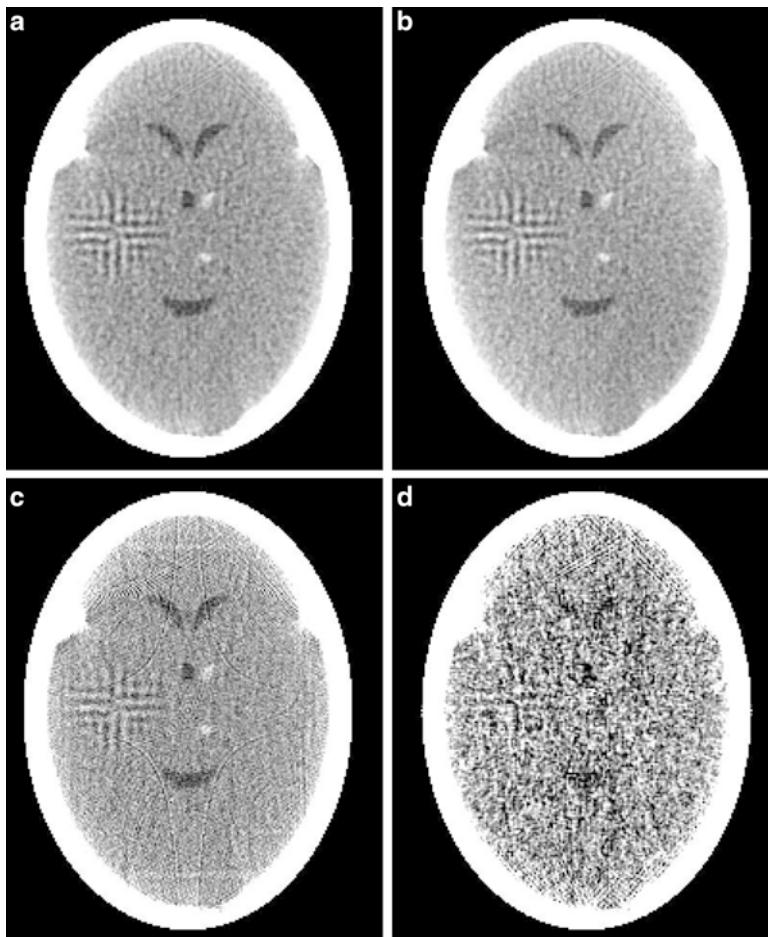

Fig. 23 Reconstructions from the standard projection data using ART. (a) ART with blobs, $\lambda^{(k)} = 0.05$, 5 I th iteration and efficient ordering. (b) ART with blobs, $\lambda^{(k)} = 0.05$, 5 I th iteration and sequential ordering. (c) ART with pixels, $\lambda^{(k)} = 0.05$, 5 I th iteration and efficient ordering. (d) ART with blobs, $\lambda^{(k)} = 1.0$, 2 I th iteration and efficient ordering (based on Fig. 11.4 of [23])

sequential ordering needs several cycles through the data. In addition, the efficacy of the reconstruction produced by the efficient ordering may very well be superior to that produced by the sequential ordering.

This is illustrated in Fig. 23 and Table 1. The reconstructions produced by the efficient and sequential orderings after five cycles through the data (the images of $x^{(5I)}$) are shown in Figs. 23a and b, respectively. Visually there is hardly any difference between them. This is confirmed by the picture distance measures in Table 1, they are only slightly better for the efficient ordering than for the sequential ordering. On the other hand, the execution time (within the SNARK09 [12, 37]

Table 1 Picture distance measures and timings (in seconds, of the implementations in SNARK09) for the reconstructions in Figs. 23 and 25

| Reconstruction in | d | r | t | IROI |
|-------------------|--------|--------|-------|--------|
| Figure 23a | 0.0874 | 0.0373 | 163.7 | 0.1794 |
| Figure 23b | 0.0876 | 0.0391 | 148.9 | 0.1624 |
| Figure 23c | 0.0874 | 0.0470 | 29.2 | 0.1592 |
| Figure 23d | 0.0768 | 0.0488 | 66.2 | 0.1076 |
| Figure 25b | 0.1060 | 0.0423 | 8.7 | 0.1677 |

The last column reports the values, produced by a task-oriented evaluation experiment, of the IROI for the various algorithms (based on Table 11.1 of [23])

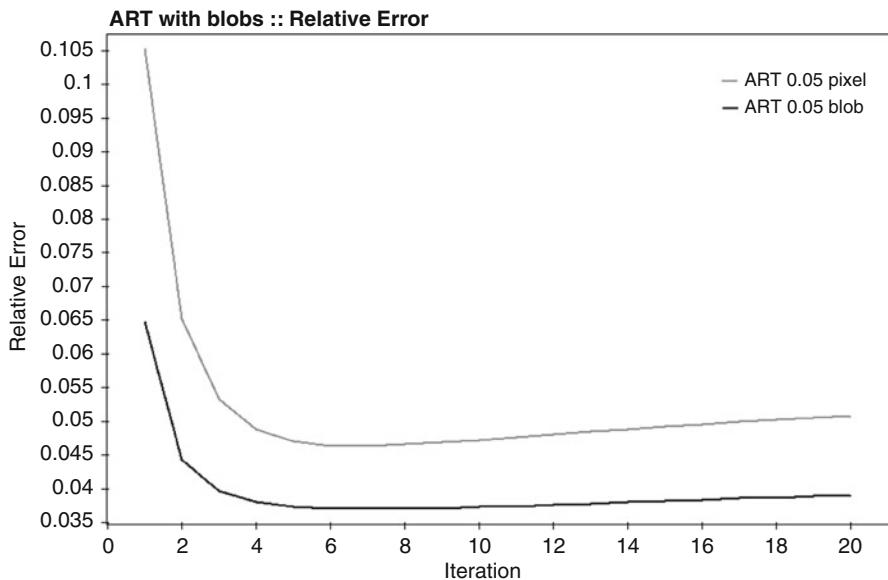

Fig. 24 Values of the picture distance measure r for ART reconstructions from the standard projection data with pixels (light) and blobs (dark), plotted at multiples of I iterations (reproduced from [23])

environment) is somewhat less for the sequential ordering. However, the task-oriented evaluation is unambiguous in its result: the IROI is larger for the efficient ordering and the associated P -value is less than 10^{-9} . This means that we can reject the null hypothesis that the two data access orderings are equally good in favor of the alternative hypothesis that the efficient ordering is better with extreme confidence.

Next we emphasize the importance of the basis functions. In Fig. 24 we plot the picture distance measure r against the number of times ART cycled through all the data, where we kept all other choices the same (in particular, efficient data access ordering and $\lambda^{(k)} = 0.05$, for all k). The two cases that we compare are when the basis functions are based on pixels (10) and when they are based on blobs (12). The results are impressive: as measured by r , blob basis functions are much better. The

result of the $5I$ th iteration of the blob reconstruction is shown in Fig. 23a, while that of the $5I$ th iteration of the pixel reconstruction is shown in Fig. 23c. The blob reconstruction appears to be clearly superior. In Table 1 we see a great improvement in the picture distance measure r but not in d . This reflects the fact, not visible in our display mode, that there are a few but relatively large errors in the blob reconstruction near the edges of the bone of the skull. From the points of view of the task-oriented figure of merit IROI, ART with blobs is found superior to ART with pixels with the relevant P -value less than 10^{-10} . As implemented in SNARK09, ART with blobs requires significantly more time than ART with pixels, but there exist more sophisticated implementations of ART with blobs that are much faster.

Underrelaxation is also a must when ART is applied to real, and hence imperfect, data. In the experiments reported so far $\lambda^{(k)}$ was set equal to 0.05 for all k . If we do not use underrelaxation (that is, we set $\lambda^{(k)}$ to 1 for all k), we get from the standard projection data the unacceptable reconstruction shown in Fig. 23d. Note that in this case we used the $2I$ th iterate, further iterations give worse results. The reason for this is in the nature of ART: after one iterative step with $\lambda^{(k)} = 1$, the associated measurement is satisfied exactly as shown in (25) and so the process jumps around satisfying the noise in the measurements. Underrelaxation reduces the influence of the noise. The correct value of the relaxation parameter is application dependent; the noisier the data the more we should be underrelaxing. Note in Table 1 that the figure of merit IROI produced by the task-oriented study for the case without underrelaxation is much smaller than for the other cases.

Now we compare the best of our ART reconstruction (Fig. 23a, reproduced in Fig. 25a) with one produced by a carefully selected variant of FBP, see (6)–(9). For comparison, we show in Fig. 25b the reconstruction from our standard projection data obtained by FBP for divergent beams with linear interpolation and sinc window (also called the Shepp–Logan window, see [56]). For details of the meanings of these choices and the reasons for them, see Chapter 10 of [23]. The visual quality is similar to the best ART reconstruction. According to the picture distance measures in Table 1, ART is superior to FBP, and the same is true according to IROI with extreme significance (the P -value is less than 10^{-13}). This experiment confirms the reports in the literature that ART with blobs, underrelaxation and efficient ordering generally outperforms FBP in numerical evaluations of the quality of the reconstructions.

One thing though is indisputable: the ART with blob reconstruction took nearly 19 times longer than FBP. However, this should not be the determining factor, especially since the implementation of ART with blobs in SNARK09 is far from optimal and can be greatly improved. An advantage of ART over FBP is its flexibility. Even though until now we have reported its application only to data collected according to the standard geometry, ART is capable of reconstructing from data collected over any set of lines, as we soon demonstrate by an example of using ART for helical CT. FBP-type algorithms need to be reinvented for each new mode of data collection.

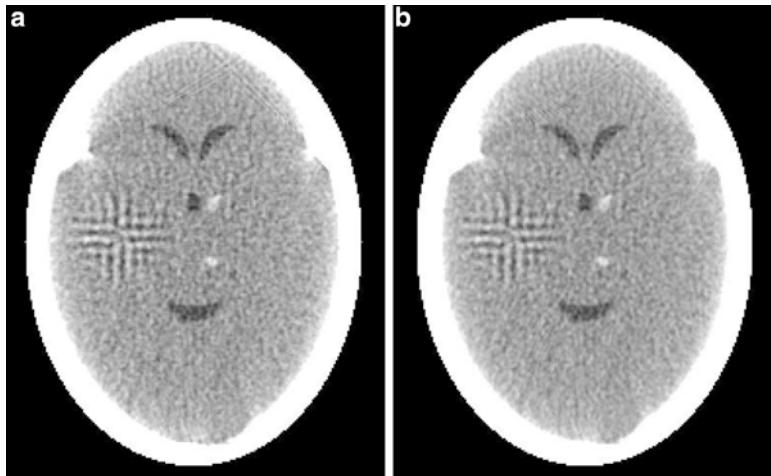

Fig. 25 Comparison of reconstructions from the standard projection data using (a) ART (the same as Fig. 23a) and (b) FBP (based on Fig. 11.4 of [23])

We now switch over to demonstrating the ART algorithm specified in (30) and (31). As stated before, that algorithm converges to the Bayesian estimate that is the minimizer of (29), provided that the condition expressed in (27) holds. This is the case if we set $\lambda^{(k)} = 0.05$, for all k , which is what we chose for the experiments on which we now report. The other choices that we made are blob basis functions, efficient ordering and that, in (29), $t = 10$ and μ_X represents a uniform picture with the estimated average value of the phantom assigned to every component.

There are alternative methods in the literature for minimizing (29), a particularly popular one is the method of *conjugate gradients* (CG); for a description of it that is appropriate for our context, see Section 12.5 of [23]. The CG method is also an iterative one, but one in which all the data are considered simultaneously in each iterative step. For this reason, the time of one iterative step of the CG method is approximately the same as that needed by ART for one cycle through all the data. In Fig. 26 we show a comparison of the picture distance measure r for CG and for ART.

Figure 26 and the picture distance measures in Table 2 imply that the quality of the reconstruction obtained by the 20th iterate of the conjugate gradient method should be as good as that obtained by the 51th iterate of additive ART. However this is not really so, as can be seen by looking at the reconstructed image in Fig. 27b. Indeed it needs another 20 iterations of the conjugate gradient method before the visual quality of the reconstruction matches that of the ART of (30) and (31) after 51 iterations, shown in Fig. 27a. So (for the standard projection data) the conjugate gradient method is not as fast as ART. This slower convergence of conjugate gradients relative to ART seems to be shared by other series expansion

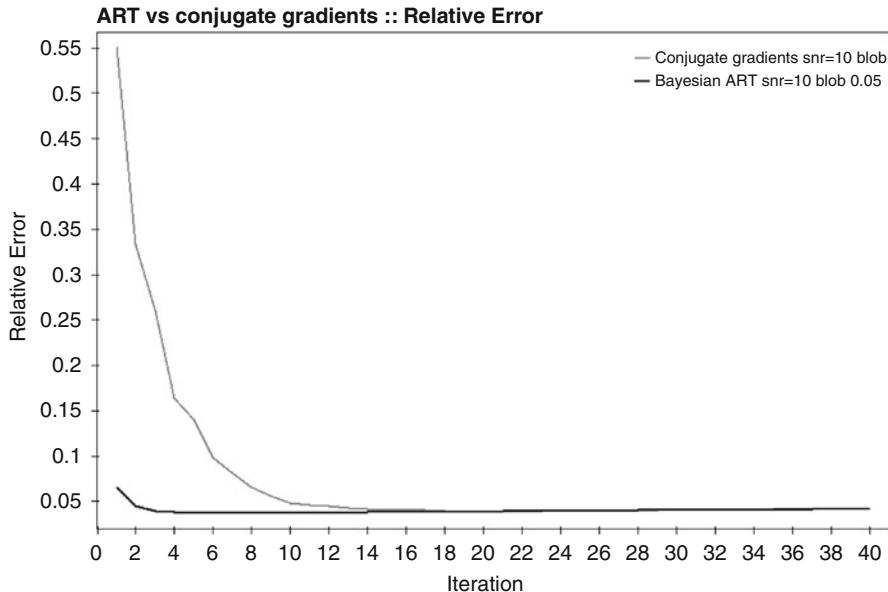

Fig. 26 Values of the picture distance measure r for reconstructions from the standard projection data using the conjugate gradient method (light) and ART (dark), plotted for comparable computational costs (reproduced from [23])

Table 2 Picture distance measures and timings (in seconds) for the reconstructions that minimize (29)

| Algorithm | d | r | t |
|---|--------|--------|-------|
| ART, 51th iterate | 0.0878 | 0.0374 | 166.5 |
| Conjugate gradient method, 20th iterate | 0.0799 | 0.0387 | 489.1 |

Based on Table 12.2 of [23]

reconstruction methods that use all the data simultaneously in each iteration; see, for example, [58].

If we wish to reconstruct a three-dimensional body by the methods discussed till now, the only option available to us is to reconstruct the body cross section by cross section and then stack the cross sections to form the three-dimensional distribution. This may cause a number of problems, the most important of which are associated with time requirements. During the time needed to collect all the data, the patient may move, causing a misalignment between the cross sections. More basically, in moving organs such as the heart, changes in the organ over time are unavoidable, and it is usually not possible to collect data for all cross sections simultaneously.

Sometimes, it is actually the change in the object over time that is the desired information. If we wish to see cardiac wall motion, then it is essential that we reconstruct the whole three-dimensional object at short time intervals. One may consider this as a four-dimensional (spatio-temporal) reconstruction. One approach

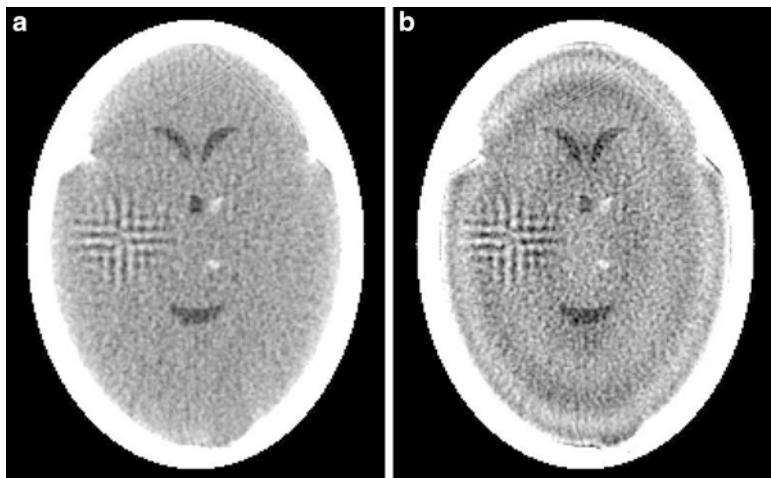

Fig. 27 Reconstructions from the standard projection data using iterative methods that minimize (29). (a) ART, 51th iterate. (b) Conjugate gradient method, 20th iterate (based on Fig. 12.2 of [23])

to obtaining reconstructions of dynamically moving objects, such as the heart, from data that can be collected by helical CT (see Fig. 8) is to assume that the movement is cyclic. Assuming also that there exists a way of recording where we are in the cyclic movement as we take the 2D views of the moving 3D object, it is possible to bin the views into subsets such that all views that are binned into any one of the subsets have been taken at approximately the same phase of the cyclic movement, and so they are views of approximately the same (time frozen) 3D object. In the case of the heart this can be done by recording the electrocardiogram and noting on it the times when views have been taken. These views can then be binned, after the fact, according to the phases of the cardiac cycle.

We complete this section by giving a summary of such experiments, details can be found in Chapter 13 of [23]. The reconstructions were done by ART (here we made good use of the fact that ART does not require any particular arrangement of the lines for which the data were collected), using three-dimensional blobs [41] as the basis functions. We designed a phantom of the human thorax based on the description of the so-called FORBILD thorax phantom. We added to that stationary phantom two dynamically changing spheres representing the myocardium and a single contrast material filled cavity. We assumed that we are interested in this phantom at 24 equally spaced (in time) phases of the cardiac cycle. The first row of Fig. 28 shows a central cross section of this dynamic phantom at the two extremes of the 24 phases.

Projection taking was done by integrating the density of the phantom along lines between the X-ray source position and detectors in a two-dimensional array. For every source position, data were collected for 384 equally spaced detectors in each of 16 rows in the array. The size of each detector was assumed to be

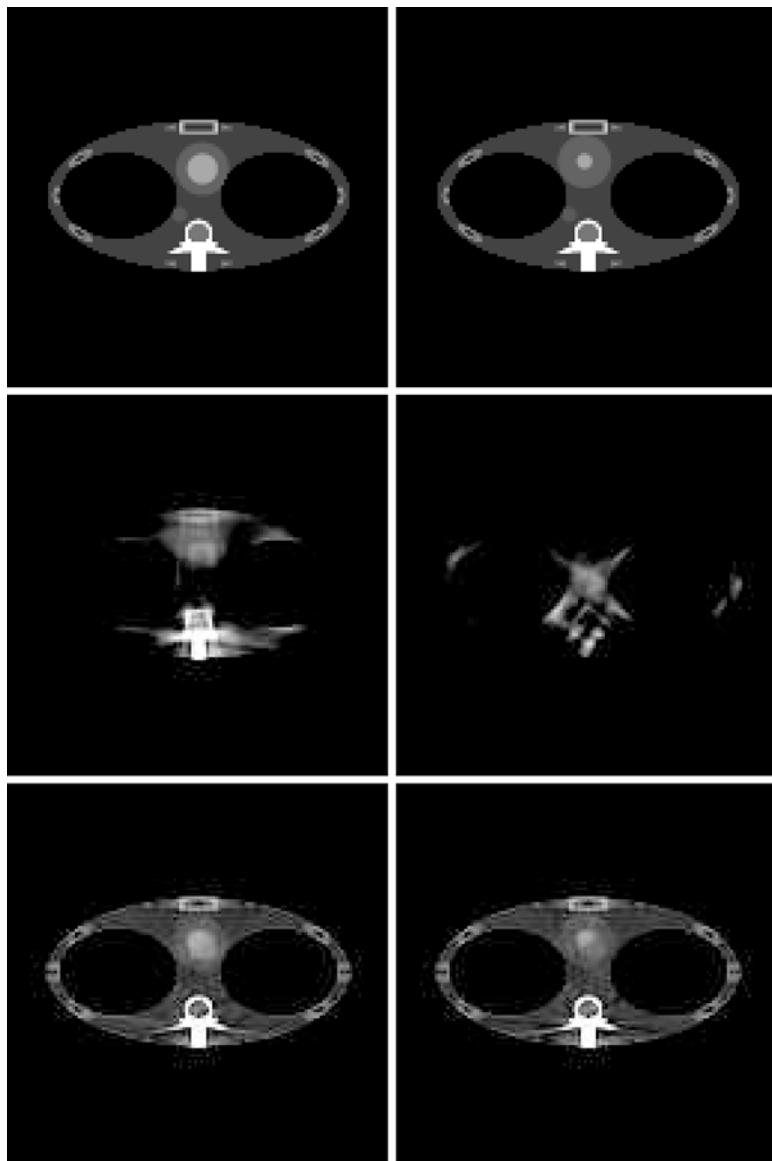

Fig. 28 The central cross section of the thorax phantom at the two extreme phases of the cardiac cycle. *First row:* the phantom. *Second row:* reconstruction from data collected at the time when the heart was in the appropriate phase after five cycles of simple ART. *Third row:* reconstruction from data collected at the time when the heart was in the appropriate phase after three cycles of Bayesian ART initialized with the reconstruction by two cycles of simple ART (based on Fig. 13.1 of [23])

0.425×0.425 cm. Data were collected (i.e., the pulsing of the X-ray source was simulated) at every 0.0015 second, using a total of 8,400 pulses. The number of turns of the helix in which the X-ray source moved during the data collection was 30. The radius of the helix was 57 cm, and the total movement parallel to the axis of the helix was 17.28 cm. The distance from the source to the detector array was 104 cm. Integrals of the density were collected for $I = 51,609,600$ rays (8,400 pulses times 16 rows of 384 detectors). Detector area and the effect of photon statistics were also simulated. The numbers used in this paragraph are not inappropriate for helical CT, but a state-of-the-art helical CT scanner would have more and smaller detectors and would be pulsed more frequently. In all our experiments we used $J = 2,153,935$ three-dimensional blobs to describe the reconstructed three-dimensional distributions.

In the first experiment we reconstructed the 24 phases of the cardiac cycle independently of each other. This was done by subdividing all the projection data into 24 subsets, each corresponding to one of the phases. A ray sum was put into a particular subset if it was collected due to a pulsing of the X-ray source at a time nearer to the central time for that phase than to the central time of any other phase. This results in a number of consecutive pulses producing data for the same phase and then there is a relatively large gap before the collected data are again used for that phase. This very nonuniform mode of data collection results in unacceptably bad reconstructions, two of which are demonstrated in the second row of Fig. 28. These reconstructions were produced using the simple ART of (23) and (24) with the three-dimensional blob basis functions, with all components of x^0 given the estimated average value based on the projection data, all $\lambda^{(k)} = 0.05$ and an efficient ordering. The results are shown at the end of the fifth cycle through the data associated with the particular phase of the cardiac cycle.

In the second experiment we used the other extreme: all the data were combined into a single projection data set, without any attention paid to the phases of the cardiac cycle. Because of the stationarity of most of the phantom and the overabundance of the projection data, we get (using the same choices for ART as in the previous paragraph) reconstructions that are good overall, but naturally the movement of the heart is blurred out due to the various views used in the reconstruction having been taken all through the cardiac cycle. We note that in this case there is no need to cycle through the data five times: the reconstruction at the end of the second cycle through the data is just about indistinguishable from the reconstruction at the end of the fifth cycle through the data.

However, our aim here is to see the dynamic changes in the heart. This can be achieved by using the Bayesian approach of (30) and (31). We selected in (29) μ_X as the reconstruction obtained at the end of the second ART cycle through all the data as described in the previous paragraph and $t = 0.8$. For each separate phase of the cardiac cycle, we used the algorithm specified by (30) and (31) for a further three cycles through the data that are associated with that particular phase. The relaxation parameter was again the constant 0.05. The results, for the two extreme phases of the cardiac cycle, are shown in the last row of Fig. 28. Here the overall reconstruction of the thorax is quite good and, at the same time, one can observe that the heart is

dynamically changing. With a state-of-the-art helical CT scanner (that would have more and smaller detectors and would be pulsed more often) we would get even better reconstructions.

5 Conclusion

Tomography is the process of producing an image of a distribution from estimates of its line integrals along a finite number of lines of known locations. There are a number of mathematical approaches to achieve this and we discussed and illustrated some of them. Of the investigated approaches, we found the performance of the method referred to as ART with blobs particularly good, especially if it is used with the appropriate data access ordering and relaxation parameters.

We subdivided the recommended readings into categories. For additional relevant information see [23] that has 280 references, 83 of which have been published since 2005.

Abstract

Several limited data problems in tomography will be presented in this chapter, including ones for X-ray tomography, electron microscopy, and radar imaging. First, reconstructions from limited data will be evaluated to observe their strengths and weaknesses. Then, the basic analytic properties of the transforms will be presented. The concept of microlocal analysis will be introduced to make the notion of singularity precise. Finally, the microlocal properties of the tomographic transforms are given and then used to explain the observed strengths and limitations of the reconstructions. This will show that these limitations are intrinsic to these limited data problems themselves.

1 Introduction

In this chapter, a range of tomography problems are introduced, including X-ray imaging, limited data problems, electron microscopy, and radar imaging. The goal is to recover the singular features of the medium or object rather than to develop exact inversion formulas. Toward this end, microlocal analysis is used to understand the strengths and limitations inherent in these tomography problems. Microlocal analysis aids researchers in understanding those singular features that can be stably recovered, which could be very important when only limited or partial data are available. Furthermore, it helps explain the presence of artifacts in certain image reconstruction methods. In some cases, it might help to distinguish the true singularities from the false ones. These are the themes emphasized in this chapter.

In Sect. 2, the tomography problems are introduced. Reconstructions are presented for each problem and reconstruction quality is evaluated with the goal of finding strengths and limitations for each method. In Sect. 3, some basic properties of tomographic transforms are introduced. Microlocal analysis is introduced in Sect. 4. Finally, several applications in tomography and radar imaging are given in Sect. 5 with the goal of emphasizing the microlocal properties of these transforms. This powerful tool is used to clarify the strengths and limitations that are really intrinsic to the data.

2 Motivation

Several modalities in tomography, including X-ray tomography, limited data tomography, electron microscope tomography, and synthetic-aperture radar (SAR), are introduced in this section. For each problem, some history is given and then

reconstructions using such data are evaluated for strengths and weaknesses. The goal of this section is to observe, for each problem, object features that are well reconstructed and features that are not. These reconstructions are provided to motivate the study of microlocal analysis, which will be used in Sect. 5 to explain these reconstructions.

X-Ray Tomography (CT) and Limited Data Problems

In the 1970s, X-ray tomography revolutionized diagnostic medicine. For the first time, doctors were able to get clear and accurate pictures of the inside of the body without doing exploratory surgery. One part of this story began in the early 1960s. At that time, Allan Cormack consulted as a medical physicist at the Groote Schuur hospital in Cape Town, South Africa, and he checked whether X-ray machines were calibrated properly. He felt that there should be more information in the X-ray data than just what is obtained from single pictures, which project all organs onto the same plane, and he believed that X-rays could be used more effectively. He posited that if one takes X-ray images from multiple directions, one should be able to piece together the internal structure of the body. He then developed two algorithms [10, 11] for the problem. To give a proof of concept, he built a prototype scanner that showed his second algorithm was effective. Along with Godfrey Hounsfield of EMI in England, he received the 1979 Nobel Prize in Medicine. You can read more about him in the excellent biography [97].

X-ray CT is now used routinely in medicine and in industrial nondestructive testing, and it allows doctors to image the internal structure of the body without exploratory surgery. The basic physics and mathematical model are now described. Let ℓ be a line along which X-rays travel, and for $x \in \ell$, let $I(x)$ be the intensity (number of photons) at the point x . Let $f(x)$ be the attenuation coefficient of the body at x . For monochromatic light, f is proportional to the density at x , and by using a scale factor, they become the same. Beer's law [66] states that the decrease in intensity at x is proportional to the intensity $I(x)$, and the proportionality constant is $-f(x)$:

$$\frac{dI}{dx} = -f(x)I(x). \quad (1)$$

This makes sense heuristically because the more dense the material at x (i.e., the larger $f(x)$ is), the more the beam is attenuated and the greater the decrease of I at x . Equation (1) is a simple differential equation for I that can be solved using separation of variables. If I_0 is the intensity at the X-ray emitter – the point $x_0 \in \ell$ – and I_1 is the intensity at the detector, $x_1 \in \ell$, then one can integrate (1) to find

$$\ln\left(\frac{I_0}{I_1}\right) = \int_{x_0}^{x_1} f(x) dx = \int_{x \in \ell} f(x) dx.$$

This leads to the definition

$$\mathcal{R}_L(f)(\ell) = \int_{x \in \ell} f(x) dx$$

where in this case, $\mathrm{d}x$ is the arc length measure on ℓ . The transform \mathcal{R}_L was studied by the Austrian mathematician Johann Radon [84] in the early twentieth century because it was intriguing pure mathematics. This transform is called the *Radon line transform* (or X-ray transform).

To proceed mathematically, more notation is given. Let $\omega \in S^1$ and let $p \in \mathbb{R}$. Then, the line

$$\ell(\omega, p) = \{x \in \mathbb{R}^2 : x \cdot \omega = p\} \quad (2)$$

is perpendicular to ω and contains $p\omega$. Sometimes it will be useful to let ω be a function of polar angle $\varphi \in \mathbb{R}$,

$$\omega(\varphi) = (\cos(\varphi), \sin(\varphi)) .$$

In this parameterization

$$\mathcal{R}_L f(\omega, p) = \int_{x \in \ell(\omega, p)} f(x) \mathrm{d}x = \int_{t \in \mathbb{R}} f(p\omega + t\omega^\perp) \mathrm{d}t \quad (3)$$

where ω^\perp is the unit vector $\pi/2$ radians counterclockwise from ω . This integral is defined for $f \in C_c(\mathbb{R}^2)$, and in fact \mathcal{R}_L is continuous in a number of norms (see section “Continuity Results for the X-Ray Transform”). The basic properties of this transform are proven in Sect. 3.

First, consider the forward problem and a simple case that will show in a naive sense how the X-ray transform detects object boundaries.

Example 1. Let f be the characteristic function of the unit disk in \mathbb{R}^2 . Then, using the Pythagorean Theorem, one sees that

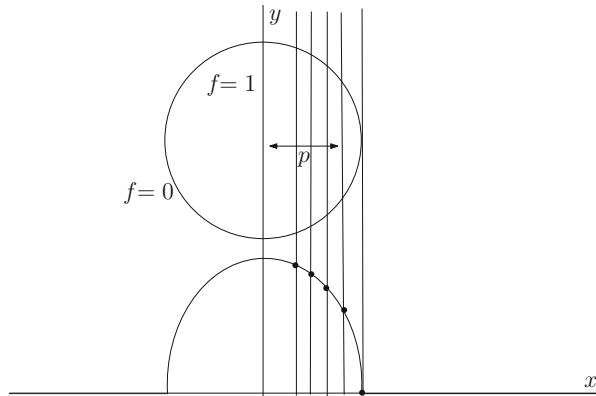

$$\mathcal{R}_L f(\omega, p) = \begin{cases} 2\sqrt{1-p^2} & |p| \leq 1 \\ 0 & |p| > 1 \end{cases} . \quad (4)$$

The function $\mathcal{R}_L f(\omega, p)$ in (4) is smooth except at $p = \pm 1$, that is, except for lines $\ell(\omega, \pm 1)$ as can be seen from Fig. 1. The data are not smooth at those lines and those lines are tangent to the boundary of the disk. This suggests that lines tangent to boundaries give special information about the specimen. In Sect. 4, the reader will discover what is mathematically special about those lines, and this will be related back to limited data tomography in Sect. 5.

For complete data, that is, data over all lines through the object, good reconstruction methods such as filtered backprojection (Theorem 9) are effective to reconstruct from X-ray CT data.

However, one cannot obtain complete data in many important tomography problems. These are called *limited data tomography problems*, and several important ones are now described. The goal at this point is to observe how the reconstructions look compared to the original objects.

Fig. 1 This graph shows the calculation of the Radon transform in (4). The unit disk is above the graph. For $|p| \leq 1$, the Pythagorean theorem shows that the length of the intersection of $\ell(\omega, p)$ and the disk is $2\sqrt{1 - p^2}$

Here are some guidelines as you read this section. For each problem and reconstruction, conjecture what is special about the object boundaries that are well reconstructed (and those that are badly reconstructed) in relation to the limited data set used.

Exterior X-Ray CT Data

Exterior CT data are data for lines that are outside an excluded region. Typically, that region is a circle of radius $r > 0$, so lines $\ell(\omega, p)$ for $|p| \geq r$ are in the data set. Theorem 5 in the next section shows that compactly supported functions can be uniquely reconstructed outside the excluded region from exterior data.

The exterior problem came about in the early days of tomography for CT scans around the beating heart. In those days, a single scan of a planar cross section could take several minutes, and movement of the heart would create artifacts in the scan. If an excluded region were chosen to contain the heart and be large enough so the outside of that region would not move, then data exterior to that region would be usable. However, scanners soon began to use fan beam data (see section “Fan Beam and Cone Beam CT”), and data could be acquired much more quickly. If the data acquisition is timed (gated), then data are acquired while the heart is in the same position over several heartbeats. Because more data can be taken more quickly with fan beam data, the heart can now be imaged using newer scanners, and movement of the heart is not as large a problem.

Exterior data are still important for imaging large objects such as rocket shells. Even with an industrial CT scanner, the X-rays will not penetrate the thick center of the rocket [88]. However, they can penetrate the outer rocket shell, and this gives exterior data.

One can recover functions of compact support from exterior data, at least outside the excluded region (see Theorem 5). Effective inversion methods were developed for exterior data by researchers including Bates and Lewitt [3], Natterer [65], Quinto [77, 79], and a stability analysis using singular value decompositions was done in [58].

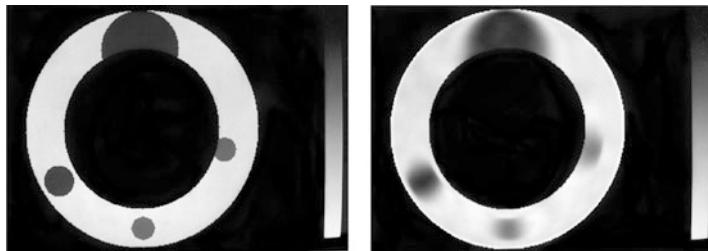

Fig. 2 Exterior reconstruction. Phantom (*left*) and reconstruction (*right*) from simulated data [77, ©IOP Publishing. Reproduced by permission of IOP Publishing. All rights reserved]. The outer diameter of the annulus is 1.5 times the inner diameter

Figure 2 is a reconstruction from exterior data: integrals are given over lines that do not meet the black central disk. The reconstruction method uses a singular value decomposition for the exterior Radon transform that includes a null space; it recovers the component of the object in the orthogonal complement of the null space and does an extrapolation to recover the null space component [77].

Note how some boundaries of the small circles are clearly reconstructed and others are not. In this case, how can you describe the boundaries that are well reconstructed in relation to the data set? Another question is whether the fuzzy boundaries are fuzzy because the algorithm is bad or could there be an additional explanation.

Allan Cormack's first algorithm [10] solved the exterior problem, but the algorithm was not numerically effective. The integrals in his algorithm were difficult to evaluate numerically with any accuracy because the integrand grew too rapidly. Other mathematicians tried to improve this method, but it was difficult. Because of this problem, Cormack developed a second method that uses full data and that gave good reconstructions [11].

It would be useful to know if limitations of Quinto's and Cormack's algorithms are problems with their algorithms or reflect something intrinsic to this limited data problem.

Limited Angle Data

Limited angle tomography is a classical problem from the early days of tomography [3, 60, 61]. In this case, data are given over all lines in a limited range of directions, or data for $\{(\omega(\varphi), p) : \varphi \in (-\Phi, \Phi), p \in \mathbb{R}\}$ where $\Phi \in (0, \pi/2)$. One can uniquely recover compactly supported functions from limited angle data, but this is not true for arbitrary functions (see Theorem 3).

Limited angle tomography is used in certain luggage scanners in which the X-ray source is on one side of the luggage and the detectors are on the other, and they move in opposite directions. Limited angle data are used in important current problems including dental X-ray scanning [68] and tomosynthesis (a tomographic technique to image breasts using transmitter and receiver that move on opposite

sides of the breast) [72]. Other algorithms were developed for this problem such as [12, 26, 49, 68].

The reconstruction in Fig. 3 is from limited angle data. Data are taken over all lines $\ell(\omega(\varphi), p)$ for $p \in \mathbb{R}$ and $\varphi \in [-\pi/4, \pi/4]$.

The algorithm used in this reconstruction is a truncated filtered backprojection (FBP) algorithm which is given in (26). Some boundaries in this reconstruction are well reconstructed and others are not. How do these boundaries relate to lines in the data set? How do the streaks in the reconstruction relate to the data set?

Region of Interest (ROI) Data

In region of interest tomography, one chooses a subset of the object, called a *region of interest (ROI)*, to reconstruct. ROI data consist of all lines that meet this region, and the ROI problem is to reconstruct the structure of the ROI from these data. Such data are also called interior data (and the interior problem). ROI CT is important in the CT of small parts of objects, so-called micro-CT [18, p. 460]. Other algorithms in ROI CT include [104] (when one knows the value of a function in part of the interior) and [105] (when the density is piecewise constant in the ROI), as well as algorithms including [52]. A singular value decomposition was developed for this problem in [63].

ROI CT is useful for medical CT and industrial nondestructive evaluation in which one is interested only in a small region of interest in an object, not the entire object. An advantage for medical applications is that ROI data gives less radiation than with complete data.

Lambda tomography [17], [18] is one important algorithm for ROI CT which will be described in section “Filtered Backprojection (FBP) for the X-Ray Transform,” and the ROI reconstruction presented here uses this algorithm. The data are severely limited – they include only lines near the disk and the ROI transform is not injective (see Theorem 6), so why do the reconstructions look so good?

Limited Angle Region of Interest Tomography

In this modality data are given over lines in a limited angular range and that are restricted to pass through a given ROI. It comes up in single axis tilt electron microscopy (ET) (see Öktem’s chapter in this book [71]). However, in general, ET is better understood as a three-dimensional problem, and this will be presented in the next paragraph.

Electron Microscope Tomography (ET) Over Arbitrary Curves

Now a full three-dimensional problem, electron microscope tomography (ET), is considered. The notation is as in Öktem’s chapter in this book [71], which has detailed information about the physics, biology, model, and mathematics of ET. A reconstruction of a simple 3D phantom – the union of the following disks: with center $(0, 0, 0)$, radius $1/2$; center $(0, 0, 1)$, radius $1/2$; center $(1, -1, 1)$, radius $1/4$;

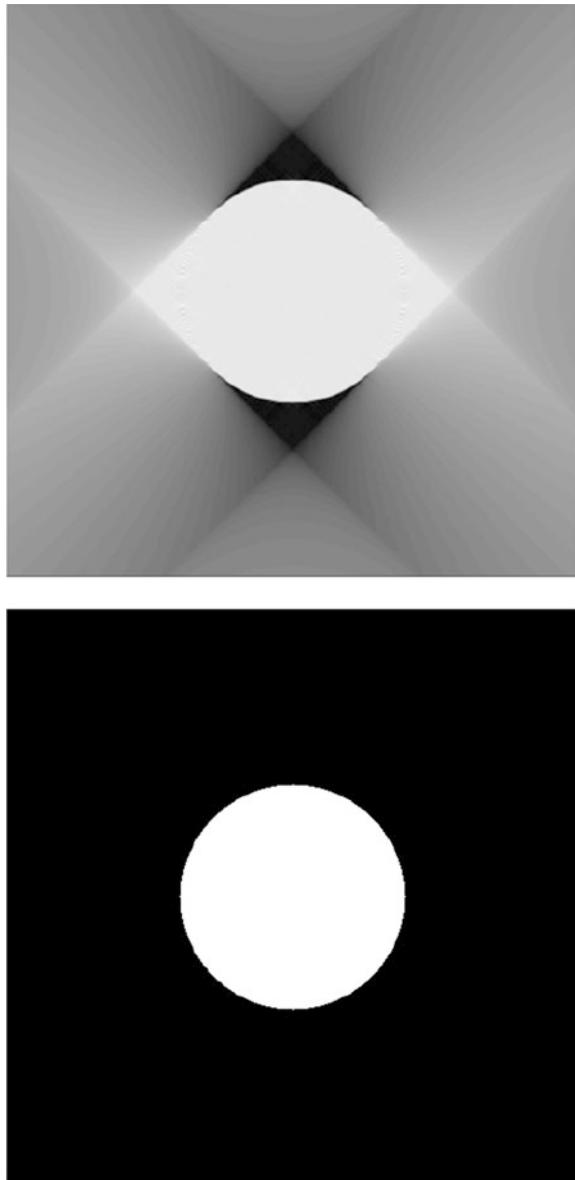

Fig. 3 Limited angle reconstruction of a disk. Original image (*left*) and reconstruction (*right*) from a truncated filtered backprojection (FBP) algorithm (26) using data in the angular range, $\varphi \in [-\pi/4, \pi/4]$. Note the streak artifacts and the missing boundaries in the limited angle reconstructions [26, ©IOP Publishing. Reproduced by permission of IOP Publishing. All rights reserved]

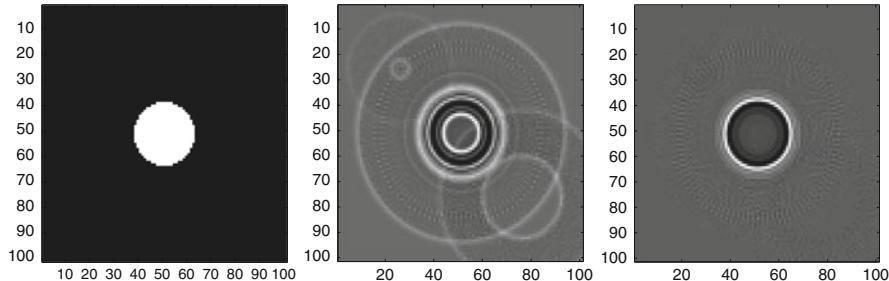

Fig. 4 Reconstruction from conical tilt data. Cross section with the $x - y$ plane of the phantom described in this section (left), \mathcal{L}_Δ reconstruction (center, see Eq. (28)) and \mathcal{L}_S reconstruction (right, see Eq. (29)). The center of the cross section is the origin, and the range in x and y is from -2 to 2 . This research was done with Soohyun Chung and Tania Bakhos while they were Tufts undergraduates [82], ©Scuola Normale Superiore, Pisa. Reproduced by permission with Scuola Normale Superiore, Pisa, all rights reserved]

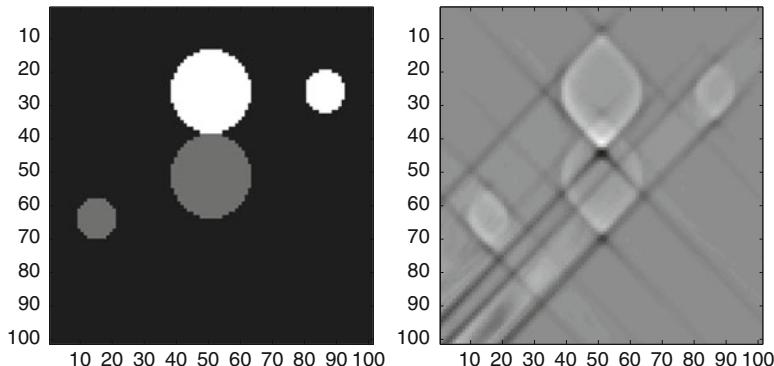

Fig. 5 Reconstruction from conical tilt data. Cross section of phantom in the plane $x = -y$ (left) and \mathcal{L}_Δ reconstruction in that plane (right). The $x - y$ plane cuts the picture in half with a horizontal line [82], ©Scuola Normale Superiore, Pisa. Reproduced by permission with Scuola Normale Superiore, Pisa, all rights reserved]

and center $(-1, 1, -1/2)$, radius $1/4$ – is analyzed. The disks above the $x - y$ plane have density two and the others have density one.

Conical tilt ET data is described in section “Algorithms in Conical Tilt ET” and Öktem’s chapter in this book [71]. In this example, line integrals are given over all lines in space with angle $\alpha = \pi/4$ with the z –axis. Reconstructions are given from two algorithms that are described in section “Electron Microscope Tomography (ET) Over Arbitrary Curves.” The operators are \mathcal{L}_Δ (given in Eq. (28)) and \mathcal{L}_S (given in Eq. (29)).

Artifacts are added in the \mathcal{L}_Δ reconstruction in Fig. 4 and in Fig. 5 which shows the plane containing the centers of the disks and the z –axis (axis of rotation of the scanner). These figures are remarkable because the \mathcal{L}_Δ reconstruction has so

many added artifacts compared to the \mathcal{L}_S reconstruction, although these operators are not very different (see section “Algorithms in Conical Tilt ET”). Why are the reconstructions so different?

Reconstructions of real specimens from single axis tilt data show some of the same strengths and limitations (see, e.g., [80, 83] and Öktem’s chapter in this book [71]). However, the added artifacts have different properties, and since the data are so noisy, other factors affect reconstructions.

Synthetic-Aperture Radar Imaging

In synthetic-aperture radar (SAR) imaging, a region of interest on the surface of the earth is illuminated by electromagnetic waves from an airborne platform such as a plane or satellite. For more detailed information on SAR imaging, including several open problems in SAR imaging, the reader is referred to [7, 8] and to the chapter in this handbook by Cheney and Borden [9]. The backscattered waves are picked up at a receiver or receivers, and the goal is to reconstruct an image of the region based on such measurements. In monostatic SAR, the transmitter and receiver are located on the same platform. In bistatic SAR, the transmitter and receiver are on independently moving trajectories.

While monostatic SAR imaging is the one that is widely used, bistatic SAR imaging offers several advantages. The receivers in comparison to transmitters are not active sources of electromagnetic radiation and hence are more difficult to detect if flown in an unsafe environment. Since the transmitter and receiver are at different points in space, bistatic SAR systems are more resistant to electronic countermeasures such as target shaping to reduce scattering in the direction of incident waves [48].

The reconstruction of the image based on the measurement of the backscattered waves is in general a hard problem. However, ignoring contributions of multiply backscattered waves linearizes the relation between the image to be recovered and the backscattered waves and is easier to analyze. Due to this reason, a linearizing approximation called the Born approximation that ignores contribution from multiply scattered waves is widely used in SAR image reconstruction.

The Linearized Model in SAR Imaging

Let $\gamma_T(s)$ and $\gamma_R(s)$ for $s \in (s_0, s_1)$ be the trajectories of the transmitter and receiver, respectively. The propagation of electromagnetic waves can be described by the scalar wave equation

$$\left(\Delta - \frac{1}{c^2} \partial_t^2 \right) E(x, t) = -P(t) \delta(x - \gamma_T(s)), \quad (5)$$

where c is the speed of electromagnetic waves in the medium, $E(x, t)$ is each component of the electric field, and $P(t)$ is the transmit waveform sent to the transmitter antenna. The wave speed c is spatially varying due to inhomogeneities

present in the medium, and one can assume that it is a perturbation of the constant background speed of propagation c_0 of the form

$$\frac{1}{c^2(x)} = \frac{1}{c_0^2} + \tilde{V}(x).$$

One assumes that $\tilde{V}(x)$ only varies over a two-dimensional surface: the surface of the earth. Therefore, \tilde{V} can be represented as a function of the form

$$\tilde{V}(x) = V(x)\delta_0(x_3)$$

where it will be assumed that the earth's surface is represented by the $x = (x_1, x_2)$ plane. The background Green's function g is the solution of the following equation:

$$\left(\Delta - \frac{1}{c_0^2} \partial_t^2 \right) g(x, t) = -\delta_0(x)\delta_0(t).$$

This is given by

$$g(x, t) = \frac{\delta(t - \|x\|/c_0)}{4\pi \|x\|}. \quad (6)$$

Now the incident field E^{in} due to the source $s(x, t) = P(t)\delta(x - \gamma_T(s))$ is

$$\begin{aligned} E^{\text{in}}(x, t) &= \int g(x - y, t - \tau)s(y, \tau)dyd\tau \\ &= \frac{P(t - \|x - \gamma_T(s)\|/c_0)}{4\pi \|x - \gamma_T(s)\|}. \end{aligned}$$

Let E denote the total field of the medium, $E = E^{\text{in}} + E^{\text{sc}}$, where E^{sc} is the scattered field. This can be written using the Lippmann-Schwinger equation:

$$E^{\text{sc}}(z, t) = \int g(z - x, t - \tau)\partial_t^2 E(x, \tau)V(x)dxd\tau. \quad (7)$$

This equation is linearized by replacing the total field E on the right-hand side of the above equation by E^{in} . This is known as the Born approximation. The linearized scattered wave field $E_{\text{lin}}^{\text{sc}}(\gamma_R(s), t)$ at the receiver location $\gamma_R(s)$ is then

$$E_{\text{lin}}^{\text{sc}}(\gamma_R(s), t) = \int g(x - \gamma_R(s), t - \tau)\partial_t^2 E^{\text{in}}(x, \tau)V(x)dxd\tau.$$

Substituting the expression for E^{in} into this equation and integrating, one obtains the following expression for the linearized scattered wave field:

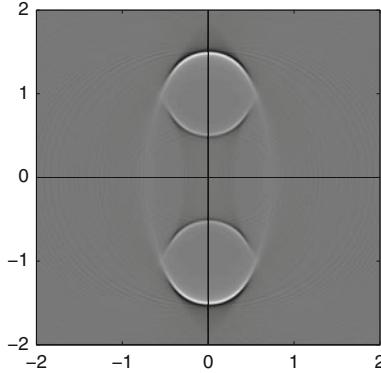

Fig. 6 Reconstruction of a disk centered on the positive y -axis from integrals over ellipses (with constant distance between the foci) centered on the x -axis and with foci in $[-3, 3]$. Notice that some boundaries of the disk are missing, and there is a copy of the disk below the axis. This was originally from the Tufts University Senior Honors thesis of Howard Levinson and published in [55]. Reproduced with kind permission from Springer Science+Business Media: © Springer Verlag

$$E_{\text{lin}}^{\text{sc}}(\gamma_R(s), t) = \int e^{-i\omega(t - \frac{1}{c_0} R(s, x))} A(s, x, \omega) V(x) dx d\omega, \quad (8)$$

where

$$R(s, x) = \|\gamma_T(s) - x\| + \|x - \gamma_R(s)\|$$

and

$$A(s, x, \omega) = \omega^2 p(\omega)((4\pi)^2 \|\gamma_T(s) - x\| \|\gamma_R(s) - x\|)^{-1}, \quad (9)$$

where p is the Fourier transform of P . The function A includes terms that take into account the transmitted waveform and geometric spreading factors. The inverse of the norms appears in A due to the background Green's function, (6).

The reconstruction in Fig. 6 of a disk centered on the positive y -axis from integrals of it over ellipses with foci moving along the x -axis offset by a constant distance (which is simplified model of (8)) highlights some of the features in SAR image reconstruction. Some part of the boundary is not stably reconstructed, and an artifact of the true image appears as a reflection about the x -axis along with streak artifacts. Looking at the reconstructed image, one sees that at least visually, the created artifact is as strong as the true image. Microlocal analysis of the operators appearing in SAR imaging will make precise and justify all these observations. This will be addressed in section “SAR Imaging.”

General Observations

In each reconstruction in this section, some object boundaries are visible and others are not. In fact, if one looks more carefully at the reconstructions, one can notice that in each case, the only feature boundaries that are clearly defined are those tangent to lines in the data set for the problem. Example 1 illustrates this in a naive way: one sees singularities in the Radon data exactly when the lines of integration are tangent to the boundary of the object. The goal of this chapter is to make the idea mathematically rigorous.

The conical tilt ET reconstructions in section “Electron Microscope Tomography (ET) Over Arbitrary Curves” have artifacts if one uses a certain algorithm but apparently not when one uses another similar one. The reconstruction related to radar in Fig. 6 has an artifact that is a reflected image of the disk.

In Sect. 4, deep mathematical ideas from microlocal analysis will be introduced to classify singularities and what certain operators do to them. In Sect. 5 these microlocal ideas will be used to explain the visible and invisible singularities for limited data X-ray CT as well as the added singularities in ET and radar.

3 Properties of Tomographic Transforms

In this section, after introducing some functional analysis, basic properties of transforms in X-ray tomography and electron microscope tomography are presented. The microlocal properties of radar will be given later in section “SAR Imaging.”

Function Spaces

The open disk in \mathbb{R}^2 centered at the origin and of radius $r > 0$ will be denoted $D(r)$.

The set $C^\infty(\mathbb{R}^n)$ consists of all smooth functions on \mathbb{R}^n , that is, functions that are continuous along with their derivatives of all orders, and $\mathcal{D}(\mathbb{R}^n)$ is the set of smooth functions of compact support. Its dual space – the set of all continuous linear functionals on $\mathcal{D}(\mathbb{R}^n)$ (given the weak-* topology) – is denoted $\mathcal{D}'(\mathbb{R}^n)$ and is called the *set of distributions*. If u is a locally integrable function, then u is a distribution with the standard definition

$$\langle u, f \rangle = u(f) = \int_{\mathbb{R}^n} u(x) f(x) dx$$

for $f \in \mathcal{D}(\mathbb{R}^n)$ since $u(x) f(x)$ is an integrable function of compact support.

If Ω is an open set in \mathbb{R}^n , then $\mathcal{D}(\Omega)$ is the set of smooth functions compactly supported in Ω . Its dual space with the weak-* topology is denoted $\mathcal{D}'(\Omega)$.

The *Schwartz space* of rapidly decreasing functions is the set $\mathcal{S}(\mathbb{R}^n)$ of all smooth functions that decrease (along with all their derivatives) faster than any power of $1/\|x\|$ at infinity. Its dual space, $\mathcal{S}'(\mathbb{R}^n)$, is the set of all continuous linear

functionals on $\mathcal{S}(\mathbb{R}^n)$ with the weak-* topology (convergence is pointwise: $u_k \rightarrow u$ in $\mathcal{S}'(\mathbb{R}^n)$ if, for each $f \in \mathcal{S}(\mathbb{R}^n)$, $u_k(f) \rightarrow u(f)$). They are called *tempered distributions*. Any function that is measurable and bounded above by some power of $(1 + \|x\|)$ is in $\mathcal{S}'(\mathbb{R}^n)$ since its product with any Schwartz function is integrable.

A distribution u is supported in the closed set K if for all functions $f \in \mathcal{D}(\mathbb{R}^n)$ with support disjoint from K , $u(f) = 0$. The support of u , $\text{supp}(u)$, is the smallest closed set in which u is supported.

Example 2. The *Dirac delta function at zero* is an important distribution that is not a function. It is defined $\langle \delta_0, f \rangle = \delta_0(f) = f(0)$. Note that if f is supported away from the origin, then $\delta_0(f) = 0$ since $f(0) = 0$. Therefore, the Dirac delta function has support $\{0\}$.

Let $\mathcal{E}'(\mathbb{R}^n)$ be the set of distributions that have compact support in \mathbb{R}^n . If Ω is an open set in \mathbb{R}^n , then $\mathcal{E}'(\Omega)$ is the set of distributions with compact support contained in Ω . For example, on the real line, $\delta \in \mathcal{E}'((-1, 1))$.

If $f \in L^1(\mathbb{R}^n)$, then its Fourier transform and inverse are

$$\begin{aligned}\mathcal{F}f(\xi) &= \hat{f}(\xi) = \frac{1}{(2\pi)^{n/2}} \int_{x \in \mathbb{R}^n} e^{-ix \cdot \xi} f(x) dx \\ \mathcal{F}^{-1}f(x) &= \check{f}(x) = \frac{1}{(2\pi)^{n/2}} \int_{\xi \in \mathbb{R}^n} e^{ix \cdot \xi} f(\xi) d\xi.\end{aligned}\tag{10}$$

The Fourier transform is linear and continuous from $L^1(\mathbb{R}^n)$ to the space of continuous functions that converge to zero at ∞ . Furthermore, \mathcal{F} is an isomorphism on $L^2(\mathbb{R}^n)$ and an isomorphism on $\mathcal{S}(\mathbb{R}^n)$ and, therefore, on $\mathcal{S}'(\mathbb{R}^n)$. More information about these topics can be found in [86], for example.

Basic Properties of the Radon Line Transform

In this section fundamental properties of the Radon line transform, \mathcal{R}_L , are derived, see [66]. This will provide a connection between the transforms and microlocal analysis in Sect. 4.

Theorem 1 (General Projection Slice Theorem). *Let $f \in L^1(\mathbb{R}^2)$. Now let $h \in L^\infty(\mathbb{R})$ and $\omega \in S^1$. Then,*

$$\int_{x \in \mathbb{R}^2} f(x)h(x \cdot \omega) dx = \int_{p=-\infty}^{\infty} \mathcal{R}_L f(\omega, p)h(p) dp.\tag{11}$$

Proof. Let $\omega \in S^1$. First, note that the function $x \mapsto f(x)h(x \cdot \omega)$ is in $L^1(\mathbb{R}^2)$ since h is bounded and measurable. For the same reason, the function

$$(p, t) \mapsto f(p\omega + t\omega^\perp)h(p)$$

is in $L^1(\mathbb{R}^2)$. Therefore,

$$\int_{x \in \mathbb{R}^2} f(x)h(x \cdot \omega) dx = \int_{p=-\infty}^{\infty} \int_{t=-\infty}^{\infty} f(p\omega + t\omega^\perp)h(p) dt dp \quad (12)$$

$$= \int_{p=-\infty}^{\infty} \mathcal{R}_L f(\omega, p)h(p) dp \quad (13)$$

where (12) holds by rotation invariance of the Lebesgue integral and then Fubini's theorem and since $p = \omega \cdot (p\omega + t\omega^\perp)$. The equality (13) holds by the definition of \mathcal{R}_L . \square

Let $\mathcal{S}(S^1 \times \mathbb{R})$ be the set of smooth functions on $S^1 \times \mathbb{R}$ that decrease (along with all their derivatives) faster than any power of $1/|p|$ at infinity uniformly in ω , and let $\mathcal{S}'(S^1 \times \mathbb{R})$ be its dual. The *partial Fourier transform* is defined for $g \in L^1(S^1 \times \mathbb{R})$ as

$$\mathcal{F}_p g(\omega, \tau) = \frac{1}{\sqrt{2\pi}} \int_{p \in \mathbb{R}} e^{-ip\tau} g(\omega, \tau) d\tau. \quad (14)$$

Because the Fourier transform is an isomorphism on $\mathcal{S}(\mathbb{R})$, this transform and its inverse are defined and continuous on $\mathcal{S}'(S^1 \times \mathbb{R})$.

The *Fourier Slice Theorem* is an important corollary of Theorem 1.

Theorem 2 (Fourier Slice Theorem). *Let $f \in L^1(\mathbb{R}^2)$. Then for $(\omega, \tau) \in S^1 \times \mathbb{R}$,*

$$\mathcal{F}f(\tau\omega) = \frac{1}{\sqrt{2\pi}} \mathcal{F}_p \mathcal{R}_L f(\omega, \tau).$$

To prove this theorem, one applies the General Projection Slice Theorem 1 to the function $h(p) = e^{-ip\tau}$.

The Fourier Slice Theorem provides a proof that \mathcal{R}_L is invertible on domain $L^1(\mathbb{R}^2)$ since \mathcal{F}_p is invertible on domain $L^1(S^1 \times \mathbb{R})$. Zalcman constructed a nonzero function that is integrable on every line in the plane and whose line transform is identically zero [107]. Of course, his function is not in $L^1(\mathbb{R}^2)$.

This theorem also provides a proof of invertibility for the limited angle problem.

Theorem 3 (Limited Angle Theorem). *Let $f \in \mathcal{E}'(\mathbb{R}^2)$ and let $\Phi \in (0, \pi/2)$. If $\mathcal{R}_L f(\omega(\varphi), p) = 0$ for $\varphi \in (-\Phi, \Phi)$ and all p , then $f = 0$.*

However, there are nonzero functions $f \in \mathcal{S}(\mathbb{R}^2)$ with $\mathcal{R}_L f(\omega(\varphi), p) = 0$ for $\varphi \in (-\Phi, \Phi)$ and all p .

Proof. Let $f \in \mathcal{E}'(\mathbb{R}^2)$ and assume $\mathcal{R}_L f(\omega(\varphi), p) = 0$ for $\varphi \in (-\Phi, \Phi)$ and all p . By the Fourier Slice Theorem, which is true for $\mathcal{E}'(\mathbb{R}^2)$ [45],

$$\mathcal{F}f(\tau\omega(\varphi)) = \frac{1}{\sqrt{2\pi}} \mathcal{F}_p \mathcal{R}_L f(\omega(\varphi), \tau) = 0 \quad \text{for } \varphi \in (-\Phi, \Phi), \tau \in \mathbb{R} \quad (15)$$

and this expression is zero because $\mathcal{R}_L f(\omega(\varphi), \tau) = 0$ for such (φ, τ) . This shows that $\mathcal{F}f$ is zero on the open cone

$$V = \{\tau\omega(\varphi) : \tau \neq 0, \varphi \in (-\Phi, \Phi)\}.$$

Since f has compact support, $\mathcal{F}f$ is real analytic, and so $\mathcal{F}f$ must be zero everywhere since it is zero on the open set V . This shows $f = 0$.

To prove the second part of the theorem, let \tilde{f} be any nonzero Schwartz function supported in the cone V and let $f = \mathcal{F}^{-1}(\tilde{f})$. Since \tilde{f} is nonzero and in $\mathcal{S}(\mathbb{R}^2)$, so is f . Using (15) but starting with $\mathcal{F}f = 0$ in V , one sees that $\mathcal{R}_L f$ is zero in the limited angular range. \square

Another application of these theorems is the classical Range Theorem for this transform.

Theorem 4 (Range Theorem [28, 41]). *Let $g \in \mathcal{S}(S^1 \times \mathbb{R})$. Then g is in the range of \mathcal{R}_L on domain $\mathcal{S}(\mathbb{R}^2)$ if and only if*

1. $g(\omega, p) = g(-\omega, -p)$ for all $(\omega, p) \in S^1 \times \mathbb{R}$
2. For each $m \in \{0, 1, 2, \dots\}$, $\int_{p \in \mathbb{R}} g(\omega, p) p^m \, dp$ is a polynomial in $\omega \in S^1$ that is homogeneous of degree m .

Proof (Sketch). The necessary part of the theorem follows by applying the General Projection Slice Theorem to $h(p) = p^m$ for m a nonnegative integer:

$$\int_{p \in \mathbb{R}} \mathcal{R}_L f(\omega, p) p^m \, dp = \int_{x \in \mathbb{R}^2} f(x)(x \cdot \omega)^m \, dx$$

and after multiplying out $(x \cdot \omega)^m$ in the coordinates of ω , one sees that the right-hand integral is a polynomial in these coordinates homogeneous of degree m . The sufficiency part is much more difficult to prove. One uses the Fourier Slice Theorem to construct a function f satisfying $\mathcal{F}f(\tau\omega) = \frac{1}{\sqrt{2\pi}} \mathcal{F}_p g(\omega, \tau)$. Since $\mathcal{F}_p g$ is smooth and rapidly decreasing in p , $\mathcal{F}f$ is smooth away from the origin and rapidly decreasing in x . The subtle part of the proof in [41] is to show $\mathcal{F}f$ is smooth at the origin, and this is done using careful estimates on derivatives using the moment conditions, (2) of Theorem 4. Once that is known, one can conclude $\mathcal{F}f \in \mathcal{S}(\mathbb{R}^2)$ and so $f \in \mathcal{S}(\mathbb{R}^2)$. \square

The support theorem for \mathcal{R}_L is elegant and has motivated a large range of generalizations such as [5, 6, 42, 53, 57, 78].

Theorem 5 (Support Theorem [10, 28, 41]). *Let f be a distribution of compact support (or a function in $\mathcal{S}(\mathbb{R}^2)$) and let $r > 0$. Assume $\mathcal{R}_L f$ is zero for all lines that are disjoint from the disk $D(r)$. Then $\text{supp}(f) \subset D(r)$.*

This theorem implies that the exterior problem has a unique solution; in this case, $D(r)$ is the excluded region. The proof is tangential to the main topics of this chapter, and it can be found in [10, 28, 41, 43, 92].

Counterexamples to the support theorem exist for functions that do not decrease rapidly at ∞ (e.g., [43, 106] or the singular value decompositions in [73, 76]).

A corollary of these theorems shows that exact reconstruction is impossible from ROI data where $D(r)$ is the disk centered at the origin in \mathbb{R}^2 and of radius $r > 0$.

Theorem 6. *Consider the ROI problem with region of interest the unit disk $D(1)$. Let $r \in (1, \infty)$. Then there is a function $f \in \mathcal{D}(D(r))$ that is not identically zero in $D(1)$ but for which $\mathcal{R}_L f$ is zero for all lines that intersect $D(1)$.*

Proof (Sketch). Let $h(p)$ be a smooth nonzero nonnegative function supported in $(1, r)$ and let $g(\omega, p) = h(|p|)$. Since g is independent of ω , the moment conditions from the Range Theorem (Theorem 4), are trivially satisfied, so that theorem shows that there is a function $f \in \mathcal{S}(\mathbb{R}^2)$ with $\mathcal{R}_L f = g$. By the support theorem, f is supported in the disk $D(r)$. To show f is nonzero in the ROI, $D(1)$, one uses [10, p. 2725, equation (18)]. This is also proven in [66, p. 169, VI.4], and Natterer shows that such null functions do not oscillate much in the ROI. It will be shown in Sect. 5 that null functions are smooth in the ROI, too. \square

Continuity Results for the X-Ray Transform

In this section some basic continuity theorems for \mathcal{R}_L are presented.

A simple proof shows that \mathcal{R}_L is continuous from $C_c(D(M))$ to $C_c(S_M)$ where we define $S_M = S^1 \times [-M, M]$. First, one uses uniform continuity of f to show $\mathcal{R}_L f$ is a continuous function. Then, the proof that \mathcal{R}_L is continuous is based on the estimate

$$|\mathcal{R}_L f(\omega, p)| \leq \pi M^2 \|f\|_\infty$$

where $\|f\|_\infty$ is the (essential) supremum norm of f . A stronger theorem has been proven by Helgason.

Theorem 7 ([41]). $\mathcal{R}_L : \mathcal{S}(\mathbb{R}^2) \rightarrow \mathcal{S}(S^1 \times \mathbb{R})$ is continuous.

The proof of the next theorem follows from the calculations in the proof of the General Projection Slice Theorem.

Theorem 8. $\mathcal{R}_L : L^1(\mathbb{R}^2) \rightarrow L^1(S^1 \times \mathbb{R})$ is continuous.

Proof. By taking absolute values in (11) with $h = 1$ and then integrating with respect to ω , one sees that $\|f\|_{L^1(\mathbb{R}^2)} \geq (2\pi) \|\mathcal{R}_L f\|_{L^1(S^1 \times \mathbb{R})}$ and so \mathcal{R}_L is continuous on L^1 . \square

Continuity results for \mathcal{R}_L in Sobolev spaces were given in [40, 45, 59] for functions of fixed compact support.

Filtered Backprojection (FBP) for the X-Ray Transform

To state the most commonly used inversion formula, filtered backprojection, one first defines the *dual line transform*. For $g \in L^1(S^1 \times \mathbb{R})$ and $x \in \mathbb{R}^2$,

$$\mathcal{R}_L^* g(x) = \int_{\omega \in S^1} g(\omega, x \cdot \omega) d\omega. \quad (16)$$

For each $\omega \in S^1$, $x \in \ell(\omega, x \cdot \omega)$, so $\mathcal{R}_L^* g(x)$ is the integral of g over all lines through x . The transform \mathcal{R}_L^* is the formal dual to \mathcal{R}_L in the sense that for $f \in \mathcal{S}(\mathbb{R}^2)$ and $g \in \mathcal{S}(S^1 \times \mathbb{R})$,

$$\langle \mathcal{R}_L f, g \rangle_{L^2(S^1 \times \mathbb{R})} = \langle f, \mathcal{R}_L^* g \rangle_{L^2(\mathbb{R}^2)}.$$

Because $\mathcal{R}_L : \mathcal{S}(\mathbb{R}^2) \rightarrow \mathcal{S}(S^1 \times \mathbb{R})$ is continuous, $\mathcal{R}_L^* : \mathcal{S}'(S^1 \times \mathbb{R}) \rightarrow \mathcal{S}'(\mathbb{R}^2)$ is weakly continuous.

The Lambda operator is defined on functions $g \in \mathcal{S}(S^1 \times \mathbb{R})$ by

$$\Lambda_p g(\omega, p) = \mathcal{F}_p^{-1}(|\tau| (\mathcal{F}_p g(\omega, \cdot))). \quad (17)$$

Theorem 9 (Filtered Backprojection (FBP) [66, 85, 87]). Let $f \in \mathcal{S}(\mathbb{R}^2)$. Then,

$$f = \frac{1}{4\pi} \mathcal{R}_L^* \Lambda_p \mathcal{R}_L f. \quad (18)$$

This formula is valid for $f \in \mathcal{E}'(\mathbb{R}^2)$.

Filtered backprojection is an efficient, fast reconstruction method that is easily implemented [67] by using an approximation to the operator Λ_p that is convolution with a function (see, e.g., [66] or [87]). Note that FBP requires data over all lines

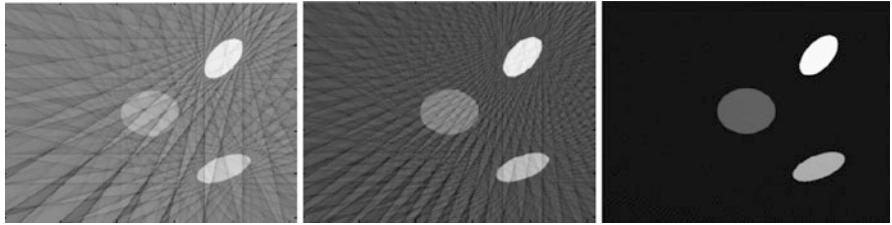

Fig. 7 FBP reconstructions of phantom consisting of three ellipses. The *left* reconstruction uses 18 angles, the *middle* 36 angles, and the *right* one 180 angles

through the object – it is not local: in order to find $f(x)$, one needs data $\mathcal{R}_L f$ over all lines in order to evaluate $\Lambda_p \mathcal{R}_L f$ (which involves a Fourier transform).

To see the how sensitive FBP is to the number of the angles used, reconstructions are provided in Fig. 7 using 18, 36, and 180 angles. One can see that using too few angles creates artifacts. An optimal choice of angles and values of p can be determined using sampling theory [15, 16, 66].

Proof (Proof of Theorem 9). Let $f \in \mathcal{S}(\mathbb{R}^2)$. First, one writes the two-dimensional Fourier inversion formula in polar coordinates:

$$f(x) = \frac{1}{2(2\pi)} \int_{\omega \in S^1} \int_{\tau \in \mathbb{R}} e^{ix \cdot (\tau\omega)} \hat{f}(\tau\omega) |\tau| d\tau d\omega \quad (19)$$

$$= \frac{1}{4\pi} \int_{\omega \in S^1} \int_{\tau \in \mathbb{R}} \frac{e^{i\tau(\omega \cdot x)}}{\sqrt{2\pi}} |\tau| (\mathcal{F}_p \mathcal{R}_L f)(\omega, \tau) d\tau d\omega \quad (20)$$

$$= \frac{1}{4\pi} \int_{\omega \in S^1} (\Lambda_p \mathcal{R}_L f)(\omega, \omega \cdot x) d\omega = \frac{1}{4\pi} \mathcal{R}_L^* \Lambda_p \mathcal{R}_L f(x). \quad (21)$$

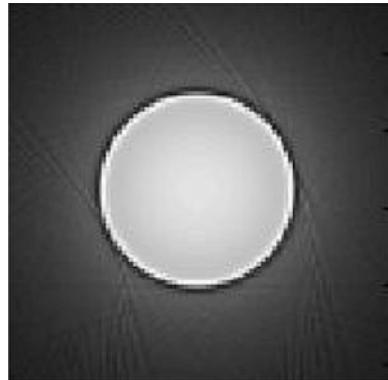

The factor of $1/2$ in front of the integral in (19) occurs because the integral is over $\tau \in \mathbb{R}$ rather than $\tau \in [0, \infty)$. The Fourier Slice Theorem (Theorem 2) is used in (20), and the definitions of Λ_p and of \mathcal{R}_L^* are used in (21). The integrals above exist because f , $\mathcal{F}f$, and $\mathcal{R}_L f$ are all rapidly decreasing at infinity.

The proof that the FBP formula is valid for $f \in \mathcal{E}'(\mathbb{R}^2)$ will now be given. Since $f \in \mathcal{E}'(\mathbb{R}^2)$, the Fourier Slice Theorem holds for f [45], and

$$\mathcal{F}_p \mathcal{R}_L f(\omega, \tau) = \sqrt{2\pi} \mathcal{F}f(\tau\omega)$$

is a smooth function that is polynomially increasing [86]. So, $|\tau| \mathcal{F}_p \mathcal{R}_L(\omega, \tau)$ is a polynomially increasing continuous function and therefore in $\mathcal{S}'(S^1 \times \mathbb{R})$. Since the inverse Fourier transform, \mathcal{F}_p^{-1} , maps \mathcal{S}' to \mathcal{S}' , $\Lambda_p \mathcal{R}_L f$ is a distribution in $\mathcal{S}'(S^1 \times \mathbb{R})$. By duality with \mathcal{S} , $\mathcal{R}_L^* : \mathcal{S}'(S^1 \times \mathbb{R}) \rightarrow \mathcal{S}'(\mathbb{R}^2)$, so $\mathcal{R}_L^* \Lambda_p \mathcal{R}_L f$ is defined for $f \in \mathcal{E}'(\mathbb{R}^2)$. Since the Fourier Slice Theorem holds for f [45], the FBP formula can be proved for f as is done above for \mathcal{S} (see [26] more generally). \square

Limited Data Algorithms

In limited data problems, some data are missing, and reconstruction methods are now presented for ROI CT, limited angle CT, and limited angle ROI CT.

ROI Tomography

Lambda tomography [17, 18, 96] is an effective and easy-to-implement algorithm for ROI CT. The fundamental idea is to replace Λ_p by $-d^2/dp^2$ in the FBP formula. The relation between these two operators is that $\Lambda_p^2 = -d^2/dp^2$, which will be justified in Example 9. This motivates the definition

$$\mathcal{L}_x f := \frac{1}{4\pi} \mathcal{R}_L^* \left(-\frac{d^2}{dp^2} \mathcal{R}_L f \right). \quad (22)$$

FBP is not local; to calculate $\Lambda_p \mathcal{R}_L f(\omega, p)$, one needs data over all lines to take the Fourier transform \mathcal{F}_p . Therefore, one needs data over all lines through the object to calculate f using FBP (18). This means that FBP cannot be used on ROI data.

The advantage of Lambda tomography over FBP is that \mathcal{L}_x is local in the following sense. To calculate $\mathcal{L}_x f$, one needs the values of $(-d^2/dp^2) \mathcal{R}_L f$ at all lines through x (since \mathcal{R}_L^* evaluated at x integrates over all such lines). Furthermore, $(-d^2/dp^2)$ is a local operator, and to calculate $(-d^2/dp^2) \mathcal{R}_L f$ at a line through x , one needs only data $\mathcal{R}_L f$ over lines close to x . Therefore, one needs only data over all lines near x to calculate $\mathcal{L}_x f$. Therefore, \mathcal{L}_x can be used on ROI data. Although Lambda CT reconstructs $\mathcal{L}_x f$, not f itself, it shows boundaries very clearly (see Fig. 8 and [17]).

Kennan Smith developed an improved local operator that shows contours of objects, not just boundaries. His idea was to add a positive multiple of $\mathcal{R}_L^* \mathcal{R}_L f$ to the reconstruction to get

$$\mathcal{L}_{x,\mu} f = \frac{1}{4\pi} \mathcal{R}_L^* \left(\left(-\frac{d^2}{dp^2} + \mu \right) \mathcal{R}_L f \right) \quad (23)$$

for some $\mu > 0$. Using (35), one sees that

$$\mathcal{R}_L^* (\mu \mathcal{R}_L f)(x) = \left(\frac{2\mu}{\|x\|} * f \right)(x), \quad (24)$$

so this factor adds contour to the reconstruction since the convolution with $2\mu/\|x\|$ emphasizes the values of f near x . Lambda reconstructions look much like FBP reconstructions even though they are local. A discussion of how to choose μ to counteract a natural cupping effect of \mathcal{L}_x is given in [17]. The operator $\mathcal{L}_{x,\mu}$ is local for the same reasons as \mathcal{L}_x is, and it was used in the ROI reconstruction in Fig. 8.

The ideas behind Lambda CT can be adapted to a range of limited data problems including limited angle tomography (e.g., [49, 56]), exterior tomography [79], and three-dimensional problems such as cone beam CT [2, 25, 51, 103] and conical tilt electron microscopy [23]. Here is one such application.

Limited Angle CT

There are several algorithms for limited angle tomography (e.g., [3, 12, 49, 61, 104]), and two will be presented that are generalizations of FBP and Lambda CT. The key to each is to use the limited angle backprojection operator that uses angles in an interval $(-\Phi, \Phi)$ with $\Phi \in (0, \pi/2)$:

$$\mathcal{R}_{L,\lim}^* g(x) = \int_{\varphi=-\Phi}^{\Phi} g(\omega(\varphi), x \cdot \omega(\varphi)) d\varphi. \quad (25)$$

The limited angle FBP and limited angle Lambda algorithms are

$$\mathcal{R}_{L,\lim}^* \Lambda_p \mathcal{R}_L f \quad \text{and} \quad \mathcal{R}_{L,\lim}^* \left(-\frac{d^2}{dp^2} \right) \mathcal{R}_L f \quad (26)$$

respectively. The objects in Fig. 3 are reconstructed using this limited angle FBP algorithm. Limited angle Lambda CT is local, so it can be used for the limited angle ROI data in electron microscope tomography [80, 83].

Fan Beam and Cone Beam CT

The parallel beam parameterization of lines in the plane used above is more convenient mathematically, but modern CT scanners use a single X-ray source that emits X-rays in a fan or cone beam. The source and detectors (on the other side of

the body) move around the body and quickly acquire data. This requires different parameterizations of lines.

The *fan beam parameterization* is used if the X-rays are collimated to one reconstruction plane. Let C be the curve of sources in the plane, typically a circle surrounding the object, and let $(\omega, \theta) \in C \times S^1$. Then,

$$L(\omega, \theta) = \{\omega + t\theta : t > 0\}$$

is the ray starting at ω in direction θ , and the *fan beam line transform* is

$$\int_{t=0}^{\infty} f(\omega + t\theta) dt.$$

In this case the analogs of the formulas proved above are a little more complicated. For example, a Lambda-type operator can be designed by taking the negative second derivative in $\theta \in S^1$. The other formulas are similar and one can find them in [66, 90].

In cone beam tomography, the source is collimated to illuminate a cone in space, and the source moves in a curve around the body along with the detectors. This scanner images a volume in the body, rather than a planar region as \mathcal{R}_L , and the fan beam transform does. However, the reconstruction formulas are more subtle [50], and one can understand these difficulties using microlocal analysis [25, 30]. Related issues come up in conical tilt ET as will be described in section “Microlocal Analysis of Conical Tilt Electron Microscope Tomography (ET).”

These data acquisition methods have several advantages over parallel beam data acquisition. First, the scanners are simpler to build than the original CT scanners, which took data using the parallel geometry, and so a single X-ray source (or several collimated sources) and detector(s) were translated to get data over parallel lines in one direction, and then the source and detector were rotated to get lines for other directions. Second, they can acquire data more quickly than old style parallel beam scanners since the fan beam X-ray source and detector array move in a circle around the object.

This is all discussed in Herman’s chapter in this book [44].

Algorithms in Conical Tilt ET

Conical tilt ET [108] is a new data acquisition geometry in ET that has the potential to provide faster data acquisition as well as clearer reconstructions. The algorithms used for the conical tilt ET reconstructions will be given in section “Electron Microscope Tomography (ET) Over Arbitrary Curves.” This will lay the groundwork to understand why the reconstructions in that section from two very similar algorithms are so dramatically different. The model and mathematics are fully discussed in Öktem’s chapter in this book [71].

First the notation is established. For $\omega \in S^2$, denote the plane through the origin perpendicular to ω by

$$\omega^P = \{x \in \mathbb{R}^3 : x \cdot \omega = 0\}. \quad (27)$$

The tangent space to the sphere S^2 is

$$T(S^2) = \{(\omega, x) : \omega \in S^2, x \in \omega^P\}$$

since the plane ω^P is the tangent plane to S^2 at ω . This gives the *parallel beam* parameterization of lines in space: for $(\omega, x) \in T(S^2)$, the line

$$L(\omega, x) = \{x + t\omega : t \in \mathbb{R}\}.$$

If ω is fixed, then the lines $L(\omega, x)$ for $x \in \omega^P$ are all parallel. As noted in Öktem's chapter in this book [71], ET data are typically taken on a curve $S \subset S^2$. This means the lines in the data set are parameterized by

$$\mathcal{M}_S = \{(\omega, x) : \omega \in S, x \in \omega^P\}.$$

So, for $f \in L^1(\mathbb{R}^3)$, the ET data of f for lines parallel to S can be modeled as the *parallel beam transform*

$$\mathcal{P}_S f(\omega, x) = \int_{t \in \mathbb{R}} f(x + t\omega) dt \quad \text{for } (\omega, x) \in \mathcal{M}_S.$$

Its dual transform is defined for functions g on \mathcal{M}_S as

$$\mathcal{P}_S^* g(x) = \int_{\omega \in S} g(\omega, x - (x \cdot \omega)\omega) d\omega,$$

where $d\omega$ is the arc length measure on S . This represents the integral of g over all lines through x .

In this section, conical tilt ET is considered; an angle $\alpha \in (0, \pi/2)$ is chosen, and data are taken for angles on the latitude circle:

$$S_\alpha = \{(\sin(\alpha) \cos(\varphi), \sin(\alpha) \sin(\varphi), \cos(\alpha)) : \varphi \in [0, 2\pi]\}.$$

Let C_α be the cone with vertex at the origin and opening angle α from the vertical axis:

$$C_\alpha = \{t\omega : \omega \in S_\alpha\}.$$

Note that C_α is the cone generated by S_α .

Here are the two algorithms for which reconstructions were given in section “Electron Microscope Tomography (ET) Over Arbitrary Curves.” The first operator is a generalization of one developed for cone beam CT by Louis and Maas [62]:

$$\mathcal{L}_\Delta f = \mathcal{P}_S^*(-\Delta_S)\mathcal{P}_S f, \quad (28)$$

where Δ_S is the Laplacian on the detector plane, ω^P . The second operator is defined

$$\mathcal{L}_S f = \mathcal{P}_S^*(-\mathcal{D}_S)\mathcal{P}_S f, \quad (29)$$

where \mathcal{D}_S is the second derivative on the detector plane ω^P in the tangent direction to the curve S at ω (see Öktem’s chapter in this book [71]). The next theorem helps clarify these operators by writing them as convolution operators.

Theorem 10. *Let \mathcal{P}_S be the conical tilt ET transform with angle $\alpha \in (0, \pi/2)$. Let $f \in \mathcal{E}'(\mathbb{R}^3)$. Then*

$$\mathcal{P}_S^*\mathcal{P}_S f = f * I = \int_{y \in C_\alpha} \frac{f(x+y)}{\|y\|} dy \quad (30)$$

$$\mathcal{L}_\Delta f = (-\Delta)(f * I) \quad (31)$$

$$\mathcal{L}_S f = \left(-\Delta + \csc^2(\alpha) \frac{\partial^2}{\partial z^3} \right) f * I \quad (32)$$

where I is the distribution defined for $f \in \mathcal{D}(\mathbb{R}^2)$ by

$$I(f) = \int_{y \in C_\alpha} f(y) \frac{1}{\|y\|} dy$$

and dy is the surface area measure on the cone C_α .

Equation (30) makes sense since \mathcal{P}_S^* integrates $\mathcal{P}_S f$ over all lines in the data set through x , and these are exactly the lines in the shifted cone $x + C_\alpha$. The theorem implies that each of the operators is related to a simple convolution with a singular weighted integration over the cone C_α .

Proof. The theorem is first proven for $f \in \mathcal{D}(\mathbb{R}^3)$, by calculating (30):

$$\begin{aligned} \mathcal{P}_S^*\mathcal{P}_S f(x) &= \int_{\omega \in S} \int_{t \in \mathbb{R}} f(x - (x \cdot \omega)\omega + t\omega) dt d\omega \\ &= \int_{\omega \in S} \int_{t \in \mathbb{R}} f(x + s\omega) ds d\omega \end{aligned}$$

where the substitution $s = t - (x \cdot \omega)$ is used. Now, one converts this to an integral over C_α :

$$\begin{aligned}\mathcal{P}_S^* \mathcal{P}_S f(x) &= \int_{\omega \in S} \int_{s \in \mathbb{R}} f(x + s\omega) \frac{1}{|s|} |s| ds d\omega \\ &= \int_{y \in C_\alpha} \frac{f(x + y)}{\|y\|} dy\end{aligned}$$

since the measure on the cone C_α is $dy = |s| ds d\omega$ where $y = s\omega$.

To prove (31), one moves Δ inside the integral. Then one uses rotation invariance of Δ (to write Δ in coordinates:

$$(s, t, p) \mapsto (s\omega + t\omega' + p\omega \times \omega')$$

where ω' is the unit vector tangent to S at ω and in direction of increasing φ). Finally, one uses an integration by parts to show that \mathcal{P}_S^* intertwines Δ and Δ_S . To prove (32), one uses (31) and a calculation to show that $(-\Delta + \csc^2(\alpha) \frac{\partial^2}{\partial z^2})$ and \mathcal{D}_S are intertwined by \mathcal{P}_S^* .

The theorem is now proven for $f \in \mathcal{E}'(\mathbb{R}^3)$. Since f has compact support, the convolution $f * I$ is defined by [86, 6.37 Theorem]. Then, the proof is completed using the fact that the equalities are true for $f \in \mathcal{D}(\mathbb{R}^3)$ and continuity of the operators (since \mathcal{P}_S is a Fourier integral operator, which will be discussed in section ‘‘Microlocal Analysis of Conical Tilt Electron Microscope Tomography (ET)’’). \square

4 Microlocal Analysis

The reader has seen how limited data reconstructions can image different singularities (or add artifacts) depending on the type of data. This section will be devoted to developing the mathematics to understand those differences. The key point is to develop a precise definition of singularities and to understand what our tomographic transforms do to singularities.

Singular Support and Wavefront Set

Definition 1. Let $\Omega \subset \mathbb{R}^n$ be an open set and let $u \in \mathcal{D}'(\Omega)$. The singular support of u , denoted by $\text{spp}(u)$, is the complement in Ω of the largest open set on which u is C^∞ smooth.

In other words, a point $x_0 \in \Omega$ is not in the singular support of u if u is smooth in a neighborhood of x_0 . Let us consider some examples.

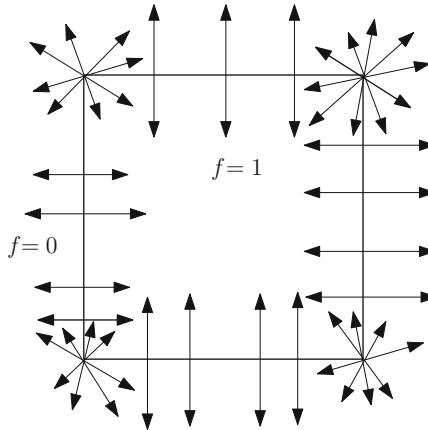

Fig. 9 The function $f = 1$ in the interior of the square and $f = 0$ in the complement. The singular support, $\text{ssupp}(f)$, is the boundary of the rectangle, and the wavefront set directions are shown in the figure

Example 3. Consider the square $S = [0, 1]^2$ in \mathbb{R}^2 . Let f be the characteristic function

$$u(x, y) = \begin{cases} 1 & \text{if } (x, y) \in S; \\ 0 & \text{otherwise.} \end{cases} \quad (33)$$

Then $\text{ssupp}(u)$ is the boundary of the square because that is where u is not smooth; see Fig. 9.

Smoothness of a distribution $u \in \mathcal{E}'(\mathbb{R}^n)$ is related to the rapid decay of its Fourier transform. Recall the following definition.

Definition 2. A function $f : \mathbb{R}^n \rightarrow \mathbb{C}$ is *rapidly decaying at infinity* if for every $N \geq 0$, there is a C_N such that $|f(x)| \leq C_N(1 + \|x\|)^{-N}$ for all $x \in \mathbb{R}^n$.

Theorem 11 ([86]). A distribution $u \in \mathcal{E}'(\Omega)$ is in $C_c^\infty(\Omega)$ if and only if its Fourier transform is rapidly decaying at infinity.

This theorem implies that if a distribution u is not C^∞ smooth, then there are nonzero frequency directions ξ such that the Fourier transform \hat{u} does not satisfy the estimate of Theorem 11 in any conic neighborhood Γ containing ξ . However, this is global information; it does not yet relate to singular support – the points where u is not smooth. To make this connection, one needs to consider directions near which a localized Fourier transform of u does not satisfy these estimates. This leads us to the concept of C^∞ wavefront set.

Definition 3. Let u be a distribution defined on an open set $\Omega \subset \mathbb{R}^n$. One says that $(x_0, \xi_0) \in \Omega \times \mathbb{R}^n \setminus \mathbf{0}$ is *not* in the wavefront set of u , if there is a $\psi \in C_c^\infty(X)$ identically 1 near x_0 and an open cone Γ containing ξ_0 such that given any N , there is a C_N such that

$$|\widehat{\psi u}(\xi)| \leq C_N(1 + \|\xi\|)^{-N} \text{ for } \xi \in \Gamma.$$

On the other hand, the C^∞ wavefront set of a distribution u will be denoted by $\text{WF}(u)$.

Remark 1. To be more precise, one views elements of the wavefront set to be elements of the cotangent bundle $T^*\Omega \setminus \mathbf{0}$ using the notation

$$\xi dx = \xi_1 dx_1 + \cdots + \xi_n dx_n \text{ for } \xi \in \mathbb{R}^n \setminus \mathbf{0}.$$

Through this, one can define wavefront sets for distributions on manifolds.

Note that the cutoff function, ψ , in this definition is somewhat more restrictive than what is sometimes given (just that $\psi(x_0) \neq 0$) but it is equivalent [47].

Theorem 12 ([47]). *Let u be a distribution defined on an open set $\Omega \subset \mathbb{R}^n$ and π_x denote the x -projection $\text{WF}(u)$. Then $\pi_x(\text{WF}(u)) = \text{ssupp}(u)$.*

Example 4. Consider the Dirac delta distribution δ_0 in \mathbb{R}^n . Then $\text{ssupp}(\delta_0) = \{0\}$ because δ_0 is zero away from the origin and supported at the origin. So, by Theorem 12, $x = 0$ is the only point above in which there can be wavefront set. Furthermore, if ψ is a cutoff function at $x_0 = 0$, then $\mathcal{F}(\psi \delta_0) = 1/(2\pi)^{n/2}$, so $\text{WF}(\delta_0) = \{(0, \xi dx), \xi \neq 0\}$.

Example 5. Consider the function f given in Example 3. The wavefront set $\text{WF}(f)$ consists of the nonzero normal directions at all the singular support points except the four corner points. At these corner points, all nonzero directions are in the wavefront set, as illustrated in Fig. 9.

The proof is as follows. Consider first a non-corner point x_0 in the singular support. One can assume that this point is on the x -axis, $x_0 = (a, 0)$, where $a \in (0, 1)$. Fix a direction $\xi^0 = (\xi_1^0, \xi_2^0)$ with $\xi_1^0 \neq 0$. One can show that the localized Fourier transform is rapidly decaying in a conic neighborhood of ξ^0 . To see this, one can find a narrow conic neighborhood Γ containing ξ^0 such $|\xi_1| \geq c \|\xi\|$ for some $c > 0$ and all $\xi \in \Gamma$ (here $\xi = (\xi_1, \xi_2)$). Let $\varphi \in C_c^\infty(\mathbb{R}^2)$ be a function of the form $\varphi(x_1, x_2) = \varphi_1(x_1)\varphi_2(x_2)$ that is identically 1 near x_0 . Without loss of generality, one can assume φ_1 is even about a and φ_2 is even about 0. Consider

$$\widehat{\varphi f}(\xi) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{-ix_1 \cdot \xi_1} \varphi_1(x_1) dx_1 \frac{1}{\sqrt{2\pi}} \int_0^{\infty} e^{-ix_2 \xi_2} \varphi_2(x_2) dx_2.$$

Denote the left-hand integral in this expression by $L(\xi_1)$ and the right-hand integral by $R(\xi_2)$. Note that the R is bounded in ξ_2 because the integrand is uniformly bounded and of compact support. Because φ_1 is in $\mathcal{S}(\mathbb{R})$, $L(\xi_1)$ is also in $\mathcal{S}(\mathbb{R})$, since it is the one-dimensional Fourier transform of φ_1 . Therefore, $L(\xi_1)$ is rapidly decaying at infinity as a function of ξ_1 . Since $|\xi_1| > c \|\xi\|$ in Γ , the function $\xi \mapsto L(\xi_1)$ decays rapidly at infinity for ξ in Γ . Since the function $R(\xi_2)$ is bounded, one sees that $\widehat{\varphi f}(\xi)$ decays rapidly in Γ . This shows that the only possible vectors in $\text{WF}(f)$ above $x_0 = (a, 0)$ are vertical ones.

Since f is not smooth at x_0 , at least one vertical vector at x_0 must be in $\text{WF}(f)$ by Theorem 11. Therefore, $R(\xi_2)$ must not rapidly decay in either the positive direction ($\xi_2 > 0$) or the negative direction. Since φ_2 is an even function in $\mathcal{S}(\mathbb{R})$, $\mathcal{F}(\varphi_2)(\xi_2) = R(\xi_2) + R(-\xi_2)$ is rapidly decreasing at $\pm\infty$, so $R(\xi_2)$ must not be rapidly decaying for $\xi_2 > 0$ and for $\xi_2 < 0$ (since $R(\xi_2)$ is not rapidly decaying in at least one direction and the sum is rapidly decaying in both positive and negative directions). Therefore, both vertical vectors are in $\text{WF}(f)$ at x_0 . (In another proof, one shows $R(\xi_2) = \mathcal{O}(1/|\xi_2|)$ by performing two integrations by parts on that integral.)

Now it will be shown that all directions are in $\text{WF}(f)$ above $(0, 0)$. One can use symmetric cutoffs in x_1 and x_2 at 0. Then

$$\widehat{\varphi f}(\xi) = \frac{1}{\sqrt{2\pi}} \int_0^{\infty} e^{-ix_2 \xi_2} \varphi_2(x_2) dx_2 \frac{1}{\sqrt{2\pi}} \int_0^{\infty} e^{-ix_1 \cdot \xi_1} \varphi_1(x_1) dx_1.$$

The proof for $R(\xi_2)$ above can be used to show that neither integral decays rapidly at infinity in this case. This shows that $\text{WF}(\varphi f)$ consists of all directions at $x_0 = 0$. The proofs at the other corners are similar.

Example 6. If f is the characteristic function of a set, Ω with a smooth boundary, then $\text{WF}(f)$ is the conormal bundle:

$$N^*(\Omega) = \{(x, \xi dx) : x \in \text{bd}(\Omega), \xi \text{ is normal to } \text{bd}(\Omega) \text{ at } x\}$$

This is suggested by Example 5 and it follows from the results in [47].

If f is a linear combination of characteristic functions of sets with smooth boundary, then $\text{WF}(f)$ is the union of the conormal sets of the individual sets unless cancellation occurs along shared boundaries.

Pseudodifferential Operators

To motivate the definition of these operators, consider the following example.

Theorem 13. *For $f \in \mathcal{S}(\mathbb{R}^2)$,*

$$\mathcal{R}_L^* \mathcal{R}_L u(x) = \int e^{ix \cdot \xi} \frac{2}{\|\xi\|} \hat{u}(\xi) d\xi = \frac{1}{\pi} \int e^{i(x-y) \cdot \xi} \frac{1}{\|\xi\|} u(y) dy d\xi. \quad (34)$$

Proof. Using a polar integration about x , one shows that

$$\mathcal{R}_L^* \mathcal{R}_L f = f * \frac{2}{\|x\|}. \quad (35)$$

Then, since $\mathcal{F}(1/\|x\|) = 1/\|\xi\|$ [43, Lemma 6.2, p. 238], one sees that

$$\mathcal{R}_L^* \mathcal{R}_L u = \mathcal{F}^{-1} \mathcal{F} \left(u * \frac{2}{\|x\|} \right) = \mathcal{F}^{-1} \left(2\pi \frac{2}{\|\xi\|} \hat{u} \right)$$

using the fact that the Fourier transform of a convolution in \mathbb{R}^2 (with the normalization of (10)) is the product of the Fourier transforms times 2π . Writing \mathcal{F}^{-1} as an integral in the right-hand expression proves the theorem. \square

It should be pointed out that the left-hand integral in (34) converges for $f \in \mathcal{S}(\mathbb{R}^2)$, but the right-hand integral in (34) does not converge. However, one can do integrations by parts at infinity to make it converge for $f \in \mathcal{S}(\mathbb{R}^2)$ or $f \in \mathcal{E}'(\mathbb{R}^2)$ as is done for pseudodifferential operators (e.g., [74]).

With this as the model, consider operators with integral representation

$$\mathcal{P}u(x) = \int e^{i(x-y) \cdot \xi} p(x, y, \xi) u(y) dy d\xi. \quad (36)$$

The study of the operator \mathcal{P} is important in imaging for the following reasons:

1. Assuming p satisfies certain estimates (see Definition 4), one can describe precisely the action of \mathcal{P} on the singularities of u .
2. If one has a procedure to invert or approximately invert the operator \mathcal{P} by another operator \mathcal{Q} having a similar integral representation as that of \mathcal{P} , then by (a), one would have that the singularities of $\mathcal{Q}\mathcal{P}u$ are identical to those of u . Now through this approximate inversion process, one has a procedure to recover the singularities of u .

An operator \mathcal{P} of the form (36) with p satisfying certain estimates is called a *pseudodifferential operator* (Ψ DO) [33, 47, 89, 93, 94]. This will be given below (see Definition 5).

In order to motivate the appropriate conditions and estimates that p should satisfy, let us look at the following simple example:

Consider a linear partial differential operator of the form

$$\mathcal{P}(x, D) = \sum_{|\nu| \leq m} a_\nu(x) D_x^\nu. \quad (37)$$

Here $\nu = (\nu_1, \dots, \nu_n)$ is a multi-index and

$$D_x^\nu = (-i)^{\nu_1 + \dots + \nu_n} \frac{\partial^{\nu_1}}{\partial x_1^{\nu_1}} \cdots \frac{\partial^{\nu_n}}{\partial x_n^{\nu_n}}.$$

For simplicity let u be a compactly supported function. Applying the Fourier transform,

$$\widehat{D_x^\nu u}(\xi) = \frac{1}{(2\pi)^{n/2}} \int e^{-ix \cdot \xi} D_x^\nu u(x) dx. \quad (38)$$

Integrating by parts $|\nu|$ times, one obtains

$$\widehat{D_x^\nu u}(\xi) = \xi^\nu \hat{u}(\xi). \quad (39)$$

With this one has

$$\mathcal{P}(x, D)u(x) = \frac{1}{(2\pi)^{n/2}} \int e^{i(x-y) \cdot \xi} p(x, \xi) u(y) dy d\xi \quad (40)$$

where

$$p(x, \xi) = \sum_\nu a_\nu(x) \xi^\nu.$$

The function $p(x, \xi)$ is called the *symbol* of the partial differential operator (PDO), $\mathcal{P}(x, D)$.

The function $p(x, \xi)$ satisfies the following property: Let $\alpha = (\alpha_1, \dots, \alpha_n)$ be a multi-index. Then $\partial_\xi^\alpha p(x, \xi)$ lowers the degree with respect to ξ of the resulting function by $|\alpha|$, whereas $\partial_x^\beta p(x, \xi)$ where $\beta = (\beta_1, \dots, \beta_n)$ is a multi-index does not alter the degree of homogeneity with respect to ξ of the resulting function.

More precisely one has the following estimate:

Let α and β be any multi-indices. For x in a bounded subset of \mathbb{R}^n , there is a constant C such that

$$\left| \partial_x^\alpha \partial_\xi^\beta p(x, \xi) \right| \leq C(1 + \|\xi\|)^{m - |\alpha|}. \quad (41)$$

Here m is the order of the PDO, $\mathcal{P}(x, D)$. In order to get this inequality, first rewrite the terms of $p(x, \xi)$ by combining terms of the same homogeneous degree with respect to the ξ variable.

Differentiate ξ^ν $\alpha = (\alpha_1, \dots, \alpha_n)$ times with respect to ξ_1, \dots, ξ_n , where the number of times one differentiates ξ^ν with respect to each particular ξ_l is α_l . One sees that this reduces the degree of homogeneity of ξ^ν by $|\alpha|$ and the highest-order terms dominate. On a bounded subset of \mathbb{R}^n , all derivatives of the a_ν are bounded. This gives the estimate (41).

Now one can generalize the class of operators that have Fourier integral representations of the form (40) by admitting a larger class of functions $p(x, \xi)$ to be symbols. Consider those functions p that satisfy the estimate as in (41) and that behave like polynomials or the inverse of polynomials in ξ as $\|\xi\| \rightarrow \infty$. In other words, one wants $p(x, \xi)$ to grow or decay in powers of $\|\xi\|$, and differentiation with respect to ξ lowers the order of growth or raises the order of decay. Furthermore, in order to include $\mathcal{R}_L^* \mathcal{R}_L$ in the class of operators considered (see Example 13), one can allow some latitude at $\xi = 0$.

In the interest of flexibility, one can also let the function p depend on x, y , and ξ . Such functions will be denoted as *amplitudes*.

Definition 4 ([33, 47, 89, 93, 94]). Let $X \subset \mathbb{R}^n$ be an open subset. An amplitude of order m is a function that satisfies the following properties:

1. $p(x, y, \xi) \in C^\infty(X \times X \times \mathbb{R}^n \setminus \{0\})$,
2. For every compact set $K \subset X$ and for multi-index α, β, γ ,
 - (a) There is a constant $C = C(K, \alpha, \beta, \gamma)$ such that

$$\left| D_\xi^\alpha D_x^\beta D_y^\gamma p(x, y, \xi) \right| \leq C(1 + \|\xi\|)^{m - |\alpha|} \text{ for } x \text{ and } y \text{ in } K \text{ and } \|\xi\| > 1, \text{ and}$$

- (b) $p(x, y, \xi)$ is locally integrable for x and y in K and $\|\xi\| \leq 1$.

It is important to note that in Definition 4, p need not be a polynomial in ξ and m can be any real number. The local integrability condition can be relaxed if p is a sum of homogeneous terms in ξ [74].

Now pseudodifferential operators are defined.

Definition 5. Let $X \subset \mathbb{R}^n$ be an open subset. A pseudodifferential operator (Ψ DO) is an operator of the form

$$\mathcal{P}u(x) = \frac{1}{(2\pi)^n} \int e^{i(x-y) \cdot \xi} p(x, y, \xi) u(x) dy d\xi,$$

where $p(x, y, \xi)$ is a function that satisfies the properties of Definition 4.

The operator \mathcal{P} has order m if its amplitude is of order m , and \mathcal{P} is elliptic of order m if for each compact set $K \subset \Omega$, there is a constant $C_K > 0$ such that for x and y in K and $\|\xi\| \geq C_K$

$$|p(x, y, \xi)| \geq C_K^{-1} (1 + \|\xi\|)^m. \quad (42)$$

The next theorem highlights two fundamental properties of Ψ DOs.

Theorem 14 (Pseudolocal Property [94]). *If \mathcal{P} is a Ψ DO, then \mathcal{P} satisfies the pseudolocal property:*

$$\text{ssupp}(\mathcal{P}u) \subset \text{ssupp}(u) \text{ and } \text{WF}(\mathcal{P}u) \subset \text{WF}(u).$$

If, in addition, \mathcal{P} is elliptic, then

$$\text{ssupp}(\mathcal{P}u) = \text{ssupp}(u) \text{ and } \text{WF}(\mathcal{P}u) = \text{WF}(u).$$

Note that, although Ψ DOs can spread out the support of the function u , they do not spread out its singular support or wavefront set. Elliptic Ψ DOs preserve singular support and wavefront set.

Equation (34) shows that the composition $\mathcal{R}_L^* \mathcal{R}_L$ is a pseudodifferential operator since its symbol $(4\pi)/\|\xi\|$ satisfies the conditions in Definition 4. Furthermore, because the symbol satisfies the ellipticity estimate (42), $\mathcal{R}_L^* \mathcal{R}_L$ is an elliptic Ψ DO of order -1 .

Example 7. The powers of d/dp and Δ as Ψ DOs.

According to (40), the symbol of $-d^2/dp^2$ is $|\tau|^2$ where τ is the dual variable to p . So, the symbol of $\sqrt{-d^2/dp^2}$ can be considered to be $|\tau|$. The rationale is that if one calculates

$$\begin{aligned} -\frac{d^2}{dp^2} f &= \mathcal{F}^{-1} |\tau|^2 \mathcal{F} f = \mathcal{F}^{-1} |\tau| \mathcal{F} (\mathcal{F}^{-1} |\tau| \mathcal{F} f) \\ &= \sqrt{-\frac{d^2}{dp^2}} \circ \sqrt{-\frac{d^2}{dp^2}} f. \end{aligned} \quad (43)$$

This justifies why

$$\Lambda_p = \sqrt{-d^2/dp^2}. \quad (44)$$

Since

$$-\Delta = D_{x_1}^2 + \cdots + D_{x_n}^2,$$

its symbol is $\|\xi\|^2$. Since the symbol of $-\Delta$ is $\|\xi\|^2$, one can easily find symbols of powers of the Laplacian. For example, $\sqrt{-\Delta}$ has symbol $\|\xi\|$ and Fourier representation

$$\sqrt{-\Delta}u = \frac{1}{(2\pi)^n} \int e^{i(x-y)\cdot\xi} \|\xi\| u(y) dy d\xi$$

and $(-\Delta)^{-1/2}$ has symbol $1/\|\xi\|$

$$(-\Delta)^{-1/2}u = \frac{1}{(2\pi)^n} \int e^{i(x-y)\cdot\xi} \frac{1}{\|\xi\|} u(y) dy d\xi.$$

Now, as a calculation in distributions using Fourier transforms (similar to (43)), one sees that $(-\Delta)^{-1/2} \circ \sqrt{-\Delta}$ is the identity map.

Note that $\sqrt{-d^2/dp^2}$, $\sqrt{-\Delta}$, $(-\Delta)^{-1/2}$ are all elliptic Ψ DOs since the corresponding symbols satisfy the ellipticity estimate (42).

Example 8. Example 7 allows one to justify why the operator A_p is really $\sqrt{-d^2/dp^2}$. So, the FBP inversion formula (18) can be written

$$f = \frac{1}{4\pi} \mathcal{R}_L^* \left(\sqrt{-d^2/dp^2} \mathcal{R}_L f \right). \quad (45)$$

Equation (34) shows that $\mathcal{R}_L^* \mathcal{R}_L = 4\pi (-\Delta)^{-1/2}$. Using the observation at the end of Example 7, one obtains a different version of the filtered backprojection inversion formula for \mathcal{R}_L :

$$f = \frac{1}{4\pi} \sqrt{-\Delta} \mathcal{R}_L^* \mathcal{R}_L f. \quad (46)$$

These calculations can be justified for distributions of compact support [43, 45].

Example 9. Now consider the Lambda operators given in (22) and (23). To get the Lambda operator, \mathcal{L}_x , from the FBP operator, one replaces the $\sqrt{-d^2/dp^2}$ in (45) by its square, $-d^2/dp^2$.

Here is another way to understand Lambda tomography. By evaluating another $\sqrt{-\Delta}$ in (46), one sees that

$$\sqrt{-\Delta}f = -\frac{1}{4\pi} \Delta \mathcal{R}_L^* \mathcal{R}_L f = \frac{1}{4\pi} \mathcal{R}_L^* \left(-\frac{d^2}{dp^2} \mathcal{R}_L f \right)$$

where the second equality holds because \mathcal{R}_L^* intertwines $-\Delta$ and $-d^2/dp^2$ (this is proven using an argument similar to the intertwining argument in the proof of Theorem 10). Because $\mathcal{R}_L^* \mathcal{R}_L$ is an elliptic Ψ DO with symbol $4\pi/\|\xi\|$, the symbol of $\mathcal{L}_{x,\mu}$ is

$$\|\xi\| + \frac{\mu}{\|\xi\|}$$

and it is elliptic of order one. Therefore, $\mathcal{L}_{x,\mu}$ and \mathcal{L}_x (corresponding to $\mu = 0$) are both elliptic Ψ DOs.

The operator $\mathcal{L}_{x,\mu}$ does not reconstruct f but $\left((-Δ)^{1/2} + \mu\right)f$. The natural question then is how different is this from f ? It has just been established that \mathcal{L}_x and $\mathcal{L}_{x,\mu}$ are elliptic Ψ DOs. Therefore, by Theorem 14 this means that these operators recover $\text{ssupp}(f)$ and $\text{WF}(f)$. The reconstructions in Fig. 8 and others in [17, 18] show that it is effective in practice.

Fourier Integral Operators

In the analysis thus far, one studied the composition of a generalized Radon transform with its adjoint. This composed operator, as was shown, is a pseudodifferential operator. Theorem 14 shows us how Ψ DOs act on singularities and wavefront sets. In this section, more general operators will be considered, and how they change wavefront sets will be described.

Example 10. Consider \mathcal{R}_L in a special Fourier representation.

$$\begin{aligned}\mathcal{R}_L f(\omega, p) &= \frac{1}{(2\pi)^{1/2}} \int_{\tau \in \mathbb{R}} e^{ip\tau} \mathcal{F}_p(\mathcal{R}_L f)(\omega, \tau) d\tau \\ &= \int_{\tau \in \mathbb{R}} e^{ip\tau} \hat{f}(\tau\omega) d\tau \\ &= \int_{\tau \in \mathbb{R}} \int_{x \in \mathbb{R}^2} e^{i(p-(x \cdot \omega))\tau} \frac{1}{2\pi} f(x) dx d\tau.\end{aligned}\tag{47}$$

The last expression in (47) looks like a Ψ DO except that the τ and x integrals are over different sets and the exponent is not the one for Ψ DOs.

In many applications, it might be necessary to understand the properties of the Radon transform directly, rather than the composition with its adjoint. In the last example one saw that the Radon transform \mathcal{R}_L had an integral representation of the form

$$\mathcal{P}u(x) = \int e^{i\phi(x,y,\xi)} p(x, y, \xi) u(y) dy d\xi.\tag{48}$$

The important differences between the operator \mathcal{P} in (48) and a Ψ DO are the following:

- The functions $\mathcal{P}u$ and u , in general, are functions on different sets X and Y , respectively. The spaces X and Y can be of different dimensions as well.
- The phase function ϕ in (48) is more general than that of a Ψ DO, but it shares similar features. See Definition 6.
- The dimension of the frequency variable ξ can be different from that of the spaces X and Y , unlike as in the case of a Ψ DO.

Another simple example where an integral representation of (48) arises is when one uses Fourier transform techniques to determine the solution to a constant coefficient wave equation:

$$(\partial_t^2 - \Delta_x) u = 0, \quad u(x, 0) = 0, \quad \partial_t u(x, 0) = g. \quad (49)$$

Now by taking Fourier transform in the space variable, one has the following integral representation for the solution to the wave equation:

$$\begin{aligned} u(x, t) &= \frac{1}{2i(2\pi)^n} \left(\int e^{i(x-y) \cdot \xi + t\|\xi\|} \frac{1}{\|\xi\|} g(y) dy d\xi \right. \\ &\quad \left. - \int e^{i(x-y) \cdot \xi - t\|\xi\|} \frac{1}{\|\xi\|} g(y) dy d\xi \right). \end{aligned}$$

Note that the phase functions in the above solution are $\phi_{\pm}(x, y, \xi) = (x - y) \cdot \xi \pm t\|\xi\|$.

If $f : \mathbb{R}^n \rightarrow \mathbb{R}$, then the notation

$$\partial_x f(x) = \frac{\partial f}{\partial x_1} dx_1 + \cdots + \frac{\partial f}{\partial x_n} dx_n \quad (50)$$

will be used for the differential of f with respect to x . If g is a function of (φ, p) , then

$$\partial_{\varphi, p} g(\varphi, p) = \frac{\partial g}{\partial \varphi} d\varphi + \frac{\partial g}{\partial p} dp$$

will denote the differential of g with respect to the variables (φ, p) .

Definition 6. Let $X \subset \mathbb{R}^m$ and $Y \subset \mathbb{R}^n$ be open subsets. A real-valued function $\phi \in C^\infty(X \times Y \times \mathbb{R}^N \setminus \{0\})$ is called a phase function if

1. ϕ is positive homogeneous of degree 1 in ξ . That is, $\phi(x, y, r\xi) = r\phi(x, y, \xi)$ for all $r > 0$.
2. $(\partial_x \phi, \partial_\xi \phi)$ and $(\partial_y \phi, \partial_\xi \phi)$ do not vanish for all $(x, y, \xi) \in X \times Y \times \mathbb{R}^N \setminus \{0\}$.

The phase function ϕ is called nondegenerate if on the zero-set $\partial_\xi \phi = 0$, the set of vectors $\{\partial_{x,y,\xi} \frac{\partial \phi}{\partial \xi_j}, 1 \leq j \leq N\}$ is linearly independent.

Definition 7. A Fourier integral operator (FIO) \mathcal{P} is defined as

$$\mathcal{P}u(x) = \int e^{i\phi(x,y,\xi)} p(x, y, \xi) u(y) dy d\xi,$$

where ϕ is a nondegenerate phase function, and the amplitude $p(x, y, \xi) \in C^\infty(X \times Y \times \mathbb{R}^N)$ satisfies the following estimate: for every compact set $K \subset X \times Y$ and for every multi-index α, β, γ , there is a constant $C = C(K, \alpha, \beta, \gamma)$ such that

$$\left| D_\xi^\alpha D_x^\beta D_y^\gamma p(x, y, \xi) \right| \leq C(1 + \|\xi\|)^{m - |\alpha|} \text{ for all } x, y \in K \text{ and for all } \xi \in \mathbb{R}^N.$$

Finally, one has two important sets associated with this FIO.

The auxiliary manifold

$$\Sigma_\phi = \{(x, y, \xi) \in X \times Y \times (\mathbb{R}^N \setminus \mathbf{0}) : \partial_\xi \phi(x, y, \xi) = 0\} \quad (51)$$

and the *canonical relation*

$$C := \{(x, \partial_x \phi(x, y, \xi); y, -\partial_y \phi(x, y, \xi)) : (x, y, \xi) \in \Sigma_\phi\}. \quad (52)$$

Note that since the phase function ϕ is nondegenerate, the sets Σ_ϕ and C have smooth manifold structures.

One can also include the local integrability condition 2b of Definition 4 for the amplitude of FIOs.

Note that \mathcal{R}_L satisfies these conditions with phase function $\phi(\omega, p, x, \tau) = (p - x \cdot \omega)\tau$ and amplitude $p(x, y, \tau) = 1/(2\pi)$, so \mathcal{R}_L is an FIO. Guillemin originally proved that a broad range of Radon transforms are FIOs [35, 36, 38]. The operator \mathcal{R}_L will be studied more carefully in the next section.

Every Ψ DO is an FIO with phase function $\phi(x, y, \xi) = (x - y) \cdot \xi$. However, \mathcal{R}_L is an FIO that is not a Ψ DO since its phase function is not of that form.

Definition 8. Let $C \subset T^*X \times T^*Y$, $\tilde{C} \subset T^*Y \times T^*X$, and $A \subset T^*Y$. Define

$$C \circ A = \{(x, \xi dx) : \exists (y, \eta dy) \in A \text{ with } (x, \xi dx; y, \eta dy) \in C\}$$

$$\begin{aligned} \tilde{C} \circ C = & \{(\tilde{y}, \tilde{\eta} d\tilde{y}; y, \eta dy) : \exists (x, \xi dx) \text{ with } (\tilde{y}, \tilde{\eta} d\tilde{y}; x, \xi dx) \in \tilde{C}, \\ & \text{and } (x, \xi dx; y, \eta dy) \in C\}. \end{aligned}$$

The key theorem on what FIOs do to wavefront sets is the following result.

Theorem 15 ([47]). *Let \mathcal{P} be an FIO and let C be the associated canonical relation. Then*

$$\text{WF}(\mathcal{P}u) \subset C \circ \text{WF}(u).$$

Example 11. In this example, the canonical relation of any Ψ DO will be calculated. First note that since $\phi = (x - y) \cdot \xi$,

$$\partial_x \phi = \xi dx \quad \partial_y \phi = -\xi dy \quad \partial_\xi \phi = (x - y) d\xi.$$

Therefore, $\Sigma_\phi = \{(x, y, \xi) : x - y = 0\}$. Now, use (52) and these calculations to see that the canonical relation for Ψ DOs is

$$C = \{(x, \xi dx; x, \xi dx) : \xi \neq 0\}$$

which is the diagonal in $(T^*(\mathbb{R}^n) \setminus \mathbf{0})$ and which will be denoted by Δ . Using Theorem 15, one sees that if \mathcal{P} is a Ψ DO, $\text{WF}(\mathcal{P}u) \subset \text{WF}(u)$.

This section will be concluded with a key theorem on the wavefront set of the composition of two FIOs known as the Hörmander-Sato Lemma.

Theorem 16 (Hörmander-Sato Lemma [47]). *Let \mathcal{P}_1 and \mathcal{P}_2 be two FIOs with canonical relations C_1 and C_2 , respectively. Assume $\mathcal{P}_1 \circ \mathcal{P}_2$ is defined for distributions of compact support, and let u be a distribution of compact support. Then*

$$\text{WF}((\mathcal{P}_1 \circ \mathcal{P}_2)u) \subset (C_1 \circ C_2) \circ \text{WF}(u).$$

From an imaging point of view, the operator that is studied is the image reconstruction operator $\mathcal{P}^* \mathcal{P}$ where \mathcal{P}^* is the adjoint of the FIO \mathcal{P} . Using Hörmander-Sato Lemma, one can study the wavefront set of the image reconstruction operator. For this one requires the canonical relation of the adjoint \mathcal{P}^* [46] which is given by

$$C' = \{(y, \eta dy; x, \xi dx) : (x, \xi dx; y, \eta dy) \in C\}.$$

Now from Hörmander-Sato Lemma, when the composition is defined, one has

$$\text{WF}(\mathcal{P}^* \mathcal{P} f) \subset (C' \circ C) \circ \text{WF}(f).$$

5 Applications to Tomography

In this section microlocal analysis will be used to explain strengths and limitations of the reconstructions from Sect. 2.

Microlocal Analysis in X-Ray CT

As seen in section “X-Ray Tomography (CT) and Limited Data Problems,” reconstructions from different limited data problems have different strengths and weaknesses. The information in the last section will now be used to understand the microlocal properties of \mathcal{R}_L .

To make the cotangent space calculations simpler, the following coordinates will be used on $S^1 \times \mathbb{R}$: $(\varphi, p) \mapsto (\omega(\varphi), p)$ where $\omega(\varphi) = (\cos(\varphi), \sin(\varphi))$ and $\omega^\perp(\varphi) = \omega(\varphi + \pi/2)$. Thus, functions on $S^1 \times \mathbb{R}$ will now be written in terms of (φ, p) .

Theorem 17. *The Radon transform \mathcal{R}_L is an elliptic FIO associated with the canonical relation*

$$C_L = \left\{ (\varphi, p, \alpha(-x \cdot \omega^\perp(\varphi) d\varphi + dp); x, \alpha\omega(\varphi) dx) : (\varphi, p) \in [0, 2\pi] \times \mathbb{R}, x \in \mathbb{R}^2, \alpha \neq 0, x \cdot \omega(\varphi) = p \right\}. \quad (53)$$

For $f \in \mathcal{E}'(\mathbb{R}^2)$,

$$\text{WF}(\mathcal{R}_L f) = C_L \circ \text{WF}(f). \quad (54)$$

Furthermore, $C_L^t \circ C_L = \Delta$ is the diagonal in $(T^*(\mathbb{R}^2) \setminus \mathbf{0})^2$.

Proof. In Example 10, it was shown that \mathcal{R}_L is an FIO associated to the phase function

$$\phi(\varphi, p, x, \tau) = \tau(p - x \cdot \omega(\varphi)).$$

To calculate the canonical relation for \mathcal{R}_L , the general methods outlined in section “Fourier Integral Operators” (see also [47, p. 165] or [95, (6.1) p. 462]) will be followed. First, the differentials of ϕ will be calculated:

$$\begin{aligned} \partial_x \phi &= -\tau \omega(\varphi) dx, & \partial_{(\varphi,p)} \phi &= \tau (-x \cdot \omega^\perp(\varphi) d\varphi + dp) \\ \partial_\tau \phi &= (p - x \cdot \omega(\varphi)) d\tau. \end{aligned} \quad (55)$$

Note that the conditions for ϕ to be a nondegenerate phase function [95, (2.2)–(2.4), p. 315] hold because $\partial_x \phi$ and $\partial_{(\varphi,p)} \phi$ are not zero for $\tau \neq 0$. Therefore, \mathcal{R}_L is a Fourier integral operator. \mathcal{R}_L has order $-1/2$ because its symbol $1/2\pi$ is homogeneous of degree zero, $2 = \dim \mathbb{R}^2 = \dim Y$, and σ is one dimensional (see [95, p. 462 under (6.3)]). Since the symbol, $1/2\pi$, is homogeneous and nowhere zero, \mathcal{R}_L is elliptic (see [46]).

The auxiliary manifold Σ_ϕ is

$$\Sigma_\phi = \{(\varphi, p, x, \tau) \in ([0, 2\pi] \times \mathbb{R}) \times \mathbb{R}^2 \times (\mathbb{R} \setminus \mathbf{0}) : p - x \cdot \omega(\varphi) = 0\}. \quad (56)$$

The canonical relation, C_L , associated to \mathcal{R}_L is defined by the map

$$\Sigma_\phi \ni (x, \varphi, p, \tau) \mapsto (\varphi, (x \cdot \omega(\varphi)), \partial_{(\varphi,p)} \phi; x, -\partial_x \phi).$$

One uses this and a calculation to justify the expression (53).

To show $C_L^t \circ C_L = \Delta$, one starts with $(x, \xi dx) \in T^*(\mathbb{R}^2)$ and then follows through the calculation of $C_L^t \circ C_L$ using (53): First, choose $\varphi \in [0, 2\pi]$ such that $\xi = a\omega(\varphi)$ for some $a > 0$. Then, there are two vectors associated to $(x, \xi dx)$ in C_L ,

$$\lambda_1 = (\varphi, x \cdot \omega(\varphi); a(-x \cdot \omega^\perp(\varphi) d\varphi + dp)),$$

$$\lambda_2 = (\varphi + \pi, x \cdot \omega(\varphi + \pi); -a(-x \cdot \omega^\perp(\varphi + \pi) d\varphi + dp)).$$

Under C_L^t , λ_1 is associated with $((x \cdot \omega(\varphi))\omega(\varphi) + x \cdot \omega^\perp(\varphi), a\omega(\varphi)dx)$ and this is exactly $(x, \xi dx)$, and there is no other vector in $T^*(\mathbb{R}^2)$ associated with λ_1 . In a similar way, one shows that the only vector in $T^*(\mathbb{R}^2)$ associated with λ_2 is $(x, \xi dx)$. Therefore,

$$C_L^t \circ C_L = \{(x, \xi dx; x, \xi dx) : (x, \xi dx) \in T^*(\mathbb{R}^2) \setminus \mathbf{0}\} = \Delta.$$

Because the symbol of \mathcal{R}_L , $1/2\pi$, is nowhere zero and homogeneous, \mathcal{R}_L is elliptic [95]. Furthermore, because C_L is a local canonical graph (e.g., [75] and can be seen from the calculation in the last paragraph), a stronger version of the Hörmander-Sato Lemma for elliptic operators [95] can be used to show $\text{WF}(\mathcal{R}_L f) = C_L \circ \text{WF}(f)$. \square

Note that the fact $C_L^t \circ C_L = \Delta$ implies that $\text{WF}(\mathcal{R}_L^* \mathcal{R}_L(f)) \subset \text{WF}(f)$, by the Hörmander-Sato Lemma (Theorem 16). This and the composition calculus of FIO [46, Theorem 4.2.2] provide another proof that $\mathcal{R}_L^* \mathcal{R}_L$ is a Ψ DO.

This theorem has the following important corollaries.

Corollary 1 (Propagation of Singularities for \mathcal{R}_L). *Let $f \in \mathcal{E}'(\mathbb{R}^2)$.*

1. Let $(x_0, \xi_0 dx) \in T^*(\mathbb{R}^2) \setminus \mathbf{0}$ and let φ_0 be chosen so that $\xi_0 = \alpha\omega(\varphi_0)$ for some $\alpha \neq 0$. If $(x_0, \xi_0 dx) \in \text{WF}(f)$, then

$$(\varphi_0, x_0 \cdot \omega(\varphi_0); \alpha(-x_0 \cdot \omega^\perp(\varphi_0) d\varphi + dp)) \in \text{WF}(\mathcal{R}_L f).$$

2. Let $(\varphi_0, p_0) \in [0, 2\pi] \times \mathbb{R}$ and $A \in \mathbb{R}$. Assume $(\varphi_0, p_0; \alpha(-Ad\varphi + dp)) \in \text{WF}(\mathcal{R}_L f)$. Then, $(x_0, \xi_0 dx) \in \text{WF}(f)$ where $x_0 = p_0\omega(\varphi_0) + A\omega^\perp(\varphi_0)$ and $\xi_0 = \alpha\omega(\varphi_0)$.

This provides the paradigm:

\mathcal{R}_L detects singularities of f perpendicular to the line of integration (“visible” singularities), but singularities of f in other (“invisible”) directions do not create singularities of $\mathcal{R}_L f$ near the line of integration.

Remark 2. The paradigm has implications for limited data tomography. A wave-front direction $(x_0, \xi_0 dx) \in \text{WF}(f)$ will be visible from limited Radon data if and only if the line through x_0 perpendicular to ξ_0 is in the data set.

Proof (Proof of Corollary 1). Using (54), one sees that

$$(x_0, \xi_0 dx) \in \text{WF}(f) \text{ if and only if } C_L \circ \{(x_0, \xi_0 dx)\} \in \text{WF}(\mathcal{R}_L f).$$

Part (a) follows from the forward implication of this equivalence and part (b) follows from the reverse implication using the expression for C_L , (53).

Part (a) implies that \mathcal{R}_L detects singularities perpendicular to the line being integrated over, since $\omega(\varphi_0)$ is perpendicular to the line $L(\omega(\varphi_0), x_0 \cdot \omega(\varphi_0))$. Part (b) implies that if a singularity is visible in $\mathcal{R}_L f$ at (φ_0, p_0) , it must come from a point on $L(\omega(\varphi_0), p_0)$ and in a direction perpendicular to this line. This explains the paradigm in the theorem. \square

Corollary 2 (Propagation of Singularities for Reconstruction Operators). Let $f \in \mathcal{E}'(\mathbb{R}^2)$.

- (a) Let \mathcal{L} be either the FBP (see (18)), Lambda (\mathcal{L}_x , (22)), or Lambda + contour ($\mathcal{L}_{x,\mu}$, (23)) operator. Let $f \in \mathcal{E}'(\mathbb{R}^2)$. Then, $\text{WF}(f) = \text{WF}(\mathcal{L}f)$.
- (b) Let $\mathcal{R}_{L,\text{lim}}^*$ be the limited angle backprojection operator in (25) for angles $a < \varphi < b$ (where $b - a < \pi$). Let

$$\mathcal{V} = \{(x, \xi dx) : \xi = \alpha\omega(\varphi), \varphi \in (a, b)\}.$$

If \mathcal{L}_{lim} is any of the operators

$$\mathcal{R}_{L,\text{lim}}^* \Lambda_p \mathcal{R}_L, \quad \mathcal{R}_{L,\text{lim}}^* \left(-\frac{d^2}{dp^2} \mathcal{R}_L \right), \quad \mathcal{R}_{L,\text{lim}}^* \left(\left(-\frac{d^2}{dp^2} + \mu \right) \mathcal{R}_L \right),$$

then

$$\text{WF}(\mathcal{L}_{\lim} f) \cap \mathcal{V} = \text{WF}(f) \cap \mathcal{V}.$$

Note that \mathcal{V} is the set of visible singularities for the limited angle transform.

Proof. Part (a) follows from the fact that both \mathcal{L}_x and $\mathcal{L}_{x,\mu}$ are elliptic, as noted in Example 9 and the equalities stated in Theorem 14.

Part (b) follows from the fact that when one cuts off angles, one can see only wavefront parallel to the angles in the data set, that is, the visible directions in \mathcal{V} . A complete proof of this result is given in [26]. \square

Remark 3. The paradigms in Corollaries 1 and 2 have especially simple interpretations if f is the sum of characteristic functions of sets with smooth boundaries. The tangent line to any point on the boundary of a region is normal to the wavefront direction of f at that point (since the wavefront set at that point is normal to the boundary, as noted in Example 6).

So, a boundary at x (with conormal $(x, \xi dx)$) will be visible from the data $\mathcal{R}_L f$ near $(\omega(\varphi), p)$ if (x, ξ) is normal to the line of integration. This can be stated more simply as follows: *the boundary at x is tangent to a line in the data set*.

Finally, note that Example 1 provides a simple case for which $\mathcal{R}_L f$ is not smooth when the line $L(\varphi, p)$ is tangent to the boundary of $\text{supp}(f)$. The paradigm shows this principle is true generally.

Limited Data X-Ray CT

Each of the limited data problems discussed in Sect. 2 will now be examined in light of the corollaries and paradigm of the last section.

Exterior X-Ray CT Data

In the reconstruction in Fig. 2, the boundaries tangent to lines in the data set are clearer and less fuzzy than the one not tangent to lines in the data set. The paradigm in Corollary 1 and Remarks 2 and 3 explains this perfectly. When a line in the data set is tangent to a boundary, then the boundary is visible in the reconstruction. For the exterior reconstruction in Fig. 2, this is true for the inside boundary of the disk at about eight o'clock on the circle (lower left), even though that boundary is imaged by only a few lines in the exterior data set. If the line tangent to the boundary at x is not in the data set, then the boundary is fuzzier, as can be seen in that figure.

This is reflected in Quinto's algorithm [77] in the following way. That algorithm expands the reconstruction in a polar Fourier series

$$f(r\omega(\varphi)) = \sum_{\ell \in \mathbb{Z}} f_\ell(r) e^{i\ell\varphi},$$

where $f_\ell(r)$ is approximated by a polynomial which is calculated using quadrature. The calculation of f_ℓ could be done stably only up to about $|\ell| = 25$. However, for each ℓ for which this could be done, the recovery of $f_\ell(r)$ is very accurate and could be done up to a polynomial of order about 100. Thus, the algorithm has good radial resolution but bad resolution in the polar direction. However, this is, at least in part, a limitation of the problem, not just the algorithm. The singularities in Fig. 2 that are smoothed by the algorithm are intrinsically difficult to reconstruct.

Limited Angle Data

In Fig. 3, data are given over lines $L(\omega(\varphi), p)$ for $\varphi \in [-\pi/4, \pi/4]$, and the only boundaries that are visible are exactly those normal to such lines. This reflects Corollary 1 and Remarks 2 and 3. The algorithm used is FBP but with a limited angle backprojection (see (25) and the discussion below it) between $-\pi/4$ and $\Phi = \pi/4$. In this case, Corollary 2 implies that the only singularities of f that will be visible in $\mathcal{L}_{\lim} f$ (where \mathcal{L}_{\lim} is given in that corollary) are those in the cone $\mathcal{V} = \{r\omega(\varphi) : \varphi \in (-\pi/4, \pi/4), r \neq 0\}$.

However, there is also a marked streak along the lines with angle $\varphi = \pm\pi/4$ that are tangent to the boundary of the region. Frikel and Quinto have recently explained this using microlocal analysis [26], see also [49]. They also explained that in order to decrease those streaks, one needs to make the backprojection operator a standard FIO by including a smooth cutoff function ψ supported in $(-\pi/4, \pi/4)$ that is equal to 1 on most of that interval:

$$\mathcal{R}_L^* g(x) = \int_{\varphi=-\pi/4}^{\pi/4} g(\omega(\varphi), x \cdot \omega(\varphi)) \psi(\varphi) d\varphi.$$

Region of Interest (ROI) Data

The reconstruction in Fig. 8 is from Lambda CT, and all singularities of the circle are visible. This is expected because of Corollary 2 Part (a), the Lambda operator preserves wavefront set. Recall that $\mathcal{L}_x(f)(x)$ determined by data $\mathcal{R}_L f$ for lines near x . This means that the wavefront of f above x (which is the same as the wavefront set of $\mathcal{L}_x(f)$ above x), can be determined by local data for lines near x . This is why all singularities are visible in the Lambda reconstruction in that figure.

This also means that any null function for the interior problem must be smooth in the ROI since its Radon data are zero (e.g., smooth) for lines meeting the ROI.

Microlocal Analysis of Conical Tilt Electron Microscope Tomography (ET)

Using the notation of section “Algorithms in Conical Tilt ET,” let

$$S_\alpha = \{(\sin(\alpha) \cos(\varphi), \sin(\alpha) \sin(\varphi), \cos(\alpha)) : \varphi \in [0, 2\pi]\}$$

$$C_\alpha = \mathbb{R}S_\alpha.$$

Using Theorem 10, one writes the operators \mathcal{L}_Δ (see (28)) and \mathcal{L}_S (see (29)) using the convolution

$$f * I(x) = \int_{y \in C_\alpha} f(x + y) \frac{1}{\|y\|} dy$$

where dy is the surface area measure on the cone C_α . In particular the conclusion of that theorem is

$$\begin{aligned} \mathcal{P}_S^* \mathcal{P}_S f &= f * I \\ \mathcal{L}_\Delta f &= (-\Delta)(f * I) \\ \mathcal{L}_S f &= \left(-\Delta + \csc^2(\alpha) \frac{\partial^2}{\partial z^3}\right) f * I. \end{aligned}$$

As one can see from the reconstruction in the $x - y$ plane, Fig. 4, there are circular artifacts. In the reconstruction in the vertical plane $x = -y$, Fig. 5, there are streak artifacts coming off from each of the balls at a 45° angle.

These artifacts can be understood intuitively as follows. Let f be the characteristic function of a ball B . Then, $f * I(x)$ integrates f over the cone $x + C_{\pi/4}$. When this cone is tangent to B at a point besides x , it is normal to a singularity of f at this point. This singularity will cause a singularity of $f * I$ at x . The reason is, when x is perturbed, the cone moves in and out of B , so the integral changes from 0 (when the cone is disjoint from B) to nonzero values as the cone intersects B . A calculation will convince one that the singularity is a discontinuity in the first derivative. Because \mathcal{L}_Δ is a derivative of $f * I$, that singularity is accentuated in $\mathcal{L}_\Delta f$ at x . One can see this phenomenon from the artifacts in \mathcal{L}_Δ reconstructions in section “Electron Microscope Tomography (ET) Over Arbitrary Curves.” In the $x - y$ plane, the artifacts are circular shadows from the disks outside of the plane; in the $y = -x$ plane, the artifacts follow along the generating lines of the cone. However, this is not a rigorous explanation since it does not apply to arbitrary functions. It also does not explain why the \mathcal{L}_Δ reconstruction has apparent singularities, but the \mathcal{L}_S reconstruction seems not to.

The next theorem explains this using microlocal analysis. To state the theorem, recall the definition of conormal bundle of a submanifold $B \subset \mathbb{R}^3$ as

$$N^*(B) = \{(y, \xi dx) : y \in B, \xi \text{ is normal to } B \text{ at } y\}.$$

Theorem 18 ([23]). *The conical tilt ET operator \mathcal{P}_S is an elliptic Fourier integral operator. Let $f \in \mathcal{E}'(\mathbb{R}^3)$ and let $\alpha \in (0, \pi/2)$. Let \mathcal{L} be either \mathcal{L}_Δ or \mathcal{L}_S . Then,*

$$\mathrm{WF}(\mathcal{L}(f)) \subset (\mathrm{WF}(f) \cap \mathcal{V}) \cup \mathcal{A}(f)$$

where

$$\mathcal{V} = \mathbb{R}^3 \times \{\eta \in \mathbb{R}^3 \setminus \mathbf{0} : \exists \omega \in S_\alpha, \eta \cdot \omega = 0\}$$

represents the set of possible visible singularities. The added artifacts come from

$$\mathcal{A}(f) = \{(x, \xi dx) : \exists (y, \xi dx) \in N^*(x + C_\alpha) \cap \mathrm{WF}(f)\}.$$

Furthermore, the added artifacts in $\mathcal{A}(f)$ are more pronounced (stronger in Sobolev scale) in $\mathcal{L}_\Delta f$ than in $\mathcal{L}_S f$.

Here \mathcal{V} is the set of visible singularities, those from f that should appear in $\mathcal{L}f$. The set $\mathcal{A}(f)$ consists of added artifacts, those caused by wavefront of f normal to $x + C_\alpha$ at points besides x . In Fig. 4, the added artifacts in the \mathcal{L}_Δ reconstruction are exactly those that come from cones $x + C_\alpha$ that are tangent to boundaries of disks in $\mathrm{supp}(f)$, and this gives the same conclusions as the heuristic description given above Theorem 18.

The final statement in the theorem follows from the fact that \mathcal{L}_Δ is in a class of singular FIOs (so-called $I^{p,l}$ classes studied in [31, 32, 39, 64]) and \mathcal{L}_S is in a better behaved class. These classes of singular FIOs also come up in radar imaging, as discussed in the next section.

The set of visible singularities \mathcal{V} is larger for conical tilt ET than for the standard data acquisition geometry, single axis tilt ET, and this is one reason to take conical tilt data, even though acquiring data can be technically more difficult.

The proof of this theorem uses the Hörmander-Sato Lemma (Theorem 16). One first calculates the canonical relation, C , and then one calculates $C^t \circ C$ and shows $C^t \circ C$ has two parts. One part generates \mathcal{V} , the set of visible singularities, singularities of f that will be visible in $\mathcal{L}_\Delta f$. The second part generates the set of added artifacts, $\mathcal{A}(f)$.

Deep results in [31] are used to explain why \mathcal{L}_S suppresses the added singularities better than \mathcal{L}_Δ . This can be explained intuitively as follows. If an added singularity at x comes from a point $(y, \xi dx) \in N^*(x + C_\alpha) \cap \mathrm{WF}(f)$, \mathcal{D}_S takes a derivative corresponding to a derivative in x that is normal to ξ (so it does not increase the order of this singularity) and Δ takes a derivative in the direction of this singularity (so it does increase the order of this singularity).

This conical tilt transform is an *admissible Radon transform* [27]. The microlocal analysis of such transforms was first studied in [36], and the microlocal properties of these transforms were completely analyzed in a very general setting in [30] including general results for backprojection that are related to Theorem 18.

Quinto and Rullgård have proven similar results for a curvilinear Radon transform for which the more effective differential operator (analogous to \mathcal{D}_S) decreases the strength of artifacts only locally [81].

SAR Imaging

In this section, some recent results on SAR imaging will be described from the viewpoint of microlocal analysis. The notation is from section “Synthetic-Aperture Radar Imaging.” Recall that the forward operator under consideration is

$$\mathcal{P}V(s, t) = \int e^{-i\omega(t - (\|x - \gamma_T(s)\| + \|x - \gamma_R(s)\|)/c_0)} A(s, t, x, \omega) V(x) dx d\omega. \quad (57)$$

In this section $\omega \in \mathbb{R}$. The canonical relation wherever it is well defined is given as follows. This is an important set that relates the singularities of the object V to that of the data $\mathcal{P}V$:

$$\begin{aligned} C = & \left\{ s, t, -\omega \left(\left(\frac{x - \gamma_T(s)}{\|x - \gamma_T(s)\|} \cdot \gamma'_T(s) + \frac{x - \gamma_R(s)}{\|x - \gamma_R(s)\|} \cdot \gamma'_R(s) \right) ds + dt \right); \right. \\ & x_1, x_2, -\omega \left(\frac{x - \gamma_T(s)}{\|x - \gamma_T(s)\|} + \frac{x - \gamma_R(s)}{\|x - \gamma_R(s)\|} \right) dx \\ & \left. : c_0 t = \|x - \gamma_T(s)\| + \|x - \gamma_R(s)\|, \omega \neq 0 \right\}. \end{aligned} \quad (58)$$

Note that (s, x, ω) is a global parametrization for C . Let us denote

$$Y = \{(s, t) \in (0, \infty) \times (0, \infty)\}$$

and $\{x_1, x_2\}$ space as X . One is interested in studying the imaging operator $\mathcal{P}^* \mathcal{P}$. The standard composition calculus of FIOs, the so-called transverse intersection calculus of Hörmander [46], and the clean intersection calculus of Duistermaat and Guillemin [14, 34] and Weinstein [98] do not apply in general in these situations. Therefore, one approach to understanding the imaging operator is to study the canonical left and right projections from the canonical relation $C \subset T^*Y \times T^*X$ to T^*Y and T^*X , respectively.

$$\begin{array}{ccc}
& \text{c} & \\
& \pi_L \searrow & \swarrow \pi_R \\
T^* Y & & T^* X
\end{array} \tag{59}$$

In order to motivate the results that follow, let us consider the following example.

Example 12. Let us consider a simple example from SAR imaging. This example will help us explain via microlocal analysis, some of the artifacts introduced by image reconstruction operator in 6.

Assume that a colocated transmitter/receiver traverses the straight trajectory $\gamma(s) = (s, 0, h)$ with h fixed. The forward operator in this case is

$$\mathcal{P} f(s, t) = \int e^{-i\omega(t - \frac{2}{c_0} \sqrt{(x-s)^2 + y^2 + h^2})} A(s, t, x, y, \omega) f(x, y) dx dy d\omega.$$

Using (51) and (52), the canonical relation of this operator is easily computed to be

$$\begin{aligned}
C = & \left\{ s, \frac{2}{c_0} \sqrt{(x-s)^2 + y^2 + h^2}, -\omega \left(\frac{2}{c_0} \frac{x-s}{\sqrt{(x-s)^2 + y^2 + h^2}} ds + dt \right); \right. \\
& \left. x, y, -\frac{2\omega}{c_0} \left(\frac{x-s}{\sqrt{(x-s)^2 + y^2 + h^2}} dx + \frac{y}{\sqrt{(x-s)^2 + y^2 + h^2}} dy \right) \right\}.
\end{aligned}$$

Now using Hörmander-Sato Lemma, one sees that

$$\begin{aligned}
\text{WF}(\mathcal{P}^* \mathcal{P}) \subset & \left\{ x, y, \frac{2\omega}{c_0} \left(\frac{x-s}{\sqrt{(x-s)^2 + y^2 + h^2}} dx + \frac{y}{\sqrt{(x-s)^2 + y^2 + h^2}} dy \right); \right. \\
& z, w, \frac{2\omega}{c_0} \left(\frac{z-s}{\sqrt{(z-s)^2 + w^2 + h^2}} dz + \frac{w}{\sqrt{(z-s)^2 + w^2 + h^2}} dw \right); \\
& \sqrt{(x-s)^2 + y^2 + h^2} = \sqrt{(z-s)^2 + w^2 + h^2} \text{ and} \\
& \left. \frac{x-s}{\sqrt{(x-s)^2 + y^2 + h^2}} = \frac{z-s}{\sqrt{(z-s)^2 + w^2 + h^2}}, \omega \neq 0 \right\}.
\end{aligned}$$

This implies that $(z, w) = (x, y)$ or $(z, w) = (x, -y)$. The first equality contributes to the diagonal relation of the wavefront set of $\mathcal{P}^* \mathcal{P}$, while the second contributes to the relation formed by reflection about the x -axis. In other words,

$$\text{WF}(\mathcal{P}^* \mathcal{P}) \subset \Delta \cup G, \text{ where } \Delta = \{(x, y, \xi dx + \eta dy : x, y, \xi dx + \eta dy)\}$$

and $G = \{(x, y, \xi dx + \eta dy; x, -y, \xi dx - \eta dy)\}$.

The presence of the set G as in the above example (the non-diagonal part) indicates that the imaging operator introduces artifacts in the reconstructed image. A detailed study of the class of distributions as in the example above, called $I^{p,l}$ classes, was introduced in [31, 32, 39, 64]. These classes of distributions have come up in the study of several imaging problems including X-ray, seismic, SAR, and electron tomography [1, 13, 21–24, 30–32, 54, 69]. In instances where the imaging operator introduces artifacts, it is of interest to determine whether the artifacts are of the same strength in a suitable sense as that of the true singularities and whether the artifacts can be suppressed or displaced from the true singularities. These questions are answered in the references given above.

Monostatic SAR Imaging

In monostatic SAR imaging, the transmitter and receiver are located at the same point. In other words, $\gamma_T(s) = \gamma_R(s)$. Nolan and Cheney in [70] investigated the microlocal properties of the forward operator \mathcal{P} and the associated image reconstruction operator $\mathcal{P}^*\mathcal{P}$. Using microlocal tools, synthetic-aperture inversion in the presence of noise and clutter was done in [102]. Other imaging methods in the context of SAR imaging, again using microlocal tools, were considered in [99, 101]. The forward operator \mathcal{P} was further investigated by Felea in [19], and she made a detailed analysis of the image reconstruction operator for various flight trajectories. Felea in [19] showed that for $\gamma(s) = (s, 0, h)$ with $h > 0$ fixed, the operator $\mathcal{P}^*\mathcal{P}$ belongs to $I^{2m,0}(\Delta, G)$ where $\Delta = \{(x, \xi, x, \xi) \in T^*X \times T^*X \setminus \mathbf{0}\}$ and G is the graph of the function $\chi(x_1, x_2, \xi_1, \xi_2) = (x_1, -x_2, \xi_1, -\xi_2)$. If $\gamma(s) = (\cos s, \sin s, h)$, it was shown in [20] that $\mathcal{P}^*\mathcal{P} \in I^{2m,0}(\Delta, G)$, where G is a 2-sided fold. Mappings with singularities (such as folds and blowdowns) are defined in [29, 37]. Furthermore, in [20], Felea showed that in some instances such as the flight trajectory being circular, the artifact singularities of the same strength as the true singularities can be displaced far away from the true singularities, and those that are not displaced are of lesser strength compared to the true singularities. In [91], the authors show that cancellation of singularities, that is, only certain singularities are recoverable, can occur even in curved flight paths.

Bistatic SAR Imaging

Some recent results by the authors and their collaborators investigating the microlocal properties of transforms that appear in bistatic SAR imaging are now described. For related work, the reader is referred to [100].

Common Offset Bistatic SAR Imaging

In common offset SAR imaging, the transmitter and receiver travel in a straight line offset by a constant distance at all times. More precisely, let

$$\gamma_T(s) = (s + \alpha, 0, h) \text{ and } \gamma_R(s) = (s - \alpha, 0, h)$$

be the trajectories of the transmitter and receiver, respectively, with α and h fixed positive quantities. A detailed microlocal analysis of associated forward operator \mathcal{P} and the imaging operator $\mathcal{P}^*\mathcal{P}$ was done in [54]. The authors obtained the following results analogous to the ones obtained by Nolan and Cheney in [70] and Felea in [19] for the monostatic case.

Theorem 19 ([54]). *Let $\gamma_T(s) = (s + \alpha, 0, h)$ and $\gamma_R(s) = (s - \alpha, 0, h)$ where $\alpha > 0, h > 0$ are fixed. The operator \mathcal{P} defined in (57) is an FIO. The canonical relation C associated to \mathcal{P} defined in (58) satisfies the following: the projections π_L and π_R defined in (59) are a fold and blowdown, respectively.*

Theorem 20 ([54]). *Let \mathcal{P} be defined with γ_T and γ_R given in Theorem 19. Then $\mathcal{P}^*\mathcal{P} \in I^{3,0}(\Delta, G)$, where Δ is the diagonal relation and G is the graph of the map $\chi(x_1, x_2, \xi_1, \xi_2) = (x_1, -x_2, \xi_1, -\xi_2)$.*

One important consequence of this result is that the artifacts given by the graph G of the map χ have the same strength in a Sobolev sense as that of the true singularities given by the diagonal relation Δ .

Common Midpoint SAR Imaging

In common midpoint SAR imaging, the transmitter and receiver travel in a straight line at a constant height above the ground at equal speeds away from a common midpoint. The trajectories of the transmitter and receiver for the common midpoint geometry considered here are

$$\gamma_T(s) = (s, 0, h) \text{ and } \gamma_R(s) = (-s, 0, h). \quad (60)$$

A detailed microlocal analysis of the forward operator (58) associated to γ_T and γ_R and the imaging operator $\mathcal{P}^*\mathcal{P}$ was done in [1]. In contrast to the results in [19, 54, 70], here the canonical relation C associated to \mathcal{P} is a 4-1 relation, and this is reflected in the fact the canonical left and right projections π_L and π_R drop rank on a union of two disjoint sets. More precisely, one obtains the following results for the forward operator and the imaging operator, respectively.

Theorem 21 ([1]). *Let \mathcal{P} be as in (57) with the trajectories given by (60). Then \mathcal{P} is an FIO and the canonical relation associated to \mathcal{P} defined in (58) has global parametrization*

$$(0, \infty) \times (\mathbb{R}^2 \setminus 0) \times (\mathbb{R} \setminus 0) \ni (s, x_1, x_2, \omega) \mapsto C,$$

and it satisfies the following: the left and right projections π_L and π_R drop rank simply by one on a set $\Sigma = \Sigma_1 \cup \Sigma_2$ where in the coordinates (s, x, ω) , $\Sigma_1 = \{(s, x_1, 0, \omega) : s > 0, |x_1| > \epsilon', \omega \neq 0\}$ and $\Sigma_2 = \{(s, 0, x_2, \omega) : s > 0, |x_2| > \epsilon', \omega \neq 0\}$ for $0 < \epsilon'$ small enough. The canonical relation C associated to \mathcal{P}

satisfies the following: the projections π_L and π_R defined in (59) are a fold and blowdown, respectively, along Σ .

Theorem 22 ([1]). Let \mathcal{P} be as in (57) with the trajectories given by (60). Then $\mathcal{P}^*\mathcal{P}$ can be decomposed into a sum belonging to $I^{2m,0}(\Delta, G_1) + I^{2m,0}(\Delta, G_2) + I^{2m,0}(G_1, G_3) + I^{2m,0}(G_2, G_3)$, where G_i for $i = 1, 2, 3$ are the graphs of the following functions χ_i for $i = 1, 2, 3$ on T^*X :

$$\chi_1(x, \xi) = (x_1, -x_2, \xi_1, -\xi_2), \quad \chi_2(x, \xi) = (-x_1, x_2, -\xi_1, \xi_2) \text{ and } \chi_3 = \chi_1 \circ \chi_2.$$

As with the common offset case, the artifacts given by graphs of the maps χ_1 , χ_2 , and χ_3 have the same strength in a Sobolev sense as that of the true singularities given by the diagonal relation Δ .

6 Conclusion

Finally, some important themes of this chapter will be highlighted.

Microlocal analysis can help understand strengths and limitations of tomographic reconstruction methods. For limited data X-ray tomography, microlocal analysis was used in this chapter to show which singularities of functions will be visible depending on the data, and reconstructions in this chapter illustrate the paradigm.

Each of the reconstruction methods described in this chapter is of the form

$$\mathcal{L} = \mathcal{P}^*\mathcal{D}\mathcal{P}$$

where the forward operator (operator modeling the tomography problem) \mathcal{P} is a Fourier integral operator and \mathcal{P}^* is an adjoint and \mathcal{D} is a pseudodifferential operator. In SAR imaging, $\mathcal{D} = \text{Id}$ is the identity operator and the reconstruction method is $\mathcal{P}^*\mathcal{P}$ – the normal operator. Since the operator \mathcal{D} is a differential or pseudodifferential operator, it does not add to the wavefront set of $\mathcal{P}f$, $\text{WF}(\mathcal{D}\mathcal{P}f) \subset \text{WF}(\mathcal{P}f)$. If \mathcal{D} is elliptic (on the range of \mathcal{P} , which is true in the cases considered here), $\text{WF}(\mathcal{D}\mathcal{P}f) = \text{WF}(\mathcal{P}f)$. Then, one needs to understand what \mathcal{P}^* does, and this is determined by the structure of $C' \circ C$ by the Hörmander Sato Lemma (Theorem 16):

$$\text{WF}(\mathcal{P}^*(\mathcal{D}\mathcal{P}f)) \subset (C' \circ C) \circ \text{WF}(f).$$

However, in limited angle tomography, because $\mathcal{R}_{L,\lim}^*$ is not a standard FIO, $\mathcal{R}_{L,\lim}^* \mathcal{D} \mathcal{R}_L$ adds singularities along lines at the ends of the limited angular range.

In the case of SAR and conical tilt ET, $C' \circ C$ is more complicated; it includes Δ and another set. In conical tilt ET, this second set generates $\mathcal{A}(f)$, the extra artifacts given in Theorem 18. Also, for conical tilt ET, that theorem implies that a well-chosen differential operator ($(-\mathcal{D}_S)$ rather than $(-\Delta_S)$) decreases the strength of the added singularities; they are visible if one looks carefully at the reconstructions, but they are smoother than when $(-\Delta_S)$ is used.

The only exact reconstruction method presented in this chapter is FBP (Theorem 9). The other algorithms, such as Lambda CT, involve differential operators and backprojection. Microlocal analysis was used to demonstrate that they do recover many (or all) singularities of the object.

Recovering singularities does not recover the object. So, these algorithms are not useful when one needs density values, such as in distinguishing tumor cells from benign cells in diagnostic radiology. However, in many cases (e.g., ET or industrial nondestructive evaluation) one is interested in the shapes of regions, not actual density values, so knowing the location of singularities is useful. The algorithm must be designed so that it clearly shows singularities in the reconstruction. For example, an algorithm that turns jump discontinuities in the object into discontinuities of a derivative in the reconstruction might not provide a clear picture of the object. Lambda CT and the algorithms given here for conical tilt ET actually accentuate singularities; they make the singularities more apparent since they are operators of order one (like a first derivative). The implementation smooths out the derivative since it uses numerical differentiation.

In conical tilt ET and SAR the reconstruction methods, that included a backprojection (adjoint, \mathcal{P}^*), produce added artifacts (as shown in Figs. 5 and 6), and these were explained using microlocal analysis.

Microlocal analysis will not make a bad algorithm good, but it can show that some limitations in reconstruction quality are intrinsic to the underlying tomographic problem. It can point to where reconstruction methods need to be regularized more strongly because of intrinsic instability in the specific tomography problem. In summary, microlocal analysis can be used to understand practical and theoretical issues in tomography.

Acknowledgments Both authors thank the American Institute of Mathematics and their colleagues Gaik Ambartsoumian, Raluca Felea, and Clifford Nolan in an American Institute of Mathematics (AIM) SQuaREs program for discussions at AIM on microlocal analysis and radar imaging that informed this work. They appreciate Jürgen Frikel's careful reading of the chapter. The authors thank the Mittag Leffler Institute for the congenial atmosphere as they worked on some of the research presented in this chapter. The second named author thanks Jan Boman, Alfred Louis, Frank Natterer, and many other friends and colleagues for important discussions about tomography and microlocal analysis over the years. Both authors thank Birsen Yazıcı for interesting discussions.

Abstract

In this chapter, we present the mathematical formulation of the inverse Radon transform and of the inverse attenuated Radon transform (IART), which are used in PET and SPECT image reconstruction, respectively. Using a new method for deriving transform pairs in one and two dimensions, we derive the inverse Radon transform and the IART. Furthermore, we discuss an alternative approach for

computing the Hilbert transform using cubic splines. This new approach, which is referred to as spline reconstruction technique, is formulated in the physical space, in contrast to the well-known filtered backprojection (FBP) algorithm which is formulated in the Fourier space. Finally, we present the results of several rigorous studies comparing FBP with SRT for PET. These studies, which use both simulated and real data and which employ a variety of image quality measures including contrast and bias, indicate that SRT has certain advantages in comparison with FBP.

1 Introduction

Positron emission tomography (PET) is an important, noninvasive, nuclear medicine modality that measures the *in vivo* distribution of imaging agents labeled with positron-emitting radionuclides. The importance of PET in detecting, staging, and monitoring the progress of several diseases has been established in a plethora of rigorous clinical studies [1]. Furthermore, small-animal PET is becoming an essential imaging modality for preclinical research [2–4], as well as for drug development and discovery [5].

Single-photon emission computed tomography (SPECT) is the most widely available diagnostic imaging technique which uses short-lived radiographic isotopes. In particular, it is extensively used in cardiology. For example, in 2012, nine million myocardial perfusion scintigraphic imaging studies were performed in the USA.

Image reconstruction is an essential component in tomographic medical imaging, allowing a tomographic image to be obtained from a set of two-dimensional projections. The existing image reconstruction methods can be classified into two broad categories: (a) analytic methods and (b) iterative (or algebraic) methods. In what follows, we will discuss only analytic methods. In this respect, we first consider a simple model for SPECT: let $\mu(x_1, x_2)$ denote the gamma-ray attenuation coefficient of the tissue at the point (x_1, x_2) . This means that a gamma ray traveling a small distance $\Delta\tau$ at (x_1, x_2) suffers a relative intensity loss

$$\frac{\Delta I}{I} = -\mu \Delta\tau. \quad (1)$$

We denote by I_o the initial intensity of a gamma ray and by I_f the measured intensity after undergoing attenuation through tissue of length L ; the above equation can be written in the form

$$I_f = I_o \exp \left\{ - \int_L \mu(\tau) d\tau \right\}. \quad (2)$$

This equation expresses the well-known Beer's law.

Let $f(x_1, x_2)$ denote the distribution in the tissue of the radioactive material under consideration, and let $L(x)$ denote the part of the ray from the tissue to the detector. Then, in SPECT, it is assumed that the following integral, I_{SPECT} , is known from the measurements:

$$I_{\text{SPECT}} = \int_L \exp \left\{ - \int_{L(x)} \mu \, ds \right\} f \, d\tau, \quad (3)$$

where the integral is measured over a finite number of lines L . Equation (3) is valid under the following assumptions:

- (a) The lines L are lying within a specified imaging plane,
- (b) The imaging system has perfect imaging characteristics,
- (c) The detector is collimated and can pick up radiation only along the straight lines L ,
- (d) The collimator has an infinitely high spatial resolution,
- (e) The attenuation coefficient μ obeys Eq. (2),
- (f) There is no scatter radiation in the object.

In PET, the integral in Eq. (3) simplifies to

$$I_{\text{PET}} = \exp \{-\hat{\mu}\} \int_L f \, d\tau, \quad (4)$$

where $\hat{\mu}$ denotes the *Radon transform* of μ , i.e.,

$$\hat{\mu} = \int_L \mu \, d\tau. \quad (5)$$

In order to derive Eq. (4) from Eq. (3), we recall that positrons eject particles pairwise in opposite directions, and in PET the radiation in opposite directions is measured simultaneously. Thus,

$$\int_{L(x)} \mu \, ds = \int_{L_{-(x)}} \mu \, ds + \int_{L_{+(x)}} \mu \, ds = \int_L \mu \, ds \quad (6)$$

and Eq. (3) becomes Eq. (4).

In both PET and SPECT, a projection is formed by combining a set of line integrals along a line L . Here, we will consider parallel-ray integrals at a specific angle θ , i.e., we will assume a parallel-beam geometry.

We recall that the Radon transform of the X-ray attenuation coefficient denoted by μ_{CT} is measured via computed tomography (CT). Using the values of μ_{CT} , it is possible to estimate $\mu(x_1, x_2)$ by appropriate scaling (this is necessary due to the energy difference between X-rays and gamma rays).

Equation (4) implies that in PET one needs to reconstruct a function f from the knowledge of its Radon transform denoted by \hat{f} ,

$$\hat{f} = \int_L f d\tau, \quad (7)$$

where \hat{f} can be computed via

$$\hat{f} = I_{\text{PET}} \exp \{\hat{\mu}\}. \quad (8)$$

Hence, both CT and PET involve the computation of a function from the knowledge of its Radon transform. More specifically, in CT one needs to compute μ_{CT} from the knowledge of $\hat{\mu}_{\text{CT}}$, whereas in PET one needs to compute f from the knowledge of $I_{\text{PET}} \exp \{\hat{\mu}\}$. The relevant formula, known as the *inverse Radon transform*, is given by

$$f(x_1, x_2) = \frac{1}{4\pi} (\partial_{x_1} - i \partial_{x_2}) \int_0^{2\pi} e^{i\theta} J(x_1, x_2, \theta) d\theta, \quad (9)$$

where J is defined in terms of \hat{f} by

$$J(x_1, x_2, \theta) = \frac{1}{i\pi} \oint_L \frac{\hat{f}(\rho, \theta) d\rho}{\rho - (x_2 \cos \theta - x_1 \sin \theta)}, \quad 0 \leq \theta < 2\pi, \quad (10)$$

and throughout this chapter, \oint denotes the principal value integral.

Let \hat{f}_μ denote the right-hand side (RHS) of Eq. (3). We call \hat{f}_μ the *attenuated Radon transform* of f (with attenuation specified by the given function μ). Hence, SPECT involves the computation of a function f from the knowledge of its attenuated Radon transform \hat{f}_μ and of the function μ . The relevant formula is known as the *inverse attenuated Radon transform* (IART).

According to Eq. (9), the numerical implementation of the inverse Radon transform involves the computation of the Hilbert transform $(Hf)(\rho)$ of a given function $f(\rho)$, where

$$(Hf)(\rho) = \frac{1}{\pi} \oint_L \frac{f(r)}{r - \rho} dr. \quad (11)$$

The most well-known method for this computation uses the fast Fourier transform technique, exploiting the fact that the Hilbert transform is a convolution. The application of this method to the computation of the inverse Radon transform is called *filtered backprojection* (FBP).

Most PET systems have options for both FBP and Ordered Subset Expectation Maximization (OSEM), which is the predominant iterative technique.

The analytical approach to SPECT requires the numerical implementation of the IART. However, since no analytical formula was available until recently for the IART, currently the FBP implementation to SPECT generally makes the crude approximation of $\mu = 0$ or incorporates a uniform attenuation map [6]. On the other hand, since OSEM is based on an iterative statistical approach, it does *not* require the analytical inversion formula, and hence OSEM considers the actual values of μ . Hence, in SPECT, OSEM produces more accurate images than FBP. However, for several reasons including speed (1 s vs. 2.5 min for a typical study), FBP is still used extensively. Indeed, most SPECT systems have options for both FBP and OSEM, and both are used clinically. Actually, some clinicians prefer FBP for quantification.

In this review, we will discuss an alternative approach for computing the Hilbert transform. This approach, in contrast to FBP which is formulated in the Fourier space, is formulated in the physical space, and it is based on “custom-made” cubic splines. We will refer to the application of this approach to the computation of the inverse Radon transform and to the IART as *spline reconstruction technique* (SRT) for PET and SRT for SPECT, respectively.

The results of rigorous studies comparing FBP with SRT for PET are published in [7]. In these studies, which use both simulated and real data, by employing a variety of image quality measures, including contrast and bias, it is established that SRT has certain advantages in comparison with FBP. As a result of these studies, SRT is now included in STIR (Software for Tomographic Image Reconstruction) [8], which is a widely used open-source software library in tomographic imaging (FBP and SRT are the only algorithms based on analytical formulae which are incorporated in STIR).

Rigorous studies comparing SRT for SPECT with FBP and OSEM are work in progress. Preliminary results suggest that SRT is preferable to FBP and also that SRT is comparable with OSEM; see Fig. 1 [9].

The clinical importance of PET and SPECT, as well as the mathematical formulation of the inverse Radon transform and of the IART, is further discussed in the following section. A new method for deriving transforms in one and two dimensions was introduced in [10]. Using this method, both the inverse Radon transform and the IART are derived in Sect. 3. The SRT for PET is presented in Sect. 4, and the studies of Kastis et al. [7] comparing SRT with FBP for PET are reviewed in Sect. 5. SRT for SPECT is briefly discussed in Sect. 6.

2 Background

The Importance of PET and SPECT

In 1964, the research group of Dr. David E. Kuhl, known as the “Father of Emission Tomography,” developed the Mark II SPECT series, which is a single-emission computed tomography camera. Using this unit, this group succeeded in producing

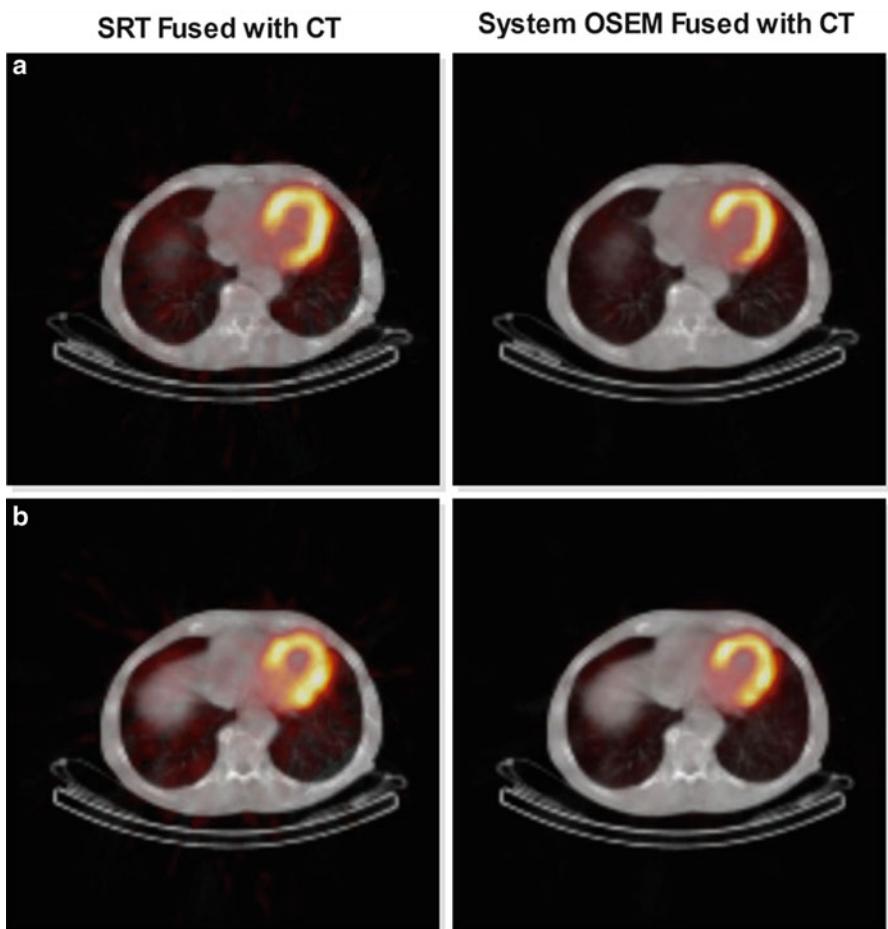

Fig. 1 Reconstructions of two consecutive slices (**a** and **b**) of the myocardium acquired with SPECT fused with CT scan. The images on the *right* are obtained by the currently used commercial software and on the *left* with SRT

the world's first tomographic images of the human body. This achievement was considerably earlier than Godfrey Hounsfield's development of the X-ray CT device in 1972. A crucial element in the evolution of emission tomography was the choice of the radioisotope injected in the patient. An important such class is those radioisotopes that emit positrons. An emitted positron almost immediately combines with a nearby electron; they annihilate each other, emitting in the process two gamma rays traveling in nearly opposite directions. PET cameras detect these gamma rays.

FDG (^{18}F -2-deoxy-2-fluoro-D-glucose) is the most suitable positron emitter that can be used with humans. It is a deoxyglucose analog with the normal hydroxyl

group in the glucose molecule substituted with the radioactive isotope ^{18}F . FDG is taken up by high-glucose-using cells, and it is metabolically trapped following phosphorylation by the hexokinase enzyme [11]. Thus, the measurement of the positron-emitting ^{18}F provides a quantitative measure of the glucose consumed in the corresponding tissue. Glucose metabolism in cancerous tissue is higher than in normal tissue. Thus, PET-CT devices are proving to be highly effective in the early detection of cancer. For example, among 91 patients with non-small-cell lung cancer, 38 pathologically confirmed mediastinal lymph node metastases were missed by CT, whereas among 98 similar patients, only 21 metastases were missed by PET-CT [12] (this means that in the former case, there were 38 futile thoracotomies, whereas in the latter case, there were only 21). Furthermore, using more specific positron emitters, it is possible to obtain additional useful information. For example, using F-fluoro-17- β -estradiol, it is possible to access *in vivo* the density of estrogen receptors as well as to monitor the response of the treatment for estrogen receptor-positive breast cancer. Similarly, using ^{18}F -annexin V, it is possible to follow tumor cell apoptosis (death) *in vivo*, as well as to monitor treatment response to various cancer types. It should also be noted that PET-CT is useful for prognosis. For example, the 2-year failure-free survival rate of patients with positive scans after chemotherapy treatment for early-stage Hodgkin's lymphoma was 69 %, as compared with 95 % of patients with negative scans [13].

In addition to oncology, PET is now used in several other areas of medicine, including cardiology and neurology. As an example of the usefulness of PET in neurology, we note that PET with the use of the Pittsburgh compound B(PIB) can be used to quantify the concentration of amyloid-beta ($\text{A}\beta$) deposition in the brain, a precursor of Alzheimer's disease [14].

SPECT is used extensively in cardiology, oncology, and neurology. In cardiology, SPECT is part of the common stress-testing procedures for the evaluation of chest pain [15]. As an example of the use of SPECT in oncology, we mention the study in [16], where lymphoscintigraphy was performed using SPECT-CT to establish a preoperative road map of lymph nodes that are at risk for metastatic melanoma and to facilitate intraoperative identification of the "sentinel" nodes (the rationale for sentinel-node biopsy relies on the concept that different regions of the skin have specific patterns of lymphatic drainage to the regional nodes, and for a given region of the skin, there exists at least a specific node, the sentinel node, in which lymphatic vessels drain first, and it is this node the most likely first site of metastasis).

In neurology, SPECT can be used to image the distribution of the blood flow in the brain, and this has been used in a plethora of pathological situations. Furthermore, by employing specific radioisotopes, it is possible to obtain useful information about several diseases. For example, using SPECT with ^{123}I -labeled CIT, it is shown in [17] that although levodopa treatment is highly effective as dopamine replacement in Parkinson's disease, this treatment apparently downregulates the endogenous dopamine transporters.

The Mathematical Foundation of the IART

Consider a line L specified by two real numbers ρ and θ , where $-\infty < \rho < \infty$ and $0 \leq \theta < 2\pi$ (Fig. 2). A unit vector along this line is given by

$$\mathbf{e}^{\parallel} = (\cos \theta, \sin \theta). \quad (12)$$

A unit vector perpendicular to L is given by

$$\mathbf{e}^{\perp} = (-\sin \theta, \cos \theta). \quad (13)$$

A point \mathbf{x} on this line can be expressed in the form

$$\mathbf{x} = \rho \mathbf{e}^{\perp} + \tau \mathbf{e}^{\parallel}. \quad (14)$$

Hence,

$$x_1 = \tau \cos \theta - \rho \sin \theta, \quad (15)$$

$$x_2 = \tau \sin \theta + \rho \cos \theta. \quad (16)$$

Solving these equations for (τ, ρ) in terms of (x_1, x_2, θ) , we find

$$\tau = x_2 \sin \theta + x_1 \cos \theta, \quad (17)$$

$$\rho = x_2 \cos \theta - x_1 \sin \theta. \quad (18)$$

Writing (x_1, x_2) in terms of the local coordinates (ρ, θ) , it follows that the equation defining the Radon transform, \hat{f} , of a function f takes the form

$$\begin{aligned}\hat{f}(\rho, \theta) &= \int_{-\infty}^{\infty} f(\tau \cos \theta - \rho \sin \theta, \tau \sin \theta + \rho \cos \theta) d\tau, \\ -\infty < \rho < \infty, \quad 0 &\leq \theta < 2\pi.\end{aligned}\quad (19)$$

Similarly, the following equation provides the definition of the attenuated Radon transform, \hat{f}_μ (with attenuation specified by μ), of a function f :

$$\begin{aligned}\hat{f}_\mu(\rho, \theta) &= \int_{-\infty}^{\infty} \exp \left\{ - \int_{\tau}^{\infty} \mu(s \cos \theta - \rho \sin \theta, s \sin \theta + \rho \cos \theta) ds \right\} \times \\ f(\tau \cos \theta - \rho \sin \theta, \tau \sin \theta + \rho \cos \theta) d\tau, \quad -\infty < \rho < \infty, \quad 0 &\leq \theta < 2\pi.\end{aligned}\quad (20)$$

The inverse Radon transform, expressing f in terms of \hat{f} , is given by Eqs. (9) and (10). Similarly, the IART, expressing f in terms of \hat{f}_μ and μ , is given by

$$f(x_1, x_2) = \frac{1}{4\pi} (\partial_{x_1} - i \partial_{x_2}) \int_0^{2\pi} e^{i\theta} J(x_1, x_2, \theta) d\theta, \quad -\infty < x_1, x_2 < \infty, \quad (21)$$

where the function J is defined by

$$\begin{aligned}J(x_1, x_2, \theta) &= \exp \left\{ \int_{\tau}^{\infty} \mu(s \cos \theta - \rho \sin \theta, s \sin \theta + \rho \cos \theta) ds \right\} \\ &\times L_\mu(\rho, \theta) \hat{f}_\mu(\rho, \theta) \Big|_{\substack{\tau = x_2 \sin \theta + x_1 \cos \theta \\ \rho = x_2 \cos \theta - x_1 \sin \theta}}\end{aligned}\quad (22)$$

and the operator $L_\mu(\rho, \theta)$ is defined by

$$\begin{aligned}L_\mu(\rho, \theta) &= \exp \{ P^- \hat{\mu}(\rho, \theta) \} P^- \exp \{ -P^- \hat{\mu}(\rho, \theta) \} \\ &+ \exp \{ -P^+ \hat{\mu}(\rho, \theta) \} P^+ \exp \{ P^+ \hat{\mu}(\rho, \theta) \},\end{aligned}\quad (23)$$

with $\hat{\mu}(\rho, \theta)$ denoting the Radon transform of $\mu(x_1, x_2)$ and the operators P^\pm denoting the usual projection operators in the variable ρ , i.e.,

$$(P^\pm g)(\rho) = \pm \frac{g(\rho)}{2} + \frac{1}{2i\pi} \oint_{-\infty}^{\infty} \frac{g(r)}{r - \rho} dr, \quad -\infty < \rho < \infty. \quad (24)$$

A General Methodology for Constructing Transform Pairs

The study of nonlinear integrable equations led to the emergence of a general method for deriving transform pair in one and two dimensions [10]. In particular,

using this method, it was shown in [10] that the two-dimensional Fourier transform of a function $u(x_1, x_2)$ can be constructed via the *spectral analysis* of the equation

$$\frac{\partial \Psi}{\partial x_1} + \frac{i \partial \Psi}{\partial x_2} - k\Psi = u(x_1, x_2), \quad (x_1, x_2) \in \mathbf{R}^2, \quad k \in \mathbf{C}, \quad (25)$$

where $\Psi(x_1, x_2, k, \bar{k})$ is a scalar function and bar denotes complex conjugate.

R. Novikov and one of the authors re-derived in [18] the Radon transform by performing the spectral analysis of the equation

$$\frac{1}{2} \left(k + \frac{1}{k} \right) \frac{\partial \Psi}{\partial x_1} + \frac{1}{2i} \left(k - \frac{1}{k} \right) \frac{\partial \Psi}{\partial x_2} = f(x_1, x_2), \quad (x_1, x_2) \in \mathbf{R}^2, \quad k \in \mathbf{C}. \quad (26)$$

Although the Radon transform can be derived in a much simpler way by using the two-dimensional Fourier transform, the advantage of the derivation of [18] was demonstrated later by Novikov [19] who showed that the inverse attenuated Radon transform can be derived by applying a similar analysis to the following slight generalization of Eq. (26):

$$\begin{aligned} & \frac{1}{2} \left(k + \frac{1}{k} \right) \frac{\partial \Psi}{\partial x_1} + \frac{1}{2i} \left(k - \frac{1}{k} \right) \frac{\partial \Psi}{\partial x_2} - \mu(x_1, x_2)\Psi \\ &= f(x_1, x_2), \quad (x_1, x_2) \in \mathbf{R}^2, \quad k \in \mathbf{C}. \end{aligned} \quad (27)$$

3 The Inverse Radon Transform and the Inverse Attenuated Radon Transform

In what follows, we discuss an algorithmic approach for the construction of a transform pair $\{f, \hat{f}\}$. The relevant analysis, which is usually referred to as *spectral analysis*, involves two main steps: (i) solve a given eigenvalue equation in terms of f . If k denotes the eigenvalue parameter, this involves constructing a solution Ψ of the given eigenvalue equation which is *bounded* for all complex values of k . This problem will be referred to as the *direct problem*. (ii) Using the fact that Ψ is bounded for all complex k , construct an alternative representation of Ψ which (instead of depending on f) depends on some “spectral function” of f denoted by \hat{f} . This problem will be referred to as the *inverse problem*.

It turns out that the inverse problem gives rise to certain problems in complex analysis known as the Riemann-Hilbert and the d -bar problems. Indeed, for certain eigenvalue problems, the function Ψ is *sectionally analytic* in k , i.e., it has different representations in different domains of the complex k -plane, and each of these representations is analytic. In this case, if the “jumps” of these representations across the different domains can be expressed in terms of \hat{f} , then it is possible to reconstruct Ψ as the solution of a Riemann-Hilbert problem which is uniquely defined in terms of \hat{f} . However, for a large class of eigenvalue problems, there

exists a domain in the complex k -plane where Ψ is *not* analytic. In this case, if $\partial\Psi/\partial\bar{k}$ can be expressed in terms of \hat{f} , then Ψ can be reconstructed through the solution of a d -bar problem which is uniquely defined in terms of \hat{f} .

We recall that the classical derivation of transform pairs involves the integration in the complex k -plane of an appropriate Green's function. However, this derivation is based on the assumption that the Green's function is an analytic function of k and it also assumes completeness. The assumption of analyticity corresponds to the case that Ψ is sectionally analytic. Therefore, the approach reviewed here has the advantage that not only it provides a simpler approach to deriving classical transforms avoiding the problem of completeness, but also it can be applied to problems that the associated Green's function is *not* an analytic function of k .

In addition to the construction of the Inverse attenuated Radon transform, the approach reviewed here has led to the construction of the X-ray fluorescence computed tomography [20].

The Construction of the Inverse Radon Transform

Let $S(\mathbf{R}^2)$ denote the space of Schwartz functions. Define the Radon transform $\hat{f}(\rho, \theta)$ of the function $f(x_1, x_2) \in S(\mathbf{R}^2)$ by Eq. (19). Then, for all $(x_1, x_2) \in \mathbf{R}^2$, $f(x_1, x_2)$ is given by Eq. (9).

We will derive the Radon transform pair by performing the spectral analysis of the eigenvalue Eq. (26). In order to solve the direct problem, we first simplify Eq. (26) by introducing a change of variables from (x_1, x_2) to (z, \bar{z}) , where z is defined by

$$z = \frac{1}{2i} \left(k - \frac{1}{k} \right) x_1 - \frac{1}{2} \left(k + \frac{1}{k} \right) x_2, \quad (28)$$

and \bar{z} follows via complex conjugation, i.e.,

$$\bar{z} = -\frac{1}{2i} \left(\bar{k} - \frac{1}{\bar{k}} \right) x_1 - \frac{1}{2} \left(\bar{k} + \frac{1}{\bar{k}} \right) x_2, \quad (x_1, x_2) \in \mathbf{R}^2, \quad k \in \mathbf{C}.$$

Using the identities

$$\partial_{x_1} = \frac{1}{2i} \left(k - \frac{1}{k} \right) \partial_z - \frac{1}{2i} \left(\bar{k} - \frac{1}{\bar{k}} \right) \partial_{\bar{z}}, \quad (29)$$

and

$$\partial_{x_2} = -\frac{1}{2} \left(k + \frac{1}{k} \right) \partial_z - \frac{1}{2} \left(\bar{k} + \frac{1}{\bar{k}} \right) \partial_{\bar{z}}, \quad (30)$$

Eq. (26) becomes

$$\nu(|k|) \frac{\partial \Psi}{\partial \bar{z}}(x_1, x_2, k) = f(x_1, x_2), \quad (x_1, x_2) \in \mathbf{R}^2, \quad k \in \mathbf{C}, \quad (31)$$

where the function $\nu(|k|)$ is defined by

$$\nu(|k|) = \frac{1}{2i} \left(\frac{1}{|k|^2} - |k|^2 \right). \quad (32)$$

We supplement Eq. (31) with the boundary condition

$$\Psi = O\left(\frac{1}{z}\right), \quad z \rightarrow \infty. \quad (33)$$

In order to solve Eqs. (31) and (33), we will use the Pompeiu formula, namely,

$$f(z, \bar{z}) = \frac{1}{2i\pi} \int_{\partial D} \frac{f(\xi, \bar{\xi}) d\xi}{\xi - z} + \frac{1}{2i\pi} \int \int_D \frac{\partial f}{\partial \bar{\xi}}(\xi, \bar{\xi}) \frac{d\xi \wedge d\bar{\xi}}{\xi - z}, \quad z \in D, \quad (34)$$

where ∂D denotes the boundary of the domain D . Using this formula, we find

$$\Psi = \frac{1}{2\pi i} \int \int_{\mathbf{R}^2} \frac{f(x'_1, x'_2)}{\nu(|k|)} \frac{dz' \wedge d\bar{z}'}{z' - z}, \quad (x_1, x_2) \in \mathbf{R}^2, \quad k \in \mathbf{C}, \quad |k| \neq 1. \quad (35)$$

Hence, using the identity

$$dz \wedge d\bar{z} = \frac{1}{2i} \left| |k|^2 - \frac{1}{|k|^2} \right| dx_1 dx_2 \quad (36)$$

it follows that for all $(x_1, x_2) \in \mathbf{R}^2$ and $k \in \mathbf{C}$, $|k| \neq 1$, Ψ satisfies

$$\Psi(x_1, x_2, k) = \frac{1}{2\pi i} \operatorname{sgn} \left(\frac{1}{|k|^2} - |k|^2 \right) \int \int_{\mathbf{R}^2} f(x'_1, x'_2) \frac{dx'_1 dx'_2}{z' - z}. \quad (37)$$

If k is either inside or outside the unit circle, the only dependence of Ψ on k is through z' and z ; thus, Ψ is a sectionally analytic function with a “jump” across the unit circle of the complex k -plane. Equation (37) provides the solution of the direct problem.

In order to solve the inverse problem, we will formulate a Riemann-Hilbert problem in the complex k -plane. In this respect, we note that Eq. (37) implies

$$\Psi = O\left(\frac{1}{k}\right), \quad k \rightarrow \infty. \quad (38)$$

Furthermore, we will show that for all $(x_1, x_2) \in \mathbf{R}^2$, Ψ satisfies the following “jump” condition:

$$\Psi^+ - \Psi^- = i(H\hat{f})(\rho, \theta), \quad -\infty < \rho < \infty, \quad 0 \leq \theta < 2\pi, \quad (39)$$

where H denotes the Hilbert transform in the variance ρ defined in Eq. (11). This equation is a direct consequence of the following equations: let Ψ^+ and Ψ^- denote the limits of Ψ as k approaches the unit circle from inside and outside, i.e.,

$$\Psi^\pm \equiv \lim_{\varepsilon \rightarrow 0} \Psi(x_1, x_2, (1 \mp \varepsilon)e^{i\theta}). \quad (40)$$

Then, for all $(x_1, x_2) \in \mathbf{R}^2$,

$$\Psi^\pm = \mp(P^\mp \hat{f})(\rho, \theta) - \int_\tau^\infty F(\rho, s, \theta) ds, \quad -\infty < \rho < \infty, \quad 0 \leq \theta < 2\pi, \quad (41)$$

where P^\pm denote the usual projectors in the variable ρ , i.e.,

$$(P^\pm \hat{f})(\rho) = \pm \frac{f(\rho)}{2} + \frac{1}{2i}(Hf)(\rho) \quad (42)$$

and F denotes f in the coordinates (ρ, τ, θ) , i.e.,

$$F(\rho, \tau, \theta) = f(\tau \cos \theta - \rho \sin \theta, \tau \sin \theta + \rho \cos \theta). \quad (43)$$

Indeed, in order to derive Eq. (41), we note that the definition of z implies

$$(z - z') = \frac{1}{2i} \left(k - \frac{1}{k} \right) (x_1 - x'_1) - \frac{1}{2} \left(k + \frac{1}{k} \right) (x_2 - x'_2). \quad (44)$$

Let

$$k^+ = (1 - \varepsilon)e^{i\theta}, \quad k^- = (1 + \varepsilon)e^{i\theta}, \quad 0 \leq \theta < 2\pi, \quad \varepsilon > 0. \quad (45)$$

Thus

$$\left(k^+ \mp \frac{1}{k^+} \right) = (1 - \varepsilon)e^{i\theta} \mp (1 + \varepsilon)e^{-i\theta} + O(\varepsilon^2) \quad (46)$$

and similarly for $(k^- \mp 1/k^-)$.

Hence, for computing Ψ^\pm via Eq. (37), we must use the formulae

$$\begin{aligned} z' - z &= (x'_1 - x_1) \sin \theta - (x'_2 - x_2) \cos \theta \\ &\pm i\varepsilon [(x'_1 - x_1) \cos \theta + (x'_2 - x_2) \sin \theta] + O(\varepsilon^2). \end{aligned} \quad (47)$$

We recall that solving Eqs. (15) and (16) for (ρ, τ) in terms of (x_1, x_2) we find Eqs. (17) and (18). The Jacobian of this transformation equals 1, hence $dx_1 dx_2 =$

$d\rho d\tau$. Replacing in Eq. (37) $z - z'$ by the RHS of equation (47) and then changing variables in the resulting equation from (x'_1, x'_2) to (ρ', τ') and from (x_1, x_2) to (ρ, τ) , we find

$$\Psi^\pm = \mp \frac{1}{2i\pi} \lim_{\varepsilon \rightarrow 0} \int \int_{\mathbf{R}^2} \frac{F(\rho', \tau', \theta) d\rho' d\tau'}{\rho' - [\rho \pm i\varepsilon(\tau' - \tau)]}. \quad (48)$$

In order to evaluate this limit, we must control the sign of $\tau' - \tau$. This suggests splitting the integral over $d\tau'$ as shown below:

$$\Psi^\pm = \mp \frac{1}{2i\pi} \lim_{\varepsilon \rightarrow 0} \int_{-\infty}^{\infty} \left\{ \int_{-\infty}^{\tau} \frac{Fd\tau'}{\rho' - [\rho \pm i\varepsilon(\tau' - \tau)]} + \int_{\tau}^{\infty} \frac{Fd\tau'}{\rho' - [\rho \pm i\varepsilon(\tau' - \tau)]} \right\} d\rho'. \quad (49)$$

In the first and second integral above, $\tau' - \tau$ is negative and positive, respectively: hence

$$\begin{aligned} \Psi^\pm &= \mp \frac{1}{2i} \int_{-\infty}^{\tau} \{ \mp iF(\rho, \tau', \theta) + (HF)(\rho, \tau', \theta) \} d\tau' \\ &\quad \mp \frac{1}{2i} \int_{\tau}^{\infty} \{ \pm iF(\rho, \tau', \theta) + (HF)(\rho, \tau', \theta) \} d\tau'. \end{aligned} \quad (50)$$

Adding and subtracting in the RHS of this equation the expression

$$\mp \frac{1}{2i} \int_{\tau}^{\infty} (\mp) iF(\rho, \tau', \theta) d\tau', \quad (51)$$

we find Eqs. (41).

The sectionally analytic function Ψ satisfies the estimate (38) and has a jump across the unit circle; thus, for all $(x_1, x_2) \in \mathbf{R}^2$, it admits the following representation:

$$\Psi = \frac{1}{2i\pi} \int_0^{2\pi} \frac{(\Psi^+ - \Psi^-)(\rho, \theta') i e^{i\theta'} d\theta'}{e^{i\theta'} - k}, \quad k \in \mathbf{C}, \quad |k| \neq 1, \quad -\infty < \rho < \infty. \quad (52)$$

Replacing in this equation $\Psi^+ - \Psi^-$ by the RHS of (39), we find the following expression valid for all $(x_1, x_2) \in \mathbf{R}^2$:

$$\Psi = -\frac{1}{2i\pi} \int_0^{2\pi} \frac{e^{i\theta'} (H \hat{f})(\rho, \theta') d\theta'}{e^{i\theta'} - k}, \quad k \in \mathbf{C}, \quad |k| \neq 1, \quad -\infty < \rho < \infty. \quad (53)$$

This expression provides the solution of the inverse problem.

Using Eqs. (26) and (53), it is straightforward to express f in terms of \hat{f} . One way of achieving this is to replace in Eq. (26) Ψ by the RHS of Eq. (53). A simpler alternative way is to compute the large k behavior of Ψ : Equation (53) implies

$$\Psi \sim \left\{ \frac{1}{2i\pi} \int_0^{2\pi} e^{i\theta} (H\hat{f})(\rho, \theta) d\theta \right\} \frac{1}{k} + O\left(\frac{1}{k^2}\right), \quad k \rightarrow \infty. \quad (54)$$

Substituting this expression in Eq. (26), we find that the $O(1)$ term of Eq. (26) yields

$$f = \frac{1}{4i\pi} \left(\partial_{x_1} + \frac{1}{i} \partial_{x_2} \right) \int_0^{2\pi} e^{i\theta} (H\hat{f})(\rho, \theta) d\theta, \quad (55)$$

which is Eq. (9).

The Construction of Inverse Attenuated Radon Transform

Let k^\pm denote the limiting values of $k \in \mathbf{C}$ as it approaches the unit circle in the complex k -plane from inside and outside the unit circle; see Eq. (45). Let z be defined in terms of $(x_1, x_2) \in \mathbf{R}^2$ and $k \in \mathbf{C}$ by Eq. (28), and let $\nu(|k|)$ be defined by Eq. (32). Then

$$\lim_{k \rightarrow k^\pm} \left\{ \partial_z^{-1} \left(\frac{f(x_1, x_2)}{\nu(|k|)} \right) \right\} = \mp(P^\mp \hat{f})(\rho, \theta) - \int_\tau^\infty F(\rho, s, \theta) ds, \\ -\infty < \rho < \infty, \quad 0 \leq \theta < 2\pi, \quad (56)$$

where \hat{f} is the Radon transform of f (see Eq. (19)), P^\pm are the usual projectors in the variable ρ (see Eq. (42)), (ρ, τ) are defined in terms of (x_1, x_2) by Eqs. (17) and (18), and F denotes f in the variables (ρ, τ, θ) (see Eq. (43)). Indeed, Eq. (56) is direct consequence of Eqs. (31) and (41).

It turns out that the derivation of the attenuated Radon transform pair is a direct consequence of Eqs. (27) and (56). Indeed, define the attenuated Radon transform $\hat{f}_\mu(\rho, \theta)$ of the function $f(x_1, x_2) \in S(\mathbf{R}^2)$ by Eq. (20). Then, $f(x_1, x_2)$ is given by Eq. (21).

In order to derive the above result, we note that Eq. (27) can be rewritten in the form

$$\frac{\partial \Psi}{\partial \bar{z}} + \frac{\mu}{\nu} \Psi = \frac{f}{\nu}. \quad (57)$$

Hence

$$\frac{\partial}{\partial \bar{z}} \left[\Psi e^{\partial_z^{-1}(\frac{\mu}{\nu})} \right] = \frac{f}{\nu} e^{\partial_z^{-1}(\frac{\mu}{\nu})}, \quad (58)$$

or

$$\Psi e^{\partial_z^{-1}(\frac{\mu}{\nu})} = \partial_z^{-1} \left[\left(\frac{f}{\nu} \right) e^{\partial_z^{-1}(\frac{\mu}{\nu})} \right], \quad (x_1, x_2) \in \mathbf{R}^2, \quad k \in \mathbf{C}. \quad (59)$$

This equation provides the solution of the direct problem, i.e., it defines a sectionally analytic function Ψ with the estimate (38), which has a jump across the unit circle of the complex k -plane. Hence, Ψ is given by Eq. (52). All that remains is to determine the jump $\Psi^+ - \Psi^-$. This involves computing the limits as $k \rightarrow k^\pm$ of $\partial_z^{-1}(\mu/v)$; thus, it can be achieved using Eq.(56). Let M denote μ in the variables (ρ, τ, θ) : then using in Eq.(59) the identity (56) with f replaced by μ , we find

$$\Psi^\pm e^{\mp P^\mp \hat{\mu}} e^{-\int_\tau^\infty M(\rho, s, \theta) ds} = \lim_{k \rightarrow k^\pm} \partial_z^{-1} \left\{ \frac{f}{v} e^{\mp P^\mp \hat{\mu}} e^{-\int_\tau^\infty M(\rho, s, \theta) ds} \right\}. \quad (60)$$

For the computation of the RHS of this equation, we use again Eq. (56) where f is now replaced by f times the two exponentials appearing in the curly bracket of Eq. (60). Hence, the RHS of Eq. (60) yields

$$\mp P^\mp e^{\mp P^\mp \hat{\mu}} \hat{f}_\mu - \int_\tau^\infty F(\rho, \tau', \theta) e^{\mp P^\mp \hat{\mu}} e^{-\int_{\tau'}^\infty M(\rho, s, \theta) ds} d\tau'. \quad (61)$$

The term $\exp[\mp P^\mp \hat{\mu}]$ is independent of τ' ; hence, this term comes out of the integral \int_τ^∞ , and furthermore, the same terms appear in the left-hand side of Eq. (60). Hence,

$$\Psi^+ - \Psi^- = -J, \quad (62)$$

where J is defined in Eq. (22). Then Eq. (52) yields

$$\Psi = -\frac{1}{2\pi} \int_0^{2\pi} \frac{e^{i\theta'} J(\rho, \tau, \theta') d\theta'}{e^{i\theta'} - k}. \quad (63)$$

Hence,

$$\Psi = \left\{ \frac{1}{2\pi} \int_0^{2\pi} e^{i\theta} J(\rho, \tau, \theta) d\theta \right\} \frac{1}{k} + O\left(\frac{1}{k^2}\right), \quad k \rightarrow \infty. \quad (64)$$

Substituting this expression in Eq. (27), we find that the $O(1)$ term of Eq.(27) yields (21).

4 SRT for PET

According to Eq. (9), the inverse Radon transform can be written in the form

$$f(x_1, x_2) = \frac{1}{2i\pi} \left(\frac{\partial}{\partial x_1} - i \frac{\partial}{\partial x_2} \right) \int_0^{2\pi} e^{i\theta} F(\rho, \theta) \Big|_{\rho=x_2 \cos \theta - x_1 \sin \theta} d\theta, \quad (65)$$

where $F(\rho, \theta)$ denotes half the Hilbert transform of $\hat{f}(\rho, \theta)$ with respect to ρ , namely,

$$F(\rho, \theta) \equiv \frac{1}{2\pi} \oint_{-\infty}^{\infty} \frac{\hat{f}(r, \theta)}{r - \rho} dr, \quad -\infty < \rho < \infty, \quad 0 \leq \theta < 2\pi. \quad (66)$$

Inserting the operator $\left(\frac{\partial}{\partial x_1} - i \frac{\partial}{\partial x_2}\right)$ inside the integral in the right-hand side of Eq. (65), we find

$$\begin{aligned} & \left(\frac{\partial}{\partial x_1} - i \frac{\partial}{\partial x_2} \right) F(x_2 \cos \theta - x_1 \sin \theta, \theta) \\ &= -(\sin \theta + i \cos \theta) \frac{\partial F(\rho, \theta)}{\partial \rho} \Bigg|_{\rho=x_2 \cos \theta - x_1 \sin \theta}. \end{aligned} \quad (67)$$

Using Eq. (67) in Eq. (65), we find

$$f(x_1, x_2) = -\frac{1}{2\pi} \int_0^{2\pi} \left[\frac{\partial F(\rho, \theta)}{\partial \rho} \right]_{\rho=x_2 \cos \theta - x_1 \sin \theta} d\theta, \quad -\infty < x_1, x_2 < \infty. \quad (68)$$

For the numerical calculation of $F(\rho, \theta)$, we assume that $\hat{f}(\rho, \theta)$ has support in the interval $-1 \leq \rho \leq 1$ and that $\hat{f}(\rho, \theta)$ is given for every θ at the n points $\{\rho_i\}_1^n$. We denote the value of \hat{f} at ρ_i by \hat{f}_i , i.e.,

$$\hat{f}_i = \hat{f}(\rho_i, \theta), \quad \rho_i \in [-1, 1], \quad 0 \leq \theta < 2\pi, \quad i = 1, \dots, n. \quad (69)$$

Furthermore, we assume that

$$\hat{f}(-1, \theta) = \hat{f}(1, \theta) = 0. \quad (70)$$

In the interval $\rho_i \leq \rho \leq \rho_{i+1}$, we approximate $\hat{f}(\rho, \theta)$ by cubic splines:

$$\begin{aligned} \hat{f}(\rho, \theta) &= a_i(\theta) + b_i(\theta)\rho + c_i(\theta)\rho^2 + d_i(\theta)\rho^3, \quad \rho_i \leq \rho \leq \rho_{i+1}, \\ & \quad 0 \leq \theta < 2\pi, \quad i = 1, \dots, n, \end{aligned} \quad (71)$$

with $\{a_i(\theta), b_i(\theta), c_i(\theta), d_i(\theta)\}_1^n$ given by the following expressions:

$$a_i(\theta) = \frac{\rho_{i+1} \hat{f}_i - \rho_i \hat{f}_{i+1}}{\Delta_i} + \frac{\hat{f}_i''}{6} \left(-\rho_{i+1} \Delta_i + \frac{\rho_{i+1}^3}{\Delta_i} \right) + \frac{\hat{f}_{i+1}''}{6} \left(\rho_i \Delta_i - \frac{\rho_i^3}{\Delta_i} \right), \quad (72)$$

$$b_i(\theta) = \frac{\hat{f}_{i+1} - \hat{f}_i}{\Delta_i} - \frac{\hat{f}_i''}{6} \left(-\Delta_i + \frac{3\rho_{i+1}^2}{\Delta_i} \right) + \frac{\hat{f}_{i+1}''}{6} \left(-\Delta_i + \frac{3\rho_i^2}{\Delta_i} \right), \quad (73)$$

$$c_i(\theta) = \frac{1}{2\Delta_i} \left(\rho_{i+1} \hat{f}_i'' - \rho_i \hat{f}_{i+1}'' \right), \quad (74)$$

$$d_i(\theta) = \frac{\hat{f}_{i+1}'' - \hat{f}_i''}{6\Delta_i}, \quad (75)$$

where

$$\Delta_i = \rho_{i+1} - \rho_i \quad (76)$$

and \hat{f}_i'' denotes the second derivative of $\hat{f}(\rho, \theta)$ with respect to ρ evaluated at ρ_i , i.e.,

$$\hat{f}_i'' = \left. \frac{\partial^2 \hat{f}(\rho, \theta)}{\partial \rho^2} \right|_{\rho=\rho_i}, \quad i = 1, \dots, n. \quad (77)$$

It is straightforward to establish the identity

$$\frac{\partial}{\partial \rho} \oint_{\rho_i}^{\rho_{i+1}} \frac{h(r)}{r-\rho} dr = \frac{h(\rho_{i+1})}{\rho - \rho_{i+1}} - \frac{h(\rho_i)}{\rho - \rho_i} + \oint_{\rho_i}^{\rho_{i+1}} \frac{\frac{\partial h(r)}{\partial r}}{r-\rho} dr, \quad -1 \leq \rho \leq 1. \quad (78)$$

Employing this identity for the function $\hat{f}(\rho, \theta)$ and recalling Eqs. (69) and (70), we find

$$\frac{\partial}{\partial \rho} \oint_{-1}^1 \frac{\hat{f}(r, \theta)}{r-\rho} dr = \sum_{i=1}^{n-1} \oint_{\rho_i}^{\rho_{i+1}} \frac{\frac{\partial \hat{f}(r, \theta)}{\partial r}}{r-\rho} dr. \quad (79)$$

Equation (71) implies

$$\begin{aligned} \oint_{\rho_i}^{\rho_{i+1}} \frac{\frac{\partial \hat{f}(r, \theta)}{\partial r}}{r-\rho} dr &= b_i(\theta) \oint_{\rho_i}^{\rho_{i+1}} \frac{dr}{r-\rho} + 2c_i(\theta) \oint_{\rho_i}^{\rho_{i+1}} \frac{r dr}{r-\rho} \\ &\quad + 3d_i(\theta) \oint_{\rho_i}^{\rho_{i+1}} \frac{r^2 dr}{r-\rho}. \end{aligned} \quad (80)$$

The integrals appearing in this equation can be evaluated by employing the following identities:

$$\oint_{\rho_i}^{\rho_{i+1}} \frac{dr}{r-\rho} = I_i(\rho), \quad (81)$$

$$\oint_{\rho_i}^{\rho_{i+1}} \frac{r dr}{r - \rho} = \Delta_i + \rho I_i(\rho), \quad (82)$$

$$\oint_{\rho_i}^{\rho_{i+1}} \frac{r^2 dr}{r - \rho} = \frac{1}{2} (\rho_{i+1}^2 - \rho_i^2) + \rho \Delta_i + \rho^2 I_i(\rho), \quad (83)$$

where

$$I_i(\rho) = \ln \left| \frac{\rho_{i+1} - \rho}{\rho_i - \rho} \right|. \quad (84)$$

Using Eqs. (80)–(84), Eq. (79) becomes

$$\frac{\partial}{\partial \rho} \oint_{-1}^1 \frac{\hat{f}(r, \theta)}{r - \rho} dr = C(\theta) + 3 \left(\sum_{i=1}^{n-1} d_i(\theta) \Delta_i \right) \rho + \sum_{i=1}^{n-1} D_i(\rho) \ln \left| \frac{\rho_{i+1} - \rho}{\rho_i - \rho} \right|, \quad (85)$$

where $C(\theta)$ and $\{D_i(\rho, \theta)\}_1^{n-1}$ are defined by the equations

$$C(\theta) = \sum_{i=1}^{n-1} \left[2c_i(\theta) \Delta_i + \frac{3}{2} d_i(\theta) (\rho_{i+1}^2 - \rho_i^2) \right], \quad (86)$$

$$D_i(\rho, \theta) = b_i(\theta) + 2c_i(\theta)\rho + 3d_i(\theta)\rho^2, \quad \rho_i \leq \rho \leq \rho_{i+1}, \quad i = 1, \dots, n. \quad (87)$$

After simplifying Eq. (85), we find

$$\begin{aligned} \frac{\partial F(\rho, \theta)}{\partial \rho} = & \frac{1}{2\pi} \left\{ C(\theta) + \frac{1}{2} \left(\hat{f}_n'' - \hat{f}_1'' \right) \rho + D_{n-1}(\rho, \theta) \ln |\rho - \rho_n| - D_1(\rho, \theta) \right. \\ & \left. \ln |\rho - \rho_1| + \sum_{i=1}^{n-2} [D_i(\rho, \theta) - D_{i+1}(\rho, \theta)] \ln |\rho - \rho_{i+1}| \right\}, \\ & 1 \leq \rho \leq 1, \quad 0 \leq \theta < 2\pi. \end{aligned} \quad (88)$$

In order to eliminate the logarithmic singularities at $\rho = \{\rho_i\}_1^n$, we impose the following n equations:

$$D_i(\rho_{i+1}, \theta) = D_{i+1}(\rho_{i+1}, \theta), \quad i = 1, \dots, n-2, \quad 0 \leq \theta < 2\pi, \quad (89)$$

$$D_1(\rho_1, \theta) = D_{n-1}(\rho_n, \theta) = 0. \quad (90)$$

In summary, the *inverse Radon transform* of a function $\hat{f}(\rho, \theta)$ approximated by the cubic spline expression (71) can be written in the form

$$f(x_1, x_2) = -\frac{1}{4\pi^2} \int_0^{2\pi} \left\{ C(\theta) + \frac{1}{2} (\hat{f}_n'' - \hat{f}_1'') \rho + D_{n-1}(\rho, \theta) \right. \\ \ln |\rho - \rho_n| - D_1(\rho, \theta) \ln |\rho - \rho_1| \\ \left. + \sum_{i=1}^{n-2} [D_i(\rho, \theta) - D_{i+1}(\rho, \theta)] \ln |\rho - \rho_{i+1}| \right\} d\theta, \quad (91)$$

where $C(\theta)$ and $\{D_i\}_{1}^{n-1}$ are defined by Eqs. (86) and (87) in terms of $\{b_i(\theta), c_i(\theta), d_i(\theta)\}_{1}^n$, which are defined by Eqs. (73)–(75) via $\{\hat{f}_i\}_{1}^n$ and $\{\hat{f}_i''\}_{1}^n$. It is assumed that the functions $\{\hat{f}_i(\theta)\}_{1}^n$ are given, whereas $\{\hat{f}_i''(\theta)\}_{1}^n$ can be computed in terms of $\hat{f}_i(\theta)$ by solving Eqs. (89) and (90).

In the construction of the so-called “natural” splines, one requires continuity of the first derivative, as well as the conditions $\hat{f}_1'' = \hat{f}_n'' = 0$. The former requirement implies Eq. (89), which eliminates the logarithmic singularities at the interior points $\rho = \rho_i$, $i = 2, \dots, n-1$. In order to eliminate the logarithmic singularities at the end points $\rho_1 = -1$ and $\rho_n = 1$, we impose Eq. (90) (instead of $\hat{f}_1'' = \hat{f}_n'' = 0$). In this way, we construct a set of splines “custom-made” for the evaluation of the Hilbert transform.

For a discrete number N of projection angles θ , Eq. (68) yields

$$f(x_1, x_2) \sim -\frac{1}{4\pi^2 N} \left\{ \sum_{j=0}^{N-1} G \left(x_1, x_2, \frac{2\pi j}{N} \right) + \frac{1}{2} G(x_1, x_2, 0) + \frac{1}{2} G(x_1, x_2, 2\pi) \right\}, \quad (92)$$

where $G(x_1, x_2, \theta)$ denotes the evaluation of the RHS of Eq. (88) at $\rho = x_2 \cos \theta - x_1 \sin \theta$.

Comparison between FBP and SRT for PET

FBP is reviewed in several publications; see, for example, [21–27]. Here, we only note that the inverse Radon transform implemented via the FBP algorithm can be expressed by the following formula [28]:

$$f(x_1, x_2) = \frac{1}{2\pi N} \sum_{n=0}^{N-1} \mathcal{F}^{-1} [S(\xi_\rho, \theta_n) \times H(\xi_\rho)], \quad (93)$$

where \mathcal{F}^{-1} denotes the inverse Fourier transform in the variable ξ and $S(\xi_\rho, \theta)$ is the sinogram in the spatial frequency domain given by the expression

$$S(\xi_\rho, \theta) = \mathcal{F}\{\hat{f}(\rho, \theta)\}, \quad (94)$$

Fig. 3 The product of the ramp function with typical filters used with FBP. The cutoff frequency ξ_c is set at 0.5 cycles/pixel

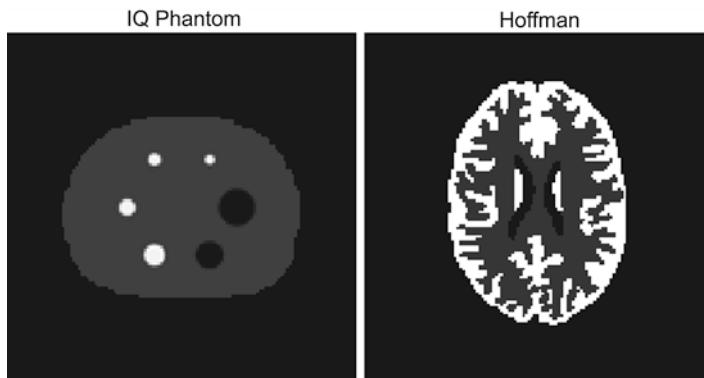

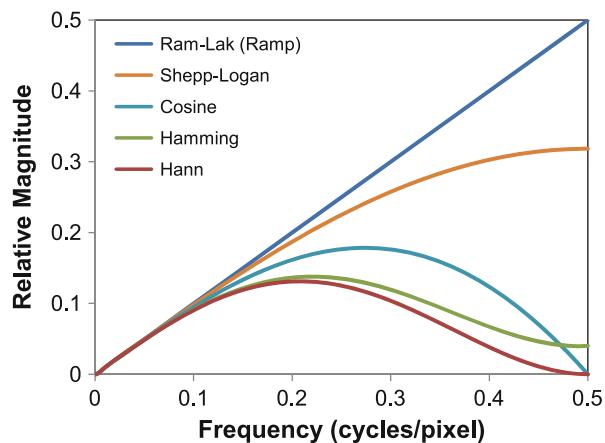

Fig. 4 The two phantoms used for the simulation studies

with \mathcal{F} denoting the direct Fourier transform. The function $H(\xi_\rho)$ appearing in Eq. (93) denotes the product of the ramp function $|\xi|$ by some appropriate filter function. Figure 3 depicts $H(\xi_\rho)$ for some commonly used filters in the FBP reconstruction algorithm.

In what follows, we compare FBP (with ramp filter) with SRT using certain well-known “quality measures.” These rigorous comparisons appear to indicate that SRT has certain advantages. Further comparisons can be found in [9] and [7].

Simulated Data

We will employ two well-known phantoms, namely, an image quality (IQ) phantom and a slice of a digital 3D Hoffman phantom [29]. These two phantoms are displayed in Fig. 4.

The IQ phantom, which simulates the human torso, will be used in order to establish how well each algorithm can determine hot and cold lesions of variable

size inside a warm background. It consists of two circular cold regions (with diameters of 38 and 32 mm) and four circular hot regions (with diameters of 25, 19, 15, and 12 mm) inside a larger warm region that simulates the background. The radioactive concentration ratio (RCR) between hot regions and the surrounding warm background is 4:1 for the three hot regions.

The Hoffman phantom simulates a cerebral PET study. It contains a complicated radioactivity distribution within small anatomical features; thus, it allows the investigation of the performance of each algorithm in a more realistic situation. The Hoffman phantom contains three distinct radioactive regions: gray matter (GM), white matter (WM), and cerebrovascular fluid (CSF). The RCR between GM and WM is 5:1. The radioactivity concentration in the CSF region is zero.

The GE Discovery ST PET scanner is simulated by employing STIR. Details of the scanner can be found elsewhere [30]. The two phantoms are placed in the center of the imaging system, and 2D projections are generated in STIR using a ray-tracing technique. Scatter and attenuation are not modeled. The relevant sinograms provide the noiseless PET measurements. For each noiseless sinogram, 20 Poisson noise realizations are generated at 5 different levels (NL1–NL5), where NL5 corresponds to the highest noise level applied.

The SRT algorithm constructs an image in a raster scan format, by scanning all pixel locations (x_1, x_2) and then calculating the integral over θ of the derivative of the half-Hilbert transform, which is approximated by Eq. (88). In the important case that the boundary of the object being imaged is convex, a pixel which is outside the object and hence has zero value, can be singled out from the sinogram by first identifying the detector locations for all angles θ that receive contribution from this pixel; then, for every (x_1, x_2) , if there is even one θ such that $\hat{f}(\rho, \theta) = 0$, it follows that $f(x_1, x_2)$ must be zero. Using this condition, we can restrict the reconstruction process only to pixels within the object boundary and hence obtain a “cleaner” reconstructed image.

By restricting reconstruction within the object boundaries (described above) and by employing certain symmetry conditions (see [7]), it is possible to decrease substantially the reconstruction time. The actual time depends on the size of the sinogram, the reconstruction grid, and the size and the complexity of the object being imaged. For example, for the simulated Hoffman phantom (sinograms of size 221×210 and 221×221 reconstruction grid), the reconstruction time is about 2.1 s per sinogram, executed on a PC with Intel® Core™ i7-920 Processor. We note that no parallel programming or other accelerating techniques are employed, which of course will decrease further the reconstruction time. The corresponding reconstruction time for FBP in STIR is about 0.3 s.

In order to determine the quality of the reconstructed images, the contrast and bias for the IQ and Hoffman phantom are calculated. The contrast for the hot and cold regions are calculated according to [30]. The bias is defined as the mean deviation over all realizations of the mean pixel value within a region of interest (ROI) from the actual activity concentration, i.e.,

$$\text{bias} = \left\{ \frac{1}{R} \sum_{r=1}^R \bar{X}_r \right\} - X_{\text{true}}, \quad (95)$$

where R is the total number of realizations, X_{true} is the true activity concentration, and \bar{X}_r is the mean activity concentration within an ROI of realization r with M number of pixels; \bar{X}_r is given by

$$\bar{X}_r = \frac{1}{N} \sum_{i=1}^N X_i. \quad (96)$$

The coefficient of variations (COV) is calculated using the expression

$$\text{COV} = \frac{\sigma}{m}, \quad (97)$$

where σ and m are the standard deviation and the mean of the measured activity in the background ROI, averaged over all realizations.

For the IQ simulated phantom, comparisons between SRT and FBP reconstructed images with no noise as well as with noise (NL2, NL4, and NL5) are shown in Fig. 5. For economy of presentation, images from NL1 and NL3 are not shown. The noisy images presented are representative reconstructions of one realization at the specific noise level. Both SRT and FBP can generate negative values in pixels (for cases where the value of the original phantom is very low or zero). In all images presented, the all-black color corresponds to zero values, whereas the white color represents the maximum value of the distribution.

Although the reconstructions from both methods appear similar, there exist two main differences: From visual inspection, it is clear that there exist differences in the noise texture between the SRT and the FBP reconstructions. Specifically, the reconstructions obtained from SRT appear more noisy than those obtained from FBP at every noise level. Furthermore, the SRT reconstructions are completely clear from streak artifacts outside the object, whereas some small streak artifacts are present in the FBP reconstructions.

The contrast, C_{hot} , for the two smallest hot spheres of the IQ phantom (15 and 12 mm) as a function of COV is presented in Fig. 6. The SRT algorithm exhibits higher contrast in all three lesions independently of noise level. This advantage in contrast increases as the size of the lesion decreases. Indeed, we observe no differences in C_{cold} for the 38-mm and 32-mm cold spheres but a small improvement for the SRT images in C_{hot} for the 25-mm lesion and larger improvement for the 19-mm lesion.

The percent bias generated by the reconstruction algorithms for the two smaller hot lesions as a function of noise level is presented in Fig. 6. The bias is negative in all cases. There are no considerable differences in bias between SRT and FBP for the cold lesion and for the largest hot lesion. The bias had small variations as

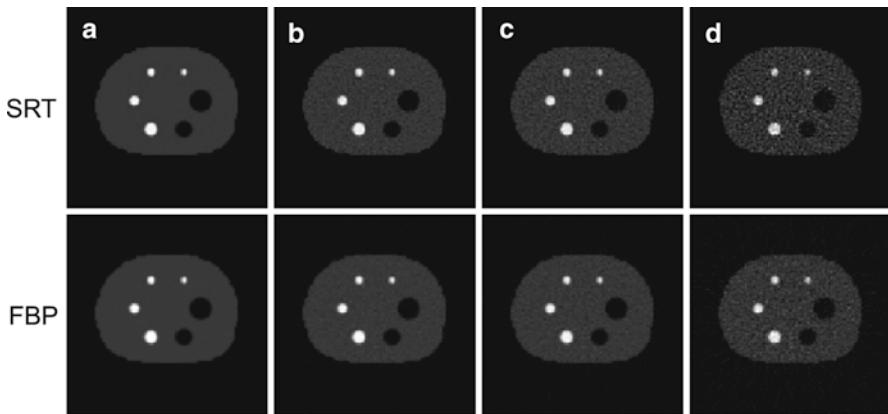

Fig. 5 Reconstructed images of the simulated IQ phantom at various noise levels (the noise level increases moving from left to right): (a) no noise, (b) noise level 2, (c) noise level 4, and (d) noise level 5

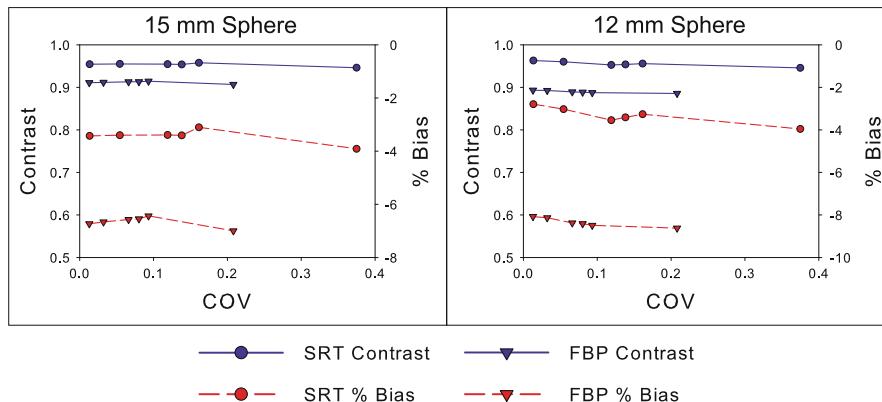

Fig. 6 Contrast and bias vs. COV for the two reconstruction algorithms obtained from the reconstructed images of the simulated IQ Phantom. Note that the leftmost data point in each line curve corresponds to the noiseless case, while the rightmost data point corresponds to the NL5 case

a function of COV for both SRT and FBP. FBP appears to give a higher bias in all cases reaching about 9 % for the 12-mm lesion. The percent bias for the FBP images increases as the lesion size decreases. The percent bias for SRT has small variations as a function of lesion size. The situation is similar for the 19-mm hot lesion.

For the Hoffman simulated phantom, comparisons between SRT and FBP reconstructed images with no noise as well as with noise (NL2, NL4, and NL5) are shown in Fig. 7. The noisy images presented are representative reconstructions of one realization at the specific noise level. All anatomical features of this phantom can clearly be identified by both algorithms for all selected noise levels. Small streak artifacts outside the object are present in the FBP reconstructions, whereas the SRT reconstruction provides images with no such artifacts.

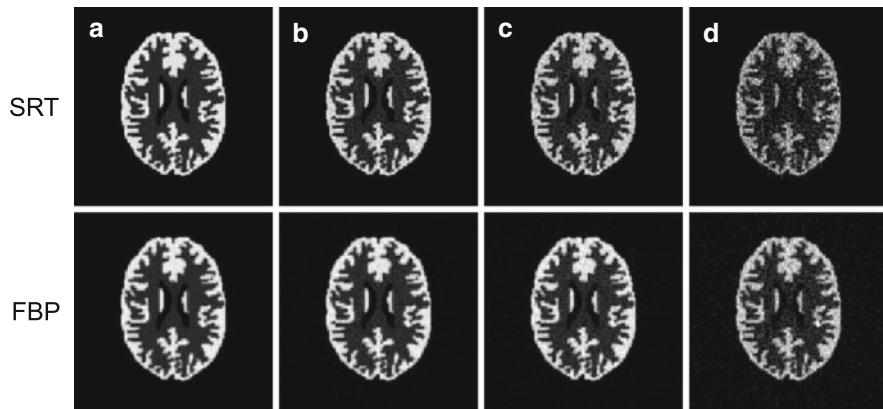

Fig. 7 Reconstructed images of the simulated Hoffman phantom at various noise levels: (a) no noise, (b) noise level 2, (c) noise level 4, and (d) noise level 5

Contrast plots between GM/CSF and WM/CSF as a function of noise level are presented in Fig. 8a, b. There exists a small improvement in contrast for the SRT algorithm, particularly for the case of the WM. RCR plots comparing the two reconstruction algorithms as a function of noise level are presented in Fig. 8c. The RCR calculations between GM and WM suggest that FBP slightly underestimates the actual RCR value (dotted line), whereas the RCR calculated from SRT reconstructions is closer to the actual value. The percent bias for the GM as a function of noise level is depicted in Fig. 8d. There is a negative bias in both algorithms, similar to the case of the IQ phantom. The bias is 4 % for the FBP and about 2 % for the SRT algorithm. The bias for the GM is under 0.8 % for both algorithms.

Real Data

Real-data acquisitions are performed using a commercial ARGUS-CT small-animal PET-CT system (SEDECAL S.A., Madrid, Spain). The PET tomograph of this system is identical to the GE Healthcare eXplore VISTA small-animal PET scanner which is described elsewhere [31].

The following two phantoms are used: (a) a NEMA image quality phantom and (b) an in-house Derenzo phantom. A NEMA phantom, designed in accordance to the specifications of the NEMA NU 4-2008 quality phantom [32], is employed in order to determine the noise and contrast properties of each algorithm. This phantom is separated into three main parts: a fillable cylindrical region 30 mm in diameter and 30 mm in length; a solid region with 5 fillable rods with dimensions of 1, 2, 3, 4, and 5 mm each; and a uniform region with two cold region chambers 8 mm in diameter. Schematics of the three distinct parts of the NEMA phantom are shown in Fig. 9. The entire phantom is filled with 15.8 MBq of ^{18}F aqueous solution, and one of the

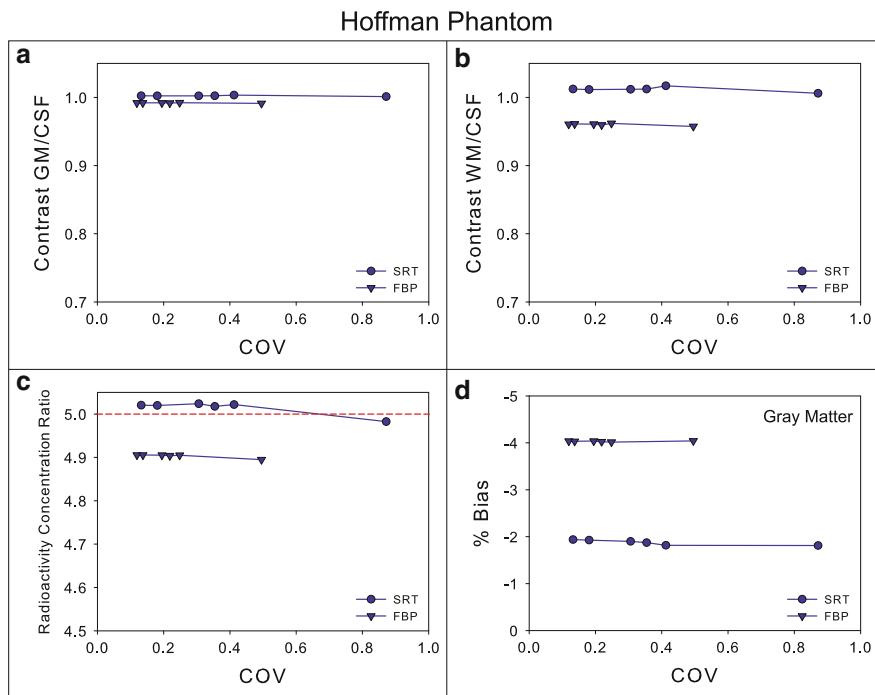

Fig. 8 Contrast, RCR, and bias vs. COV comparisons between the two reconstruction algorithms for the simulated Hoffman phantom. Contrast was determined for GM with respect to CSF (**a**) and for WM with respect to CSF (**b**). RCR between GM and WM was also determined (**c**). The *dashed line* indicates the actual RCR between GM and WM of the simulated Hoffman phantom being imaged. The bias is presented as a percentage of the true activity concentration of the lesion being measured (**d**). Note that the leftmost data point in each line curve corresponds to the noiseless case, while the rightmost data point corresponds to the NL5 case

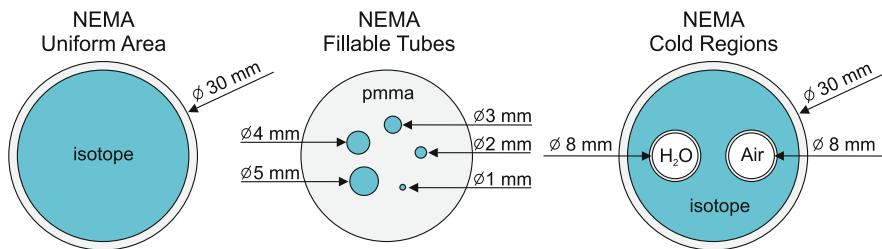

Fig. 9 Schematics of the three distinct parts of the NEMA NU 4-2008 phantom used for the real-data studies

8-mm cold chambers is filled with nonradioactive water while the other one remains with air. A 30-min PET scan is acquired in two bed positions.

An in-house Derenzo phantom is used in order to test the resolution limitations of each algorithm. The Derenzo phantom consists of 31 microcapillaries arranged

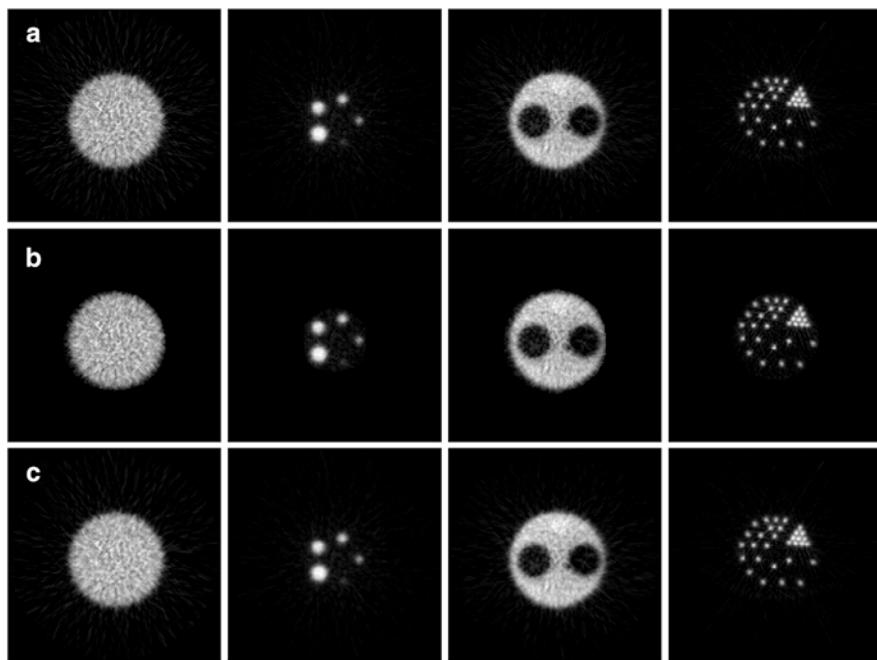

Fig. 10 Reconstructions of three slices of the NEMA NU 4-2008 image quality phantom and a slice of the Derenzo phantom, acquired by the ARGUS-CT small-animal PET-CT system: (a) SRT with no thresholding, (b) SRT with thresholding, and (c) FBP with a ramp filter. Note that the 8-mm cold chamber on the left of the NEMA 2 slice is filled with nonradioactive water and the one on the right with air

in six different sectors. The capillaries are separated by 2, 3, 4, 5, 6, and 8 mm, respectively, and there is no material between them. The phantom is filled with 5.6 MBq of ^{18}F aqueous solution, and a 60-min PET scan is performed.

Reconstructed images obtained via SRT and FBP (including SRT without sinogram thresholding) of three slices of the NEMA NU 4-2008 image quality phantom are presented in Fig. 10. Small streak artifacts are present in both SRT and FBP reconstructions. These artifacts are reduced in SRT after applying sinogram thresholding.

COV and contrast calculations using the uniform slice and the cold chamber slice of the NEMA phantom are presented in Fig. 11a, b. The SRT reconstructed images exhibit slightly higher COV values in comparison to FBP. The contrast values for both the water and air chambers are similar for both algorithms.

Reconstructed images of the Derenzo phantom are shown in Fig. 10. All reconstructed circular sources are clearly visible with both methods. Fig. 11c illustrates the contrast for the various sectors of the Derenzo phantom calculated from the SRT and FBP reconstructed images. The contrast in the SRT reconstructed images is higher than the contrast of the FBP images; the difference in contrast between SRT

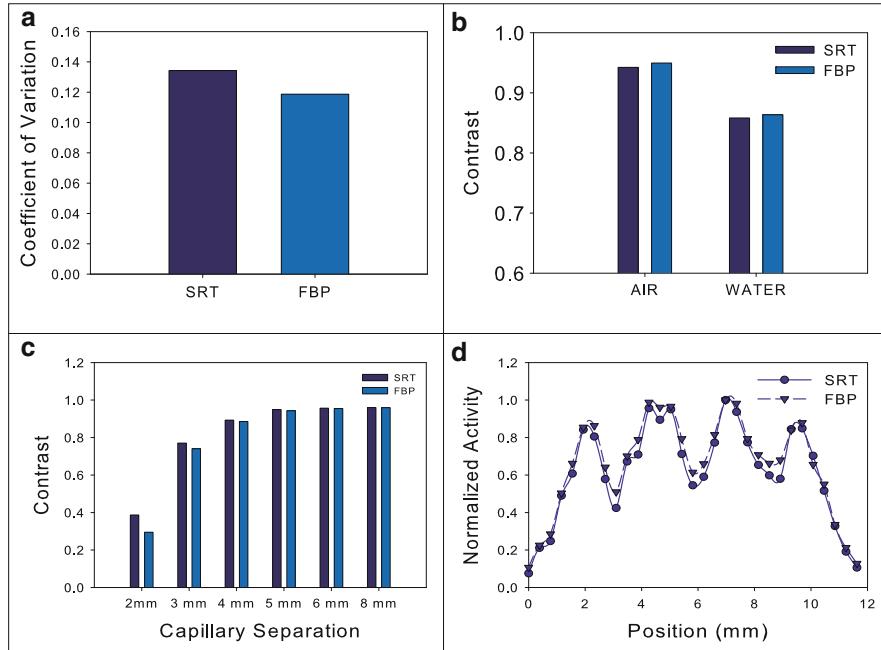

Fig. 11 Results from analyzing real NEMA NU 4-2008 and Derenzo phantom images: (a) COV, (b) contrast for water to background and air to background, (c) contrast for the different sections of the Derenzo phantom, and (d) line profiles obtained along the 2-mm separated capillaries of the Derenzo phantom. The *dashed lines* correspond to the normalized profile values through the actual phantom

and FBP images becomes larger as the center-to-center spacing between the lesions of the Derenzo phantom becomes smaller. Figure 11d illustrates the line profiles obtained along the 2-mm separated capillaries of the phantom. SRT resolves the 2-mm separated holes slightly better than FBP.

5 SRT for SPECT

In order to derive the final formula for IART, we first derive the following simplification of Eq. (21):

$$f(x_1, x_2) = \frac{1}{2\pi} \int_0^{2\pi} \exp \{M(x_1, x_2, \theta)\} \left\{ \begin{aligned} & \left[-\cos \theta \frac{\partial M(x_1, x_2, \theta)}{\partial x_2} \right. \\ & \left. + \sin \theta \frac{\partial M(x_1, x_2, \theta)}{\partial x_1} \right] G(\rho, \theta) - \frac{\partial G(\rho, \theta)}{\partial \rho} \end{aligned} \right\}_{\rho=x_2 \cos \theta - x_1 \sin \theta} d\theta, \quad (98)$$

where the functions M and G are defined by

$$M(x_1, x_2, \theta) = \int_{\tau}^{\infty} \mu(s \cos \theta - \rho \sin \theta, s \sin \theta + \rho \cos \theta) ds \Bigg|_{\begin{array}{l} \tau = x_2 \sin \theta + x_1 \cos \theta \\ \rho = x_2 \cos \theta - x_1 \sin \theta \end{array}} \quad (99)$$

and

$$G(\rho, \theta) = \exp \left\{ -\frac{\hat{\mu}(\rho, \theta)}{2} \right\} [\cos(F(\rho, \theta)) G^C(\rho, \theta) + \sin(F(\rho, \theta)) G^S(\rho, \theta)], \quad (100)$$

with F , G^C , G^S defined by

$$F(\rho, \theta) = \frac{1}{2\pi} \oint_{-\infty}^{\infty} \frac{\hat{\mu}(r, \theta)}{r - \rho} dr, \quad (101)$$

$$G^C(\rho, \theta) = \frac{1}{2\pi} \oint_{-\infty}^{\infty} \exp \left\{ \frac{\hat{\mu}(r, \theta)}{2} \right\} \cos(F(r, \theta)) \hat{f}_{\mu}(r, \theta) \frac{dr}{r - \rho}, \quad (102)$$

$$G^S(\rho, \theta) = \frac{1}{2\pi} \oint_{-\infty}^{\infty} \exp \left\{ \frac{\hat{\mu}(r, \theta)}{2} \right\} \sin(F(r, \theta)) \hat{f}_{\mu}(r, \theta) \frac{dr}{r - \rho}, \quad -\infty < \rho < \infty, \quad 0 \leq \theta < 2\pi. \quad (103)$$

In order to derive Eq. (98), we insert the operator $\partial_{x_1} - i \partial_{x_2}$ inside the integral in the RHS of (21) and use the identity

$$\begin{aligned} (\partial_{x_1} - i \partial_{x_2}) &= \frac{\partial x_1}{\partial \tau} \partial \tau + \frac{\partial x_1}{\partial \rho} \partial \rho - i \left(\frac{\partial x_2}{\partial \tau} \partial \tau + \frac{\partial x_2}{\partial \rho} \partial \rho \right) \\ &= (\cos \theta - i \sin \theta) \partial \tau + (-\sin \theta - i \cos \theta) \partial \rho = e^{-i\theta} (\partial_{\tau} - i \partial_{\rho}). \end{aligned} \quad (104)$$

Then, Eq. (21) becomes

$$\begin{aligned} (\partial_{x_1} - i \partial_{x_2}) J(x_1, x_2, \theta) &= e^{-i\theta} e^M \left\{ \left[-\mu(x_1, x_2) L_{\mu} \hat{f}_{\mu} + \left(\sin \theta \frac{\partial M}{\partial x_1} - \cos \theta \frac{\partial M}{\partial x_2} \right) \right] \left(i L_{\mu} \hat{f}_{\mu} \right) - \frac{\partial}{\partial \rho} \left(i L_{\mu} \hat{f}_{\mu} \right) \right\} \Bigg|_{\begin{array}{l} \tau = x_2 \sin \theta + x_1 \cos \theta \\ \rho = x_2 \cos \theta - x_1 \sin \theta \end{array}}. \end{aligned} \quad (105)$$

The contribution to Eq. (21) of the first term of the RHS of Eq. (105) vanishes. Indeed, this contribution equals

$$-\mu(x_1, x_2) \int_0^{2\pi} \exp \{M(x_1, x_2, \theta)\} (L_\mu \hat{f}_\mu)(\rho, \theta) \Big|_{\rho=x_2 \cos \theta - x_1 \sin \theta} d\theta = \\ -\mu(x_1, x_2) \int_0^{2\pi} J(x_1, x_2, \theta) d\theta. \quad (106)$$

But Eqs. (1.8) and (2.9) of [33] evaluated at $\lambda = 0$ imply

$$\int_0^{2\pi} J(x_1, x_2, \theta) d\theta = 0. \quad (107)$$

Thus, using Eq. (105) in Eq. (21), we find Eq. (98) provided that the following identity is valid:

$$i(L_\mu \hat{f}_\mu)(\rho, \theta) = 2G(\rho, \theta). \quad (108)$$

In order to derive this equation, we will use the equations

$$\exp \{P^- \hat{\mu}\} = \exp \left\{ -\frac{\hat{\mu}}{2} - iF \right\}, \quad \exp \{P^+ \hat{\mu}\} = \exp \left\{ \frac{\hat{\mu}}{2} - iF \right\},$$

where F denotes half the Hilbert transform of $\hat{\mu}$ in the variable ρ ; see Eq. (101). Hence,

$$\exp \{P^- \hat{\mu}\} P^- \exp \{-P^- \hat{\mu}\} \hat{f}_\mu = \\ \exp \left\{ -\frac{\hat{\mu}}{2} - iF \right\} \left[-\frac{1}{2} \exp \left\{ \frac{\hat{\mu}}{2} + iF \right\} \hat{f}_\mu + \frac{1}{2i} H \left(\exp \left\{ \frac{\hat{\mu}}{2} + iF \right\} \hat{f}_\mu \right) \right] \quad (109)$$

and

$$\exp \{-P^+ \hat{\mu}\} P^+ \exp \{P^+ \hat{\mu}\} f_\mu = \\ \exp \left\{ -\frac{\hat{\mu}}{2} + iF \right\} \left[\frac{1}{2} \exp \left\{ \frac{\hat{\mu}}{2} - iF \right\} \hat{f}_\mu + \frac{1}{2i} H \left(\exp \left\{ \frac{\hat{\mu}}{2} - iF \right\} \hat{f}_\mu \right) \right], \quad (110)$$

where H denotes the Hilbert transform in the variable ρ defined in Eq. (11). Using the above equations in Eq. (23) and simplifying, we find

$$i(L_\mu \hat{f}_\mu)(\rho, \theta) = \frac{1}{2} \exp \left\{ -\frac{\hat{\mu}}{2} \right\} \times \\ \left[\exp \{-iF\} H \left(\exp \left\{ \frac{\hat{\mu}}{2} + iF \right\} \hat{f}_\mu \right) + \exp \{iF\} H \left(\exp \left\{ \frac{\hat{\mu}}{2} - iF \right\} \hat{f}_\mu \right) \right] \quad (111)$$

It is important to note that the RHS of Eq. (111) is real.

Using the definitions (102) and (103), after some simplifications, Eq. (111) becomes

$$i \left(L_\mu \hat{f}_\mu \right) (\rho, \theta) = \exp \left\{ -\frac{\hat{\mu}}{2} \right\} [\cos(F) G^C + \sin(F) G^S]. \quad (112)$$

6 Conclusion

PET and SPECT constitute two important medical imaging techniques. Using these techniques, images can be obtained by employing either analytic methods or iterative methods.

Regarding analytical methods, we note that simple models for PET and SPECT can be formulated in terms of the inverse Radon transform and the IART, respectively. FBP provides the most well-known numerical implementation of the inverse Radon transform. FBP is currently used commercially for both PET and SPECT, in spite of the fact that SPECT involves the IART and not the inverse Radon transform (this is a consequence of the fact that until recently no analytic formula was available for the IART).

Here, we have reviewed a general method for deriving transform pairs and have used this method to derive the inverse Radon transform and the IART. Furthermore, we have presented a novel numerical technique based on “custom-made” cubic splines for the numerical implementation of both the above inverse transforms. Rigorous studies comparing this novel technique (called SRT) with FBP for PET suggest that SRT has certain advantages. In future clinical studies, efforts will be made to delineate this advantage in concrete clinical situations.

The main advantages of the analytical methods, like FBP and SRT, are speed and simplicity. However, in these methods, it is difficult to incorporate complex physical phenomena such as attenuation and scatter. In FBP, noise issues are treated by selecting appropriate filtering parameters, such as the roll-off and cutoff frequencies of the reconstruction filter (usually at the expense of spatial resolution). Another disadvantage of FBP is the streak artifacts that are particularly prominent near hot regions of the object. For SRT, it is possible to eliminate these effects at least outside the main region of interest and hence to obtain a “cleaner” image.

The predominant iterative algorithms are the maximum likelihood expectation maximization (MLEM) algorithm [34] and its accelerated successor the ordered subset expectation maximization (OSEM) algorithm [35]. The main advantage of the iterative algorithms is the ability to model several aspects of the imaging system, including elements of the noise characteristics, sinogram blurring due to detector crystal penetration, inter-crystal scatter, depth of interaction, and photon attenuation [36,37]. As a consequence, iterative methods can improve image quality and achieve considerable resolution recovery. However, iterative algorithms require more computing time and power, particularly when details of the physical model are

included. Iterative techniques are now in widespread use in clinical and preclinical systems. This is due to the speed improvement provided by OSEM and the recent computer hardware improvements (processing and storage).

Most commercial clinical and preclinical PET systems allow the use of either FBP or OSEM for image reconstruction. Currently, in OSEM, the main challenge is the selection of the proper number of subsets and iterations [38], as well as the choice of a suitable post-reconstruction filter (if needed). Stopping the algorithm at the proper number of iterations is important, since EM-based algorithms suffer from noise/bias trade-off. Stopping the iteration process after convergence is reached results in a noisy image, whereas stopping the process too soon results in a less noisy image which however is biased toward the image assumed at the initial step. In order to resolve this issue, several regularization schemes have been proposed [39]. In spite of these improvements, a recent dynamic brain PET study by Reilhac et al. [40] concludes that analytical methods are more robust to low-count data than iterative methods. Furthermore, the positivity constraint imposed to the sinogram and image space by the EM-based reconstruction algorithms leads to overestimation (positive bias) of the low-activity regions [40–42].

The advantage of analytical methods for low-count data will be increasingly more important. Indeed, in the 1980s, medical imaging was responsible for only about 15 % of the total radiation exposure to US population from all sources; now this proportion is 50 % [43]. In 2010, 70 million CT scans were performed in the USA, and the radiation dose from CT scans is 100–500 times those from conventional radiography. Taking into consideration that CT is now used for screening for lung cancer [44] and that the use of PET-CT and SPECT-CT is expanding, it is imperative to be able to produce images with the least possible radiation.

Abstract

This survey starts with a brief description of the scientific relevance of electron tomography in life sciences followed by a survey of image formation models. In the latter, the scattering of electrons against a specimen is modeled by the Schrödinger equation, and the image formation model is completed by adding a description of the transmission electron microscope optics and detector. Electron tomography can then be phrased as an inverse scattering problem and attention is now turned to describing mathematical approaches for solving that reconstruction problem. This part starts out by explaining challenges associated with the aforementioned inverse problem, such as the extremely low signal-to-noise ratio in the data and the severe ill-posedness due to incomplete data, which naturally brings up the issue of choosing a regularization method for reconstruction. Here, the review surveys both methods that have been developed, as well as pointing to new promising approaches. Some of the regularization methods are also tested on simulated and experimental data. As a final note, this is not a traditional mathematical review in the sense that focus here is on the application to electron tomography rather than on describing mathematical techniques that underly proofs of key theorems.

1 Introduction

Imaging is today an essential tool in many different areas of scientific and technological research. It is also widely used in investigations in fields as diverse as arts and jurisprudence. As such, it is integrated into a variety of devices and procedures routinely used in society. A prime example is microscopy that enables investigation of objects that are too small for the naked eye at a variety of scales, from atomic to sub-millimeter. Therefore, various forms of microscopy are crucial in industrial processes, in life sciences, in comparative studies of chemistry and geology, and in diagnostic medicine.

Traditional imaging techniques provide 2D images whose usage involves significant portion of interpretation since the object/phenomena under investigation almost always takes place in three spatial dimensions, plus time if temporal variation is included. 3D images are therefore to be preferred whenever possible. This applies in particular to life sciences and drug discovery, where a central topic is to understand the machinery within the cell responsible for supporting life and disease. An important part in this quest is to map the spatial and temporal arrangement of the molecules engaged in this machinery. The *structure determination problem*, which seeks to *recover the three-dimensional structure of an individual molecule at highest possible resolution in its natural environment*, has therefore come to play a central role.

Addressing the structure determination problem is, not surprisingly, both experimentally and computationally very challenging. X-ray crystallography and nuclear magnetic resonance are two established approaches, but these cannot recover the structure of an *individual* molecule in its *natural* environment within the cell. Electron microscopy offers alternative means to study macromolecules, molecular

complexes and supramolecular assemblies in 3D. Three approaches have been developed, electron crystallography [68], single particle analysis [61], and **ET**.

This review focuses on **ET**, which is the *only* method for 3D structural studies of *individual* assemblies and subcellular structures in their *natural* environment. The idea in **ET** is to recover the structure of a specimen from a series of *micrographs*, which are 2D **TEM** images, using principles of tomography. Since its introduction to the scientific community in 1968 [41, 85, 179], there has been tremendous progress in instrumentation and sample preparation that has resolved many of the difficulties associated with data collection. Most of the computational challenges however remain to be addressed. Established approaches for image reconstruction are direct adaptations of methods from medical imaging, used with inadequate appreciation for the finer points of mathematics. Therefore, 3D reconstructions have a resolution that is reliable only for studying cellular substructures, rather than studying individual small molecules (“small” in this context refers to protein molecules of size smaller than 200 kDa). This in turn has severely limited the usefulness of **ET** in life sciences.

Another rapidly growing application area for **ET** is 3D characterization and metrology of nano-structures in material sciences and semiconductor manufacturing. In these applications, data is often acquired using a variety of different **TEM** imaging modes (paragraph on p. 941), see [126, 127, 181] for a nice review. The focus in this review is on life sciences, even though we occasionally mention material science applications.

2 The Transmission Electron Microscope (**TEM**)

The starting point of electron microscopy can be attributed to Hans Busch who laid the theoretical basis for the electron microscope and designed the first working electron lens [23, 24]. Ten years later, based on the work of Busch, Ernst Ruska constructed the first operational **TEM** [98]. Ruska was later awarded the 1986 Nobel Prize in physics.

The operational principle of an electron microscope is similar to a light microscope (Fig. 1). A source emits electrons that are accelerated (typically by 200 kV) on their way to the specimen. A condenser system controls how the specimen is illuminated. After passing through the electron-transparent specimen, an electron optical system collects the electrons of interest and directs them onto the image plane, where an intensity is generated. This is detected and converted to a gray-scale image (micrograph) by means of a detector system. The beam electrons scatter elastically and/or inelastically against the atoms in the specimen. This interaction can generate a range of secondary signals whose analysis reveal different properties of the specimen.

A modern **TEM** can be operated under different settings (*imaging modes*) to image some of the aforementioned signals. Each imaging mode is determined by (1) how the specimen is illuminated, (2) which electrons that are selected to take part

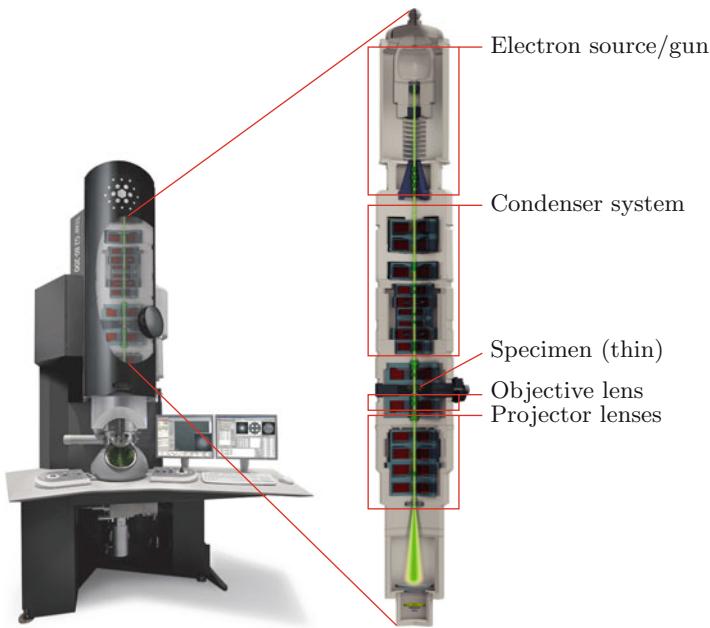

Fig. 1 A modern TEM with its column exposed. The electron gun with the source is at the *top*. Electrons travel downwards, passing through the condenser system before they scatter against the specimen. Scattered electrons pass through the optics (objective and projector lenses) and form an image at the bottom (image courtesy of [FEI](#))

in the image formation and where they are registered, and (3) the type of detector. As an example, dark-field mode uses only the deflected electrons for image formation, whereas in bright-field mode only the undeflected electrons take part in the image formation.

ET in life sciences is mostly based on *conventional bright-field* TEM imaging. The specimen is here illuminated by a parallel beam of incident electrons (uniform illumination mode), and transmitted electrons that pass through the aperture in the back focal plane of the objective lens form an image in the image plane. The aperture is centered (bright-field mode), so only electrons that scatter with very small angle take part in the image formation.

TEM Imaging Modes

The specimen can be illuminated by focusing the electrons onto a spot (scanning mode), which leads to Scanning Transmission Electron Microscope (**STEM**). Next, the objective aperture can be placed as to block the direct beam of un-scattered electrons, while one or more diffracted beams are allowed to pass (dark-field mode). Finally, instead of registering the image in the image plane, it can be registered in the back-focal plane of the objective lens (diffraction contrast mode), which corresponds to imaging the diffraction pattern of the specimen.

A common mode is selected area electron diffraction that uses uniform illumination with diffraction contrast imaging, suitable for investigating spatial variation of diffraction properties in a (crystalline) specimen. Convergent-beam electron diffraction is the corresponding set-up based on scanning mode illumination. Another mode is High-Angle Annular Dark-Field (**HAADF**) that uses scanning mode illumination and micrographs are acquired in dark-field mode. The electrons that take part in image formation are incoherent elastically scattered electrons, so contrast depends strongly on the average atomic number of the scatterer (“Z”-contrast). Finally we mention analytical **TEM** that uses energy resolving detectors, Energy-Dispersive X-ray Spectroscopy (**EDS**) or Electron Energy Loss Spectroscopy (**EELS**), combined with scanning mode for illumination. This allows one to acquire a “chemical map” of the specimen. An **EDS** spectrometer does this by measuring the X-rays emitted from the specimen, whereas an **EELS** spectrometer measures those transmitted electrons that undergo a pre-specified energy loss.

The above modes are mostly used in material sciences and semiconductor industry, even though there are usages in life sciences. The interested reader may consult [63] and [7, chapter 3] for a more detailed account.

Sample Preparation

Samples to be imaged in an electron microscope generally require processing to produce a suitable specimen. Sample preparation techniques depend on the sample, the information one seeks to image, and the type of microscope. A mathematician may safely ignore most issues related to sample preparation, but some aspects of it that do have algorithmic implications. Before we discuss these (in paragraph on p. 943), we provide a very brief overview of sample preparation.

Overview

In general, all sample preparation techniques include some kind of fixation that aims at solidifying the specimen. This is needed because electron microscopy imaging is performed under high vacuum conditions. Next, thinning might be required to ensure that the specimen is thin enough so that electrons can pass through. Both these steps are done while preserving as much as possible of the structural integrity of the specimen. Finally, a user might choose to add substrates into the specimen in order to increase contrast (contrast enhancement). A wide range of techniques are now available, see [7, 8] for a comprehensive review.

In life sciences, the preferred fixation technique is by freezing (cryo-electron microscopy) [148, section 3.1]. If the specimen is liquid, or thin enough ($<10\text{ }\mu\text{m}$), then one can use plunge-freezing. Here the specimen is applied to a support and then dropped into a cryogen (such as liquid ethane at less than $-160\text{ }^{\circ}\text{C}$) where sufficiently fast cooling speeds are reached that prevent the formation of crystalline ice. This solidifies the specimen with minimal artifacts. It is the preferred cryo-fixation method for *in vitro* specimens, i.e., specimens that contain free particles (proteins and macromolecular assemblies) in an aqueous solution. Samples that

are too thick for plunge-freezing are treated with high-pressure freezing, which combines rapid temperature decrease with the application of high pressure that lowers the melting point of water. It allows vitrification of specimens up to $200\text{ }\mu\text{m}$ in thickness.

Relevance to Mathematics

Let us first consider usage of contrast enhancement, like in negative staining. The high atomic numbers for contrast agents improve the signal-to-noise properties of the micrographs, so noise becomes less of a problem. On the other hand, contrast agents have difficulties reaching the interior of the molecular assemblies, so micrographs show outlines of the molecules rather than their internal structure. Therefore, contrast enhancement is reserved for low- or medium-resolution TEM imaging. In the context of ET, we can in the forward model often disregard phase contrast (section “Forward Operator for Amplitude Contrast Only”). Next, since focus is on determining the 3D shape of the sub-structures within the specimen, rather than their internal structure, 3D reconstruction methods should preserve edge information whereas smooth gray scale variations are of less interest. The impact of local data (p. 974) can also be quite severe in this setting (section on p. 985), so if possible, one should use reconstruction methods that are less sensitive to such issues.

Cryo-fixed unstained specimens are on the other hand thin and weakly scattering. ET of High-Resolution TEM (HRTEM) imaging data from such specimens must model phase contrast. Specimens that contain particles in aqueous buffer (in vitro specimens) are fixated by plunge freezing. These are imaged using a very low electron dose, so micrographs are very noisy and 3D reconstruction methods must efficiently utilize whatever a priori information that is available, like regularity or sparsity adapted to this setting. Impact from local data is on the other hand less severe since most of the specimen is vitrified aqueous buffer.

Specimens that are derived from tissue (in situ specimens) typically result in micrographs with much better signal-to-noise ratio (although not as good as negatively stained specimens). The background will have significant structure, so regularity assumptions, like sparsity, will have to be quite different from those used for in vitro specimens. The impact from local data is also more severe as compared to imaging data from in vitro specimens.

3 Basic Notation and Definitions

\mathbb{R} and \mathbb{C} denote the fields of real and complex numbers, \mathbb{R}_+ and \mathbb{C}_+ are positive numbers (for complex numbers, this means positive real and imaginary parts), and \mathbb{R}^n denotes the n -dimensional vector space over \mathbb{R} . Next, for $x \in \mathbb{R}^3$ we let x^\perp denote the hyperplane in \mathbb{R}^3 that is orthogonal to x , i.e., $x^\perp := \{y \in \mathbb{R}^3 : x \cdot y = 0\}$. $S^2 \subset \mathbb{R}^3$ is the 3D sphere, and for $\omega \in S^2$ and $p \in \mathbb{R}$, we let $p\omega + \omega^\perp$ denote the hyperplane of points $x = p\omega + y$ where $y \in \omega^\perp$.

Next, \mathcal{F} and $*$ denote the Fourier transform and convolution of functions defined on \mathbb{R}^n . Furthermore, given a function $U: \mathbb{R}^3 \rightarrow \mathbb{C}$ that decreases sufficiently fast at infinity, say $U \in \mathcal{S}(\Omega, \mathbb{C})$, its *ray transform* $\mathcal{P}(U)$ (also called projection in the [ET](#) community) is defined as

$$\mathcal{P}(U)(\omega, x) := \int_{-\infty}^{\infty} U(x + s\omega) ds \quad \text{for } \omega \in S^2 \text{ and } x \in \omega^\perp. \quad (1)$$

More precise mathematical conditions that are required for the existence of the ray transform are stated in [122, section 3.5]. Finally, following [136, eqs. (2.29) and (2.30)], for fixed $\omega \in S^2$ we let $\mathcal{F}_{\omega^\perp}$ and $\circledast_{\omega^\perp}$ denote the corresponding *Fourier transform* and *convolution on the (two-dimensional) hyperplane ω^\perp* :

$$\begin{aligned} \mathcal{F}_{\omega^\perp}[U](\xi) &:= \int_{\omega^\perp} U(x) e^{-ix \cdot \xi} dx \quad \text{for } \xi \in \omega^\perp, \\ (U \circledast_{\omega^\perp} H)(x) &:= \int_{\omega^\perp} U(x - y) H(y) dy \quad \text{for } x \in \omega^\perp. \end{aligned}$$

4 The Forward Model

This section gives an overview of [TEM](#) image formation models (forward models) relevant for [ET](#). It includes a short derivation of various models with discussions on their validity and computational feasibility. Much of the material is therefore physics related, so a reader primarily interested in image reconstruction could skip this part and directly consult (57) (or section “Forward Operator for Combined Phase and Amplitude Contrast” for a slightly more detailed summary).

Basic Assumptions

We only consider conventional bright-field [TEM](#) imaging of amorphous specimens, since this is the prevalent imaging mode for [ET](#) in life sciences. The starting point is to assume that the imaging electron and the specimen form a closed system, i.e., there is no interaction with the environment. Next, we also assume that successive imaging electrons can be treated independently and any interaction between them can be neglected (independent electron assumption). This holds under typical [TEM](#) imaging conditions in [ET](#) where the mean separation between two successive electrons is much larger than the specimen thickness and the length of the electron wave packet [63, p. 85]. Hence, wave mechanical notions, like “interference,” refer to the wave crests of an *individual* electron (i.e., self-interference).

Bearing in mind these two basic assumptions, an ideal model would be based on solving the Schrödinger equation for the electron microscope (including the specimen) as a whole. This is clearly unfeasible, so the first step is to separate the problem into four parts: (1) illumination, (2) electron–specimen interaction,

(3) optics, and (4) detection. A great number of approaches have been developed for modeling each of the above parts.

Contrast Mechanisms

Models for [TEM](#) imaging fall into two categories depending on how image contrast is related to electron–specimen interaction and optics.

Amplitude contrast models (section “Forward Operator for Amplitude Contrast Only”) assume all contrast variations in a micrograph are due to the removal of electrons from the beam (*amplitude contrast*). This is adequate at medium and low resolution. At higher resolution, like in [HRTEM](#) where image features of interest are smaller than the coherence length of the electron, one also needs to account for the phase shift that an electron undergoes as it scatters against the specimen (*phase contrast*). *Combined phase and amplitude contrast models*, that are briefly described below, account for both the amplitude and phase contrast.

The starting point for the combined phase and amplitude contrast model is to assume perfect coherent imaging where incident electron waves are monochromatic plane waves (uniform coherent illumination) and electrons scatter only elastically. This leads to a stationary scattering problem where the specimen remains in the same quantum state with scattering properties fully described by its electrostatic potential. The treatment of the electron is quantum mechanical. The electron–specimen interaction is then modeled by the scalar Schrödinger equation and the picture is completed by adding a description of the effects of the optics and the detector of the [TEM](#), both modeled as convolution operators. Inelastic scattering and incoherent illumination introduce partial incoherence, so the basic assumption of perfect coherent imaging must be relaxed. Inelastic scattering can be accounted for within the coherent framework by introducing an imaginary part to the scattering potential (absorption potential). Incoherence from the illumination is usually accounted for by modifying the convolution kernel that models the optics. Finally, linearizing the scattering model and the intensity yields an explicit linear relation between the measured intensity and the scattering potential.

Illumination

This is where incident electrons are generated (source/gun) and controlled (condenser).

Basic Components

Commercially available [TEMs](#) either use a thermionic or a field-emission (electron) source. The first produces electrons by heating the source, whereas the second produces electrons by applying a large electric potential between an anode and the source. The performance of the source is characterized by its brightness, temporal coherency, energy spread, spatial coherency, and stability. The brightness (the current density per unit solid angle of the source) is the most important parameter

and it influences the resolution, contrast, and signal-to-noise capabilities of the microscope. A source with smaller size gives higher brightness and better spatial coherency, but is also less stable.

The source is incorporated into a gun that can control and focus the electrons. According to the type of the source, we have either thermionic gun or field-emission gun. The size of the first one is bigger, so it can illuminate large areas on the specimen at relatively low image magnification ($<50\text{--}100,000\times$) without losing current density. The field emission gun has become the preferable electron source for [HRTEM](#) imaging (for both uniform and scanning mode illumination) due to its high brightness and small source size. More information can be found in standard text books on electron microscopy, see, e.g., [80, sections 43–50].

After leaving the gun, the electrons pass through a condenser system that typically consists of two condenser lenses and an aperture. This is the second most important part of the [TEM](#), the objective lens (section “Optics”) being the most important, since it determines how the specimen is illuminated. One can illuminate the specimen with a wide collimated parallel beam (uniform illumination) or with a parallel narrow beam (scanning mode illumination).

Model for Illumination

Since we consider conventional [TEM](#), micrographs are acquired using uniform illumination mode. Furthermore, we will not directly model the source, gun, or condenser. Instead, as a starting point, we assume that an incident electron leaving the condenser is a monochromatic plane wave traveling along a fixed direction $\omega \in S^2$ that is parallel to the [TEM](#) optical axis:

$$\Psi(\mathbf{x}, t) = \exp(-itE/\hbar) \exp(ik\mathbf{x} \cdot \omega).$$

Here, E is the energy of the electron, \hbar is the reduced Planck constant, and k is the wave number of the electron, so $k = 2\pi/\lambda$ where λ is the wavelength.

In reality, however, the illumination is only partially coherent. The effective size at the electron source is small but not point-like, and the energy spread is narrow but still appreciable. A perfectly coherent source would require vanishingly small source and negligible energy spread. The effects of such partial coherence is usually modeled by a perturbation procedure and incorporated into the [TEM](#) optics [PSF](#), as outlined in paragraph on p. [961](#).

Electron-Specimen Interaction

This is the model for the scattering of an electron against the atoms in the specimen. In the general setting, it is a fairly complex process involving a variety of phenomena depending on the energy of the electron, the atomic composition of the specimen, and the type of chemical bindings between the atoms in the specimen. An accurate

and complete model for all electron scattering phenomena, that includes both quantum and relativistic aspects, requires the theory of quantum electrodynamics. A slightly less complete framework is based on the time-dependent multi-body Schrödinger equation where one approximately accounts for relativistic effects. Here, in the full model, the specimen is a quantum-mechanical many-body system whose scattering properties are accounted for by the corresponding Hamiltonian. This leads to a computationally unfeasible model, so we need further simplifications. One is to consider elastic scattering.

Elastic Scattering

Elastic scattering refers to the case when there is no (or negligible) transfer of energy from the electron to the specimen. This allows us to treat the electron-specimen interaction as a two-body problem where the specimen is described by its electrostatic potential and the electron is represented by its wave function $\Psi: \mathbb{R}^3 \times \mathbb{R} \rightarrow \mathbb{C}$, and the aforementioned multi-body Schrödinger equation for the system simplifies to a one-body Schrödinger equation [146, section 1.5]:

$$i\hbar \frac{\partial \Psi}{\partial t}(\mathbf{x}, t) = \frac{1}{2m} \left[-i\hbar \nabla + e\mathbf{A}(\mathbf{x}) \right]^2 \Psi(\mathbf{x}, t) - eU(\mathbf{x})\Psi(\mathbf{x}, t). \quad (2)$$

In the above, m is the rest mass of the electron, e the absolute value of the elementary charge, $U: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is the electrostatic potential, and $\mathbf{A}: \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is the magnetic vector potential for the stationary electromagnetic field surrounding the system.

Stationary Model

Since the electrostatic potential U in (2) does not depend on time, it is sufficient to consider standing wave solutions to (2):

$$\Psi(\mathbf{x}, t) = \exp(-itE/\hbar)\psi(\mathbf{x}). \quad (3)$$

In the above, $\psi: \mathbb{R}^3 \rightarrow \mathbb{C}$ is the complex valued space dependent part of Ψ , henceforth called the *electron wave*. Inserting (3) into (2), and canceling the common factor $\exp(-itE/\hbar)$ that appears throughout, results in a partial differential equation (4a) (stationary Schrödinger equation) for the electron wave ψ . Furthermore, in TEM imaging the specimen is typically “slab-like,” meaning that its extension along the TEM optical axis is much smaller than its extension in the plane orthogonal to the optical axis. A natural model is therefore to assume U is supported in an infinite slab $\Omega \subset \mathbb{R}^3$ that is bounded by two parallel hyperplanes Γ_{in} and Γ_{out} .

To summarize, the electron–specimen interaction is modeled by the stationary Schrödinger equation with a Dirichlet boundary condition on Γ_{in} given by the incident electron wave and a boundary condition at infinity (Sommerfeld radiation condition):

$$\left\{ \begin{array}{l} E\psi(\mathbf{x}) = \frac{1}{2m} \left[-i\hbar\nabla + e\mathbf{A}(\mathbf{x}) \right]^2 \psi - eU(\mathbf{x})\psi(\mathbf{x}) \quad \text{for } \mathbf{x} \in \Omega, \\ \psi(\mathbf{x}) = \exp(i\mathbf{k}\mathbf{x} \cdot \boldsymbol{\omega}) \quad \text{for } \mathbf{x} \in \Gamma_{\text{in}}. \end{array} \right. \quad (4a)$$

$$\left\{ \begin{array}{l} \lim_{r \rightarrow \infty} r \left[\mathbf{n}_r(\mathbf{x}) \cdot \nabla \psi_{\text{sc}}(\mathbf{x}) - ik\psi_{\text{sc}}(\mathbf{x}) \right] = 0 \quad \text{for } |\mathbf{x}| = r. \end{array} \right. \quad (4c)$$

Here, ψ_{sc} in (4c) is the scattered part of ψ , i.e., $\psi(\mathbf{x}) = \exp(i\mathbf{k}\mathbf{x} \cdot \boldsymbol{\omega}) + \psi_{\text{sc}}(\mathbf{x})$ and $\mathbf{n}_r(\mathbf{x})$ is the outwards normal at \mathbf{x} to the sphere with radii r . Note also that Ω is not necessarily orthogonal to the **TEM** optical axis.

A further simplification is when scattering takes place in a “field-free” region, i.e., $\text{curl } \mathbf{A} = \mathbf{B} \equiv \mathbf{0}$ in Ω . Due to the invariance under Gauge transformations, this implies that $\mathbf{A} \equiv \mathbf{0}$ in Ω . Combined with $E = \hbar^2 k^2 / 2m$, transforms (4a) into an equation of Helmholtz type:

$$(\Delta + k^2)\psi(\mathbf{x}) = -\frac{2m}{\hbar^2}eU(\mathbf{x})\psi(\mathbf{x}) \quad \text{for } \mathbf{x} \in \Omega. \quad (5)$$

The Scattering Operator

The *scattering operator* $\mathcal{T}_{\boldsymbol{\omega}}^{\text{sc}}$ maps a potential U to the electron wave on the specimen exit plane Γ_{out} , i.e.,

$$\mathcal{T}_{\boldsymbol{\omega}}^{\text{sc}}(U) := \psi|_{\Gamma_{\text{out}}} \quad \text{where } \psi \text{ solves (4a)–(4c).} \quad (6)$$

Uniqueness and Stability

The scattering operator in (6) is well defined only when (4a)–(4c) has a unique solution. This follows from existence and uniqueness for the magnetic Schrödinger equation (4a) in a half space [149, theorem 2.16].

Remark 1. Formally, the uniqueness result [149, theorem 2.16] is for the case when $\boldsymbol{\omega}$ is orthogonal to Γ_{out} . The proof however extends directly to the case when $\psi = \psi_0$ on Γ_{in} where $\psi_0 \in \mathcal{L}_c^2(H, \mathbb{C})$.

Remark 2. Standard uniqueness results for the direct scattering problem, like in [36, p. 16], assume Ω is bounded and Dirichlet condition is on all of the boundary of Ω . In our scattering problem (4a)–(4c), Ω is unbounded and we only have Dirichlet conditions on a part of the boundary.

Another important aspect is stability for the direct scattering problem (4a)–(4c), which together with uniqueness implies well-posedness. The author is unaware of any stability results that are directly applicable to (4a)–(4c). On the other hand, [87] provides analytical evidence of increasing stability of the Cauchy problem for the Helmholtz equation (5) for increasing wavenumber k . Since **TEM** imaging is associated with high wave numbers, it is reasonable to conjecture that (4a)–(4c) has good stability properties.

Relativistic Corrections

The Schrödinger equation (2) is valid only for non-relativistic electron motion. In practice, this means kinetic energies should not exceed 10 keV. In TEM imaging, electron energies are between 100 and 300 keV, so one must consider relativistic wave equations.

A relativistically correct framework is offered by Dirac's equation that accurately models electron interaction and propagation in practically all electron optical systems. The computational complexity associated with using Dirac's equation has however limited its usefulness. An alternative approach is to use relativistically corrected quantities in (2) [146, section 1.9]. This is justified from a pragmatic point of view if since these corrections provide a model that has a good agreement with experimental results.

Remark 3. The Pauli approximation, which holds for TEM imaging in ET, allows one to reduce Dirac's equation to a scalar relativistic wave equation of the same type as (2) [79, section 56.3]. This introduces relativistic corrections into (2) in a way that has stronger theoretical justification.

Inelastic Scattering

Inelastic electron scattering is characterized by transfer of energy from the incident electron to the specimen, causing the latter to change state. For many TEM imaging modes, including conventional bright-field TEM imaging, inelastic scattering manifests itself as a blurring superimposed onto the image generated by the elastically scattered electrons [100]. Therefore, if possible, energy filters are used to remove inelastically scattered electrons. This however does not completely resolve the issue of inelastic scattering, since energy filtered micrographs have contributions from inelastic scattering events associated with energy losses too small to be filtered (<1–5 eV) [45].

The Absorption Potential

In a rigorous quantum mechanical model for inelastic electron scattering, the quantum state of the specimen is changed. Formally, this requires a time-dependent scattering model with a wave function and an interaction potential that depends on all internal degrees of freedom of the system (specimen and electron). This is clearly computationally unfeasible. An alternative approach, that is frequently used for modeling TEM imaging of amorphous specimens at 100–300 keV, is to approximately account for inelastic scattering within the framework offered by the one-body Schrödinger equation (2).

The idea is to split the aforementioned interaction potential into two parts, one time-dependent and the other time-independent [146, p. 3]. The time-independent part is obtained by taking the time-average of the interaction potential and it models elastic scattering, whereas the time-dependent part models inelastic scattering. Inelastic scattering can now be accounted for using a first-order perturbation analysis w.r.t. time as it tends to infinity. This gives rise to the appearance of an additive imaginary part of the time-averaged potential (*absorption (optical)*

potential) [146, p. 3], thus formally replacing the real valued function electrostatic potential in (2) with a complex valued one, i.e., $U = U_{\text{re}} + i U_{\text{im}}$ where $U_{\text{re}}: \mathbb{R}^3 \rightarrow \mathbb{R}$ is the electrostatic potential and $U_{\text{im}}: \mathbb{R}^3 \rightarrow \mathbb{R}$ is the aforementioned absorption potential.

Interpretation of the Absorption Potential

The electrostatic potential U_{re} models the phase shift that an electron undergoes as it scatters against the specimen (phase contrast), whereas the absorption potential U_{im} models the decrease in the flux, due to inelastic scattering, of the non-scattered and elastically scattered electrons (see [146, p. 5 and section 1.10] for a definition of the notion of flux in wave mechanics). Hence, the absorption potential accounts for amplitude contrast due to inelastic scattering. A more detailed quantum mechanical interpretation of the absorption potential is provided in [128][146, section 1.8 and chapter 13] [176, section 5.9].

Now, any computational treatment of **TEM** imaging data where phase contrast is important, like **HRTEM** data, has to address the phase problem (section “Phase Retrieval”). In many applications, like for **ET** in life sciences, the specimen is viewed only once from a fixed direction. Resolving the phase problem in such cases requires one to utilize further knowledge about the complex valued potential U . Now, in the context of **TEM** imaging in life sciences, we argue below that U_{re} and U_{im} can be considered approximately proportional. This is enough for resolving the phase problem in the context of **ET**.

Most inelastic scattering events in conventional bright-field **TEM** imaging are either due to plasmon excitation or atomic inner-shell ionization (atom core losses), where the former is considered more dominant. Next, inelastic scattering events are more frequent for scattering against light atoms, they are almost always incoherent and associated with low scattering angles, and their likelihood increases with specimen thickness. To summarize, plasmon excitation from light atoms constitute the main contribution to the inelastic scattering that damps the interpretable phase contrast signal. For **TEM** imaging of amorphous biological specimens, the light atoms mostly make up the background, which for cryo-fixed specimens would be the embedding medium, i.e., the main contribution to inelastic scattering comes from the vitrified aqueous buffer. Now, the imaginary part of the potential associated with plasmon excitation for an amorphous embedding medium, like vitreous ice, is expressible by the inelastic mean free path Λ_{inel} :

$$U_{\text{im}} = \frac{1}{2\sigma\Lambda_{\text{inel}}} \quad \text{where } \sigma := \frac{me}{k\hbar^2}.$$

This forms the basis for a common assumption in **ET**, namely that the real and imaginary parts U_{re} and U_{im} of U in (2) are proportional to the path length of the electron through the specimen. Stated more precisely, there is a function $Q: S^2 \rightarrow \mathbb{R}$ such that

$$\mathcal{P}(U_{\text{im}})(\omega, x) \approx Q(\omega)\mathcal{P}(U_{\text{re}})(\omega, x) \quad \text{for } x \in \omega^\perp \text{ and } \omega \in S^2. \quad (7)$$

Here, \mathcal{P} is the ray transform in (1) and ω is the direction of the incident electron. A common further simplification is to let Q be a constant (amplitude contrast ratio), which then can be estimated from data (section on p. 985).

Remark 4. Assumptions of the type in (7) that relate the real and imaginary parts of U are known as the “Pagnini approach” in X-ray phase contrast tomography community [139].

More Accurate Quantum Mechanical Models

A fundamental difference between modeling inelastic, as opposed to elastic, scattering is that the former requires knowledge of the local scattering and excitation properties of the specimen. The scattering properties of the specimen are no longer fully described by a single real-valued function (the electrostatic potential). In general one would need to specify the elements of the transition matrix that encode the probability that a specimen undergoes a specific transition from one excited state to another. This situation can be somewhat simplified, under certain conditions it is, e.g., possible to express the inelastic cross section without explicit knowledge of these excited states [79, section 68.6]. It is also clear that a computationally feasible approach cannot be based on migrating a wave function that depends on the spatial location of all subatomic particles in the specimen.

A theoretically stringent, yet computationally feasible, framework is based on migrating the mutual coherence function instead of the wave function, the former being the least amount of information needed to describe interference. The scattering properties of the specimen are then modeled by the mixed dynamic form factor that accounts for the interference in Fourier space of different scattered partial electron waves by their mutual coherence [160]. Approaches based on this framework are, e.g., described in [107, 129, 183]. Unfortunately, these approaches are still computationally unfeasible in the setting when the specimen is amorphous and/or thicker than a few atomic layers, thus limiting their usefulness in ET in life sciences.

Importance of Inelastic Scattering

The absorption potential model outlined above is adequate for modeling most conventional bright-field HRTEM imaging problems with amorphous specimens. Combined with (7) and geometric optics approximations (section on p. 954), one gets a computationally feasible model for the electron–specimen interaction in the context of ET.

The validity of this image formation model is less clear for TEM imaging of specimens in material sciences. As an example, the absorption potential approach is not sufficiently accurate when imaging crystalline specimens in diffraction mode and most of [146, chapters 1 and 7–8] is devoted to presenting various models that are more accurate. Another situation that requires more accurate models of inelastic scattering is when specimens are imaged using lower voltages. The motivation is from material sciences where thin crystalline specimens undergo radiation damage when imaged using acceleration voltages beyond 100 kV. For low accelerating voltages (~ 20 kV), most specimens act as strong scatterers. This requires accurate

modeling of inelastic scattering, especially when atoms are light as in biological specimens. In this context, models based on the mutual coherence function are the most promising [107].

Properties of the Scattering Potential

Let \mathcal{X} denote the set of complex valued functions on \mathbb{R}^3 that can serve as a potential $U: \mathbb{R}^3 \rightarrow \mathbb{C}$ in (2). Elements in \mathcal{X} have to possess certain regularity, both from a mathematical and a physics point-of-view. One such regularity property motivated from the physics is that U fulfills the Rollnick condition, which is the case when

$$\mathcal{X} \subset \mathcal{L}^1(\Omega, \mathbb{C}) \cap \mathcal{L}^2(\Omega, \mathbb{C}).$$

The Rollnick condition guarantees that the corresponding Hamiltonian is self-adjoint and one has asymptotic completeness. The latter means that no matter how the wave-packet is made, particles go far apart from each other when time becomes large, so the probability of finding them together in an arbitrary finite region of space goes to zero. This allows one to go from the time-dependent Schrödinger description to the time-independent description characterized by solutions of type (3) [31, p. 133]. See also [195] for the other regularity properties associated with physics.

Next, we claim that $U: \mathbb{R}^3 \rightarrow \mathbb{C}_+$ whenever $U \in \mathcal{X}$. The positivity of the imaginary part follows from the observation that once there is an inelastic scattering event, that partial wave can never be considered as un-scattered or inelastically scattered (for that it would have to gain energy from the specimen). Next, the real part is the electrostatic potential that, at sub-atomic scale, might actually change sign. It is made up of two contributions, one “atomic” given by the superposition of atomic potentials as if each atom was in isolation, and one from the charge redistribution due to the solvent, ions, and molecular interactions. In the context of ET, the isolated atom superposition approximation allows one to account for the latter contributions within the “atomic” contributions. Hence, the specimen can be seen as consisting of isolated neutral atoms, each modeled as a point charge representing the nuclei surrounded by a spherical shell. The sphere represents the screening imposed by the shell electrons, so the electrostatic potential from the electrons cancels the one from the nucleus outside the sphere (the atom is neutral). Since the radius of the sphere is much larger than the radius of the nucleus (which here is a point charge), the electrostatic potential from the nucleus must dominate the electrostatic potential from the shell electrons within the sphere. Hence, the electrostatic potential is non-negative everywhere.

As a final note, one can put further regularity on elements in \mathcal{X} , e.g., $\mathcal{X} \subset \mathcal{S}(\Omega, \mathbb{C})$ (rapidly decreasing) and/or $\mathcal{X} \subset \mathcal{BV}(\Omega, \mathbb{C})$ (bounded variation).

Computationally Feasibility

The Multi-scale Nature of Electron Scattering

Calculating the scattered electron wave, i.e., numerically solving (4a)–(4c), is a multi-scale problem. To see this, we compare the wavelength λ of the electron to the (1) size of the region of interest, (2) the variation of the electrostatic potential, and (3) size of pixels where the intensity is formed. TEM imaging typically operates with energies between 200 and 300 kV resulting in electrons with a wavelength between 0.0025 and 0.0020 nm. In the example below, we consider the case of 200 kV TEM imaging, so $\lambda \approx 0.0025$ nm.

Size of region: When imaging biological specimens, a typical region of interest $\Omega_0 \subset \Omega$ is a rectangular box where the smallest side is the slab thickness, which typically is ≥ 50 nm. For simplicity, let Ω_0 be a cube with a side length of 50 nm $\approx 20,000\lambda$. A straightforward numerical discretization of (4a) would require about ten points per wavelength (in theory, two points per wavelength is enough but with limited precision arithmetic, one needs 10–20 points per wavelength to reliably solve Helmholtz type of wave equations using a finite element method [121]). In this case we would have to sample $(10 \cdot 25,000)^3 \approx 1.6 \cdot 10^{16}$ points. Even in single precision (four bytes per value), this would require 58,200 Tbytes of memory!

Contrast: To compare the variation of the electrostatic potential U against the wavelength λ , we introduce

$$C := \lambda^2 \frac{me}{2\pi^2\hbar^2} \max_{x \in \Omega_0} |U(x)|.$$

For water $U(x) \approx 4.9$ V so $C \approx 1.26 \cdot 10^{-5}$, for proteins $30 \text{ V} \leq U(x) \leq 70 \text{ V}$, so $C \approx 1.8 \cdot 10^{-4}$, and for single colloidal gold particles (typically embedded in biological specimens as fiducial markers) $U(x) \approx 280 \text{ V}$ so $C \approx 7.2 \cdot 10^{-4}$.

Size of pixels: If we image at $65,000\times$ magnification (a rather common setting for imaging subcellular structures in biology), the effective pixels size of a typical TEM detector becomes $0.23 \text{ nm} \approx 115 \lambda$. Hence, the intensity (square norm of the scattered wave that is a solution to (4a)–(4c)) will be averaged over 2D squares with a side length of 115λ .

In summary, the multi-scale nature of numerically solving (4a)–(4c) requires one to consider various approximations.

Geometrical Optics Approximation

Geometrical optics is an approximate treatment of wave propagation where the wavelength is considered to be infinitesimally small (semi-classical approximation). The idea is to represent the highly oscillating solution as a product of a slowly varying amplitude function and an exponential function of a slowly varying phase multiplied by a large parameter.

The starting point is the Wentzel–Kramers–Brillouin (WKB) approximation for the stationary Schrödinger equation (4a). For a first order approximation, this method seeks an asymptotic solution of the form

$$\psi(\mathbf{x}) = a(\mathbf{x}) \exp(iS(\mathbf{x})/\hbar) + O(\hbar) \quad (8)$$

where the amplitude a and the phase S are smooth real-valued functions independent of \hbar . Substituting (8) into the stationary Schrödinger equation (4a), equating the real and imaginary parts, canceling the common phase factor $\exp(iS(\mathbf{x}, t)/\hbar)$ that appears throughout, and ignoring \hbar^2 -order terms (first order WKB approximation) give us

$$|\nabla S(\mathbf{x}) + e\mathbf{A}(\mathbf{x})|^2 = 2meU(\mathbf{x}) + 2mE \quad (9)$$

$$\operatorname{div} \left[a(\cdot)^2 (\nabla S(\cdot) + e\mathbf{A}(\cdot)) \right](\mathbf{x}) = 0. \quad (10)$$

Thus, within the first order WKB approximation, (4a) is solved by (8) in which the phase function S solves (9) (an eikonal equation of Hamilton–Jacobi type), and the amplitude term a solves (10) (transport equation).

The eikonal equation (9) can be solved by the ray tracing method [147], which in turn is based on the method of characteristics. In brief, one introduces a family of curves (rays) $s \mapsto \gamma(s)$ which are perpendicular to the level curves (wavefronts) of S . These rays define a new coordinate system where the eikonal equation reduces to a far simpler, linear, ordinary differential equation. This ordinary differential equation for the phase S can be solved simply by integrating along the aforementioned ray, leading to

$$S(\gamma(t)) = S(\gamma(0)) + \int_0^t H(\gamma(s)) - e\dot{\gamma}(s) \cdot \mathbf{A}(\gamma(s)) \, ds. \quad (11)$$

In the above, $H: \mathbb{R}^3 \rightarrow \mathbb{R}$ is given by $H(\mathbf{x}) := \sqrt{2meU(\mathbf{x}) + 2mE}$ and the ray γ is given by the Lorentz equation:

$$\frac{d}{ds} \left(H(\gamma(s)) \dot{\gamma}(s) \right) = \nabla H(\gamma(s)) + e\mathbf{B}(\gamma(s)) \times \dot{\gamma}(s) \quad (12)$$

where $\mathbf{B} = \operatorname{curl} \mathbf{A}$ is the magnetic field [79, eq.(57.11)]. Finally, combining (11) with (8) and (6) gives us

$$\mathcal{T}_\omega^{\text{sc}}(U)(x) \approx \psi_0(x) \exp\left(\frac{i}{\hbar} \int_0^t H(\gamma(s)) - \sqrt{2mE} ds\right) \quad (13)$$

with ψ_0 denoting the incident un-scattered electron wave.

Validity of the WKB Approximation

In our specific setting, the first order WKB approximation is valid if

$$\left| \frac{\Delta a(x)}{a(x)} \right| \ll \frac{1}{\lambda^2}. \quad (14)$$

For TEM imaging, the above is valid for electron motion in macroscopic fields, far from their singularities. The situation for scattering in microscopic fields is less obvious. One issue is that the eikonal equation (9) can become singular (caustic formation) at points where rays intersect and the amplitude blows up. There could also be several ray trajectories joining the two points, even though this particular issue can be handled within the semiclassical limit, see, e.g., [89, theorem 1.2].

Remark 5. The expression in (13) only makes use of the first order WKB approximation. The correct semiclassical limit to (4a) contains several phases, so the asymptotic solution is a sum of functions of the form (8).

Remark 6. Gaussian beams is another high frequency asymptotic model that is closely related to geometrical optics. Here the phase is complex-valued, so there is no breakdown at caustics. The solution is still assumed to be of the form (8), but it is concentrated near a single ray of geometrical optics, see [113, 167] for further details. See also [142] for a closely related approach.

The Small Angle, Projection, and Weak Phase Object Approximations

The following approximations all aim to further simplify (13). These approximations apply in particular to TEM imaging of weakly scattering specimens, such as unstained biological specimens.

The Small Angle Approximation

If $|eU(x)| \ll E$, which typically holds for TEM imaging in life sciences, then

$$\frac{1}{\hbar} H(x) - \sqrt{2mE} = \frac{1}{\hbar} \sqrt{2meU(x) + 2mE} - \sqrt{2mE} \approx \frac{m}{\hbar^2 k^2} eU(x).$$

Hence, introducing $\sigma := me/k\hbar^2$, (13) becomes

$$\mathcal{T}_\omega^{\text{sc}}(U)(x) \approx \psi_0(x) \exp\left(i\sigma \int_0^t U(\gamma(s)) ds\right) \quad \text{for } x = \gamma(t) \in \Gamma_{\text{out}}. \quad (15)$$

This approximation is usually referred to as the *small angle approximation*.

The Projection Approximation

Assume Ω is thin enough that we can disregard the curvature of the electron trajectories, i.e., the un-scattered electrons travel along straight lines parallel to the direction ω of the incident plane wave ψ_0 . Assuming $\mathbf{x} + t\omega \in \Gamma_{\text{out}}$, the above considerations combined with (15) result in

$$\mathcal{T}_{\omega}^{\text{sc}}(U)(\mathbf{x} + t\omega) \approx \psi_0(\mathbf{x} + t\omega) \exp\left(i\sigma \int_0^t U(\mathbf{x} + s\omega) ds\right) \quad \text{for } \mathbf{x} \in \Gamma_{\text{in}}. \quad (16)$$

Furthermore, one frequently replaces $\psi_0(\mathbf{x} + t\omega)$ with $\psi_0(\mathbf{x})$, which is perfectly fine when ψ_0 is a plane wave traveling along ω (the difference is then merely a constant pure phase factor). This is the *projection assumption* [78].

Weak Phase Object Approximation

The *weak phase object approximation* is simply based on linearizing the exponential in (16), i.e.,

$$\mathcal{T}_{\omega}^{\text{sc}}(U)(\mathbf{x} + t\omega) \approx \psi_0(\mathbf{x} + t\omega) \left(1 + i\sigma \int_0^t U(\mathbf{x} + s\omega) ds\right) \quad \text{for } \mathbf{x} \in \Gamma_{\text{in}}. \quad (17)$$

Other Approaches

A variety of approaches have been developed for simulating electron scattering in a **TEM**. Most of them, like the Bloch wave method, are only of interest for modeling **TEM** imaging in diffraction mode which is important in electron crystallography and in some material sciences applications. There are however approaches that are also applicable for computational treatment of conventional bright-field **TEM** imaging of amorphous specimens.

First Order Born Approximation

The starting point is to reformulate (4a) as an integral equation (Lippmann–Schwinger equation). The latter can be solved by means of an iterative procedure, and the first step in that procedure yields the first order Born approximation. This results in an affine model for $\mathcal{T}_{\omega}^{\text{sc}}$, the details are given in [51, section 4.3]. Related approximations of $\mathcal{T}_{\omega}^{\text{sc}}$ are the paraboloid approximation [90] and the thick-phase grating approximation [189].

Multi-Slice Method

Here one assumes that $\psi(\mathbf{x}) = \phi(\mathbf{x}) \exp(i k \mathbf{x} \cdot \omega)$ where ϕ is the slowly varying part whose sampling in real space may be spaced many wavelengths apart. Inserting into (4a) and making use of the Lippmann–Schwinger formulation result in an equation for the slowly varying part ϕ . The differential operators in this equation can now be separated into operators along ω and operators acting in ω^\perp . Ignoring back-scattering yields a recursive scheme for calculating $\mathcal{T}_{\omega}^{\text{sc}}$ on Γ_{out} , see [146, section 3.4].

Distorted Wave Born Approximation

The idea here is to express the potential as a sum of two terms, $U = U_0 + \Delta U$ where U_0 is not necessarily small and ΔU is sufficiently small that only linear terms in the expression for the scattered electron wave need to be retained. This expression for U is inserted into the Lippmann–Schwinger formulation of (4a), thereby giving rise to a series expansion [146, eq. (7.8)] where one can collect terms in ΔU and U_0 . Retaining a first order correction for U_0 results in the approximate description of the scattered electron wave, see [146, section 7.2] for details.

Optics

After interacting with the specimen, electrons pass through the **TEM** optics as they migrate from the specimen exit plane Γ_{out} to the image plane Γ_{imag} (note that the former is not necessarily orthogonal to the optical axis whereas the latter always is). An obvious role of the optics is to magnify the image. Another equally important, but more subtle, role is related to phase contrast. The optics is necessary to make phase contrast visible, which is important for **HRTEM** imaging. Phase contrast would be lost if one would measure intensity data directly on Γ_{out} .

Remark 7. There are situations when one can, at least approximately, reconstruct the electron wave function from measured image intensity. Some of these techniques involve unconventional imaging modes, of which the most successful is off-axis holography using an electron biprism, see [79, section 63.2].

Thus, *any forward model that seeks to account for phase contrast must model the **TEM** optics*. This is especially important for imaging weakly scattering specimens, like unstained thin biological specimens.

Here we only state the model for the **TEM** optics and refer to [51, section 5] for its derivation. See also [80, 161, 162] and [79, sections 64–66] for a thorough description of models for various electron optical elements.

The General Setting

The optics of the **TEM** is the portion between the specimen exit plane Γ_{out} and the image plane Γ_{imag} (Fig. 2). Here there is no specimen, but there are strong magnetic fields that can deflect the electron beam in a desirable manner. Disregarding polarization and the precession imposed by the electron spin (which does not appreciably affect the motion of the electron), the **TEM** optics is fully characterized by a specification of apertures and the magnetic vector potential that corresponds to the aforementioned magnetic fields.

We define the *optics operator* as the mapping that associates an electron wave in Γ_{out} to the corresponding wave in Γ_{imag} . In the general setting, it is the solution to (4a) with $U \equiv 0$ (no specimen) and appropriate boundary conditions:

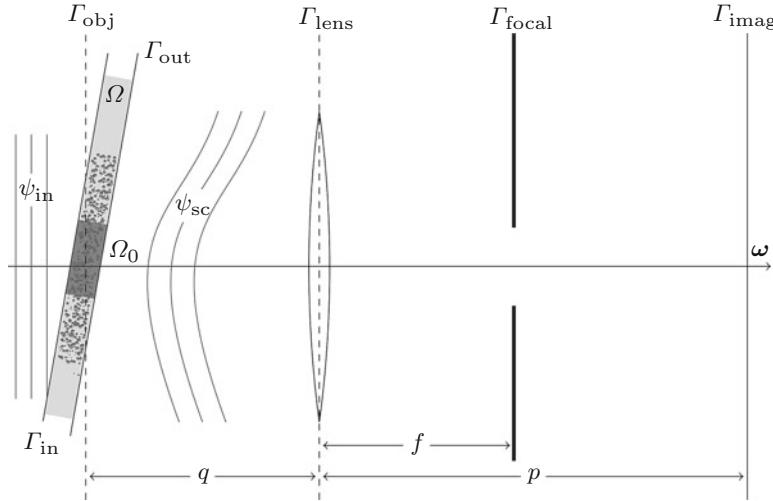

Fig. 2 The optical set-up (Ω and Ω_0 are in reality much smaller) for a single thin lens with an aperture in the focal plane (section on p. 960). The case for lens-less imaging (section on p. 960) is obtained by removing the lens and its aperture. The incident electron wave ψ_{in} (plane wave from left traveling along the optical axis ω) scatters against the atoms in the specimen characterized by $U: \Omega \rightarrow \mathbb{C}$ (scattering potential) with support in a slab Ω (*light-gray region*). The subset $\Omega_0 \subset \Omega$ (*dark-gray region*) is the region of interest. The operator $\mathcal{T}_{\omega}^{\text{sc}}(U)$ in (6) maps ψ_{in} on Γ_{in} to ψ_{sc} on Γ_{out} . The operator \mathcal{T}^{op} in (19) maps an electron wave on the object plane Γ_{obj} onto an electron wave on the image plane Γ_{imag} . Finally, $\mathcal{T}^{\text{tiltcorr}}$ defined on paragraph on p. 961 maps the electron wave on the specimen exit plane Γ_{out} onto the wave on the object plane Γ_{obj} .

$$\begin{cases} E\psi = \frac{1}{2m} \left[-i\hbar \nabla + e\mathbf{A} \right]^2 \psi & \text{on } \mathbb{R}^3 \setminus \Omega, \\ \psi = \psi_{\text{sp}} & \text{on } \Gamma_{\text{out}}, \\ \psi \text{ fulfills (4c).} \end{cases} \quad (18)$$

Since $\Gamma_{\text{imag}} := \omega^\perp + p\omega$, the optics operator is given as

$$\mathcal{T}^{\text{op}}(\psi_{\text{sp}})(x) = \psi(x + p\omega) \quad \text{for } x \in \omega^\perp \text{ and } \psi \text{ solves (18).} \quad (19)$$

The magnetic vector potential \mathbf{A} in (18) is given by the magnetic fields generated by the optical system and the electron wave ψ_{sp} on Γ_{out} is the scattered electron wave leaving the specimen.

Ray Optics

Many electron optical elements, including electron lenses, are modeled by considering geometric optics approximation of (18) where the electron is a point-like charged mass whose motion is governed by the laws of classical mechanics [162,

chapter 1] and [79, p. 1262]. The relation between the wave mechanical and classical formulations can in fact be seen directly from (12). This shows that the eikonal curve derived within the WKB approximation coincides with the classical electron trajectory, so the fundamental laws of geometrical electron optics are an approximate consequence of wave mechanics based on the first order WKB approximation. *In conclusion, electron lenses and their aberrations are adequately modeled using geometrical charged-particle optics. Modeling diffraction by an aperture (which is an opaque screen with a suitable opening) needs however to be based on wave mechanics.*

Remark 8. A theory of electron optics that does not make use of geometric optics approximation becomes quite complicated, see, e.g., [79, sections 59.4–59.6] [111]. Furthermore, there are many other elements of the TEM that we do not model, notably alignment coils, stigmators, and phase plates. Stigmators are used to correct for the unavoidable third-order (and possibly higher) spherical aberration of the objective lens [80, chapter 41].

The Optical Set-Up

The most important component of the optics is the *objective lens*, which provides the first stage of magnification (about 20–50 times). It is followed by a number of *projector lenses* that provide further magnification. Apertures are present at several places, e.g., in the back-focal plane of the objective lens (Fig. 1).

To model phase contrast imaging in ET, it turns out that one *can model the entire TEM optical system as a single thin lens with an aperture in its focal plane as illustrated in Fig. 2* (see Remark 9 for an motivation). Within this setting, except for the specimen exit plane Γ_{out} , all the other planes are parallel to each other and orthogonal to the optical axis, i.e., orthogonal to ω . Since the magnification of the single thin lens corresponds to the magnification M of the *entire* optical system (objective and projector lenses taken together), we get

$$M = p/q \quad \text{and} \quad 1/f = 1/p + 1/q. \quad (20)$$

Here, f is the focal length of the lens, and $q, p > 0$ are the distances from the lens to the objective and images planes Γ_{obj} and Γ_{imag} , respectively. This set-up does not correspond to a physical optical system, so one needs to set values for f , p , and q (section “Illumination and Optics Parameters”).

Remark 9. The nontrivial part in replacing the TEM optical system with a the system in Fig. 2 is to argue that the thin lens in Fig. 2 has the same aberration properties as the objective lens. The motivation for this is as follows: Due to the initial magnification by the objective lens, the angular range of electron beams impinging upon the first image plane is very small relative to the angular range of electron beams entering the object lens from the specimen. Since aberrations are worse at high angles than at low angles, the lens that is most affected by aberrations will be the objective lens as it has to deal with largest range of angles in the whole

microscope. The lenses below the objective lens (projector lenses) also magnify, and as the magnification increases, the range of angles that each subsequent lens must deal with is reduced. The first lens of the projector system (sometimes called the “intermediate” or “diffraction” lens) matters a little bit, but one can forget about all the other lenses. Even though they provide a huge amount of magnification, they have virtually no influence on the final image resolution.

Lens-Less Imaging

This is the simplest model where the optics is replaced by free space propagation corresponding to the distance between the parallel object and image planes. Thus, one ignores any magnetic fields (so $A \equiv \mathbf{0}$, see text preceding (5)), apertures, and the effect of specimen tilt (see paragraph on p. 961). Despite its simplicity, this model is much better than simply assuming the intensity is taken directly at the specimen exit plane. The reason is that free-space propagation gives time for the phase shift induced by the specimen to develop into visible contrast, thereby partly addressing the phase problem.

Stated mathematically, free-space propagation is given as the solution to (18) with $A \equiv \mathbf{0}$ and Γ_{out} replaced by Γ_{obj} . The resulting equation can be solved under the Fresnel approximation and the solution is expressible in terms of a 2D convolution in the object plane:

$$\mathcal{T}^{\text{op}}(\psi_{\text{sp}})(x) \approx \exp(i k(p - q)) \mathcal{T}_{p-q}^{\text{fsp}}(\psi_{\text{sp}}(q\omega + \cdot))(x) \quad \text{for } x \in \omega^\perp, \quad (21)$$

where, for $d > 0$,

$$\left\{ \begin{array}{l} \mathcal{T}_d^{\text{fsp}}(\phi)(x) := \frac{k}{2\pi i d} \left\{ \text{PSF}_d^{\text{fsp}} \circledast_{\omega^\perp} \phi \right\}(x) \\ \text{PSF}_d^{\text{fsp}}(x) := \exp\left(i \frac{k}{2d} |x|^2\right). \end{array} \right. \quad (22a)$$

$$\left\{ \begin{array}{l} \mathcal{T}_d^{\text{fsp}}(\phi)(x) := \frac{k}{2\pi i d} \left\{ \text{PSF}_d^{\text{fsp}} \circledast_{\omega^\perp} \phi \right\}(x) \\ \text{PSF}_d^{\text{fsp}}(x) := \exp\left(i \frac{k}{2d} |x|^2\right). \end{array} \right. \quad (22b)$$

Single Thin Lens with an Aperture

Here we consider the setup in Fig. 2. The optics operator can then be modeled by a suitable combination of free-space propagation (22a), a model for a thin lens, and a model for diffraction by an aperture.

For simplicity let us disregard the correction for the specimen tilt (section “Model Refinements”). After some lengthy manipulation, shown in [51], one arrives at the following explicit expression for the optics operator:

$$\mathcal{T}^{\text{op}}(\psi_{\text{sp}})(x) \approx \frac{\Phi(x)}{(2\pi)^2 M} \left\{ \text{PSF}^{\text{op}} \circledast_{\omega^\perp} \psi_{\text{sp}}(q\omega + \cdot) \right\} \left(\frac{x}{M} \right) \quad \text{for } x \in \omega^\perp. \quad (23)$$

Here, $M = (p - f)/f$ denotes the magnification, Φ is a pure phase factor (so $|\Phi(x)| = 1$) whose precise expression is given in [51, eq. (21)], and

$$\text{PSF}^{\text{op}}(\mathbf{x}) := \mathcal{F}_{\omega^\perp} \left[A_\Sigma \left(\frac{f}{k} \cdot + f\omega \right) \exp \left(i W(|\cdot|^2) \right) \right] (\mathbf{x}) \quad \text{for } \mathbf{x} \in \omega^\perp. \quad (24)$$

The Fourier transform of PSF^{op} , which by above has a closed form expression, is usually called the Contrast Transfer Function (CTF). The function $A_\Sigma: \omega^\perp \rightarrow \mathbb{R}$ is the characteristic function for the aperture $\Sigma \subset \Gamma_{\text{focal}}$ (pupil function) and $W: S^2 \times \mathbb{R} \rightarrow \mathbb{R}$ encodes the phase shift associated with imperfections on the optics (e.g., defocus, aberrations). The latter has an explicit expression [79, eq. (65.29)], which in the context of ET can be significantly simplified since terms accounting for astigmatism and higher order aberrations can be ignored [79, eq. (65.30)]:

$$W(t) := -\frac{1}{4k} t \left(\frac{C_s}{k^2} t - 2\Delta z \right) \quad \text{for } t \in \mathbb{R}. \quad (25)$$

The constant C_s is the *third-order spherical aberration of the lens* and Δz is the *defocus* (the deviation from the focal length and error in the positioning of the specimen plane).

Remark 10. The convolution with the optics PSF in (24) is actually taken against $\psi(-q\omega - \cdot)$. The minus sign in the argument of ψ comes from the fact that a single thin lens reverses the image. The actual optics consists of several lenses and microscope manufacturers do compensate for such effects, so we may disregard these minus signs.

Model Refinements

Specimen Tilt

When the specimen is tilted, i.e., when the slab Ω is not orthogonal to the optical axis, then one needs to migrate the electron wave from the specimen exit plane Γ_{out} to the object plane Γ_{obj} . We define $\mathcal{T}^{\text{tiltcorr}}$ as the operator that maps an electron wave on the specimen exit plane to the corresponding electron wave on Γ_{obj} . Since Γ_{out} and Γ_{obj} are not parallel, this amounts to a free-space propagation between two non-parallel planes.

Free-space propagation between non-parallel planes has been worked out for electromagnetic waves in [6, 125], but the methods are also applicable to TEM imaging. Approaches in TEM imaging are based on modifying the point spread function for the lens operator (“tilted CTF”), see, e.g., [78, section 3.3] and [184, 185].

Partially Incoherent Illumination

For perfect coherent illumination, the incident electron beam should have no energy spread (perfect temporal coherence) and electrons are emitted from a vanishingly small source (perfect spatial coherence). In practice, energy spread may reach a

few eV depending on the type of electron source and the finite source size spreads the directions of arrival of the incident electrons at the specimen input plane Γ_{in} .

The standard approach for accounting these effects is to represent each of them by a damping in the Fourier space of the optics **PSF**. The details are given [79, sections 66.2–66.3], below we simply state the resulting modified optics **PSF** that replaces the one in (24):

$$\text{PSF}^{\text{op}}(\mathbf{x}) := \mathcal{F}_{\omega^\perp} \left[A_\Sigma \left(\frac{f}{k} \cdot + f\omega \right) \exp \left(i W(|\cdot|^2) \right) E_{\text{spr}}(|\cdot|^2) E_{\text{size}}(|\cdot|^2) \right] (\mathbf{x}).$$

The functions E_{spr} and E_{size} are the envelope functions that accounts for the energy spread and the extension of the source, respectively:

$$\begin{aligned} E_{\text{spr}}(t) &:= \exp \left(- \frac{\pi^2}{4f^4} v_m^2 C_c'^2 t^2 \right) \\ E_{\text{size}}(t) &:= \exp \left(- \frac{1}{4} \frac{k^2}{f^2} \alpha_c^2 t \left(\frac{C_s}{f^2} t - \Delta z \right)^2 \right). \end{aligned}$$

In the above, v_m denotes the mean energy spread,

$$C'_c := \frac{1 + 2\epsilon U_{\text{acc}}}{U_{\text{acc}}(1 + \epsilon U_{\text{acc}})} C_c \quad \text{where } \epsilon := \frac{e}{2mc^2}$$

with U_{acc} denoting the acceleration voltage of the source, C_c is the chromatic aberration of the objective lens, and α_c is the aperture angle of the beam furnished by the condenser.

Detection

Intensity Generated by a Single Electron

As the electron wave ψ reaches the image plane $\Gamma_{\text{imag}} = \omega^\perp + p\omega$ (Fig. 2), it forms an intensity distribution, a process that is encoded by the *intensity operator*:

$$\mathcal{I}(\psi)(\mathbf{x}) := |\psi(\mathbf{x} + p\omega)|^2 \quad \text{for } \mathbf{x} \in \omega^\perp. \quad (26)$$

If the scattered part is a small perturbation $\Delta\psi$ to the incident wave ψ_0 , then it is natural to *linearize the intensity*:

$$\begin{aligned} \mathcal{I}(\psi_0 + \Delta\psi)(\mathbf{x}) &\approx |\psi_0(\mathbf{x} + p\omega)|^2 + \psi_0(\mathbf{x} + p\omega) \overline{\Delta\psi(\mathbf{x} + p\omega)} \\ &\quad + \overline{\psi_0(\mathbf{x} + p\omega)} \Delta\psi(\mathbf{x} + p\omega). \end{aligned} \quad (27)$$

The Total Intensity and Its Detector Response

The micrograph is given by the intensity generated from *all* electrons reaching the image plane. In an ideal detection system, this would model the image in the micrograph, but all detection systems introduce noise and distortions which we now model.

First, one can treat each electron independently (independent electron assumption, see Sect. 4). Next, the models for the distribution of intensity and detector response are identical for each electron. Hence, in the absence of stochasticity, the micrograph is simply given by the detector response distribution for a single electron scaled by a factor corresponding to the number of electrons.

Detectors Types

Charged Coupled Device ([CCD](#)) cameras, or more precisely detectors based on slow-scan [CCD](#) sensors, have become the detection technique of choice in [ET](#), so here we consider the modeling of such detectors.

Detection of electrons by a slow-scan [CCD](#) sensor can be divided into three separate stages [197]: (1) the conversion of incident electrons into photons in the scintillator (material that converts high-energy radiation like X-rays/electrons into visible light), (2) transport of photons from the scintillator to the [CCD](#) array (via fiber-optic or lens coupling), and (3) conversion of photons into electrons and the readout of the resulting digital signal. Each of these steps can be modeled at different levels of accuracy. The model outlined below is accurate enough for most computational treatments of micrographs.

Remark 11. It may seem strange to first convert an incident electron to photons, which are then converted back to an electric signal (electrons). The problem with using incident electrons directly to generate electron–hole pairs at the [CCD](#) is that they are too energetic, so they saturate the [CCD](#), see, e.g., [146, p. 389]. In this context, it is worth mentioning the new generation detectors that directly detect the electron without an intermediate conversion to photons, and therefore posses significantly better sensitivity and noise properties [55].

Detector Response Distribution for a Single Electron

Consider a slow-scan [CCD](#) sensor placed at the image plane Γ_{imag} , so the scintillator entrance surface of the detector is Γ_{imag} . The *single electron intensity distribution*, which is the intensity distribution generated by a *single* electron at the scintillator entrance surface, is now given by

$$I(x) := \mathcal{I}(\psi)(x) \quad \text{for } x \in \omega^\perp. \tag{28}$$

The corresponding detector response distribution at the plane adjacent to the [CCD](#), which models for the detector response per unit area (given as ADU per unit area) to a single electron in the absence of stochasticity, can then be modeled as [146, p. 391]

$$\mathbf{x} \mapsto C_{\text{gain}}(\mathbf{x}) \{ I \circledast_{\omega^\perp} \text{PSF}^{\text{det}} \}(\mathbf{x}) + I_b(\mathbf{x}) \quad \text{for } \mathbf{x} \in \omega^\perp. \quad (29)$$

Here, C_{gain} is the *overall gain* that measures the average number of digital counts that a single incident electron gives rise to, I_b is the distribution of the background signal, and PSF^{det} is the detector response function that models the spreading of the signal generated by a single incident electron within the scintillator and fiber-optic/lens coupling. All these components can be determined from specifications of the detector and/or estimated from specific calibration measurements (section on p. 982).

Total Detector Response Distribution

Let N_0 denote the *image dose*, which is defined as the average number of incident electrons per unit area at Γ_{imag} used when the micrograph is acquired. Then, (29) combined with the independent electron assumption allows us to model the total detector response distribution in the absence of stochasticity as

$$C(\mathbf{x}) := N_0 C_{\text{gain}}(\mathbf{x}) \{ I \circledast_{\omega^\perp} \text{PSF}^{\text{det}} \}(\mathbf{x}) + N_0 I_b(\mathbf{x}) \quad \text{for } \mathbf{x} \in \omega^\perp. \quad (30)$$

Characteristics of the Noise

To model the detector response for a pixel in the micrograph, we need to integrate the total detector response distribution in (30) over the pixel and model the stochasticity.

Shot Noise

The emission of electrons at the source (section “Illumination”) is a stochastic process. This gives rise to *shot noise* whose influence is most severe in low-dose micrographs, such as in ET when one records multiple micrographs of biological cryo-specimens.

Shot noise is not Gaussian but depends on the signal level. It originates from the fact that emission of electrons is a Poisson process, so the actual image dose is a Poisson distributed random variable with mean equal to the nominal image dose N_0 . To model shot noise, consider first the single electron intensity distribution I in (28). Each point $\mathbf{x} \in \omega^\perp$ gives rise to an intensity distribution at the plane adjacent to the CCD:

$$\mathbf{y} \mapsto C_{\text{gain}}(\mathbf{x}) I(\mathbf{x}) \text{PSF}^{\text{det}}(\mathbf{x} - \mathbf{y}) + I_b(\mathbf{x}) \quad \text{for } \mathbf{y} \in \omega^\perp.$$

Now, consider a micrograph acquired using a image dose of N_0 and let $\mathbf{C}(\Delta)$ denote the corresponding detector response from a (measurable) set $\Delta \subset \omega^\perp$. Due to the Poisson stochasticity of the total dose, it is given by

$$\mathbf{C}(\Delta) = \int_{\Delta} \int_{\omega^\perp} C_{\text{gain}}(\mathbf{x}) I(\mathbf{x}) \text{PSF}^{\text{det}}(\mathbf{x} - \mathbf{y}) + I_b(\mathbf{x}) dN(\mathbf{x}) d\mathbf{y}, \quad (31)$$

where \mathbf{N} is a Poisson random measure (see [34, chapter VI]) with mean given by $N_0 \, d\mathbf{x}$, i.e.,

$$\mathbf{N}(\Delta) \sim \text{Poisson} \left[N_0 \int_{\Delta} 1 \, d\mathbf{x} \right]. \quad (32)$$

Remark 12. The expression in (31) models the noise in a continuum setting. The reason for insisting on a continuum model is that there is no natural pixelization of the image plane (scintillator entrance plane), which is where the Poisson stochasticity is realized since the electrons generate intensities in that plane. Similar models for Poisson distributed data when data sampling is in continuum are given in [83, 84].

Pixelization and Read-Out Noise

Besides the shot noise, there is additive and multiplicative noise. Both are related to a [CCD](#) pixel, so we next consider the pixelization in the [CCD](#).

A pixelization in the [CCD](#) corresponds to a finite tessellation $\{\Delta_j\}_j$ of the bounded subregion of ω^\perp that constitutes the [CCD](#) detector. The subsets Δ_j represent pixels and are typically given as square regions centered around some suitably chosen point \mathbf{x}_j (often the midpoint). Disregarding multiplicative stochasticity, measured data from a single pixel can be modeled as a sample of the stochastic variable

$$\mathbf{C}^{\text{data}}(j) := \mathbf{C}(\Delta_j) + \mathbf{E}(j) \quad \text{for } j = 1, \dots, n_{\text{det}}. \quad (33)$$

In the above, \mathbf{C} is given by (31) and $\mathbf{E}(j) \sim \text{Normal}(\mu_j, \sigma_j)$ is a Gaussian random variable with mean μ_j and variance σ_j that models additive read-out noise, and n_{det} is the total number of pixels. The corresponding stochastic model for a micrograph is the stochastic n_{det} -vector

$$\mathbf{C}^{\text{data}} := (\mathbf{C}^{\text{data}}(1), \dots, \mathbf{C}^{\text{data}}(n_{\text{det}})). \quad (34)$$

Probability Distribution of Image Data

It is quite difficult to derive a closed form expression for the probability distribution of \mathbf{C}^{data} whose samples represent micrographs. One can however derive closed-form expressions for the expected value and covariance:

$$\begin{aligned} \mathbf{E} [\mathbf{C}^{\text{data}}(j)] &= N_0 \int_{\Delta_j} \left[C_{\text{gain}}(\mathbf{x}) \{ I \underset{\omega^\perp}{\otimes} \text{PSF}^{\text{det}} \}(\mathbf{x}) + N_0 I_b(\mathbf{x}) \right] d\mathbf{x} + \mu_j \\ \mathbf{Cov} [\mathbf{C}^{\text{data}}(j), \mathbf{C}^{\text{data}}(l)] &= N_0 \int_{\Delta_j} \int_{\Delta_l} \int_{\omega^\perp} \left[C_{\text{gain}}(\mathbf{x}) C_{\text{gain}}(\mathbf{y}) \right. \\ &\quad \left. \text{PSF}^{\text{det}}(\mathbf{x} - \mathbf{y}) \text{PSF}^{\text{det}}(\mathbf{z} - \mathbf{y}) I(\mathbf{y}) \right] d\mathbf{y} d\mathbf{z} d\mathbf{x} + \mathbf{Cov} [\mathbf{E}(j), \mathbf{E}(l)]. \end{aligned} \quad (35)$$

The Measured Image Data

The *detector operator* \mathcal{T}^{\det} maps a single electron intensity distribution to the expected detector response distribution, so it is defined through the relation

$$\mathbf{E} \left[\mathbf{C}^{\text{data}}(j) \right] = \int_{\Delta_j} \mathcal{T}^{\det}(I)(\mathbf{x}) d\mathbf{x} + \mu_j \quad (36)$$

where I is the aforementioned single electron intensity distribution. From (35) we get

$$\mathcal{T}^{\det}(I)(\mathbf{x}) = N_0 C_{\text{gain}}(\mathbf{x}) \left\{ I \circledast_{\omega^\perp} \text{PSF}^{\det} \right\}(\mathbf{x}) + N_0 I_b(\mathbf{x}) \quad \text{for } \mathbf{x} \in \omega^\perp, \quad (37)$$

so, $\mathcal{T}^{\det}(I)$ equals (30), the total detector response distribution in the absence of stochasticity.

A common approximation is to replace the integration over Δ_j in (36) with a point-evaluation at a suitable point:

$$\mathbf{E} \left[\mathbf{C}^{\text{data}}(j) \right] \approx |\Delta_j| \left\{ \mathcal{T}^{\det}(I) \circledast_{\omega^\perp} \text{PSF}_j^{\text{pix}} \right\}(\mathbf{x}_j) + \mu_j. \quad (38)$$

Here, $|\Delta_j|$ is the pixel area, $\mathbf{x}_j \in \Delta_j$ is some suitable evaluation point (typically the mid-point), and $\text{PSF}_j^{\text{pix}}$ is the associated pixel-shape function.

Remark 13. Further simplification of (38) is obtained when one considers measured data that has undergone basic pre-processing (section “Basic Pre-processing”). Then C_{gain} is constant and expected background signal μ_j can be estimated and deducted from data, so we may set $\mu_j = 0$. It is also common to consider the simplest pixel-shape function $\text{PSF}_j^{\text{pix}} = \delta_{\mathbf{x}_j}$. With these simplifications in place, the measured data associated with pixel j is modeled as

$$\mathbf{E} \left[\mathbf{C}^{\text{data}}(j) \right] \approx |\Delta_j| N_0 C_{\text{gain}} \left\{ I \circledast_{\omega^\perp} \text{PSF}^{\det} \right\}(\mathbf{x}_j). \quad (39)$$

Forward Operator for Combined Phase and Amplitude Contrast

The forward operator is defined as $\mathcal{T}: \mathcal{X} \rightarrow \mathcal{H}$, where \mathcal{X} is a vector space of functions $U: \Omega \rightarrow \mathbb{C}_+$ that represents a scattering potential (section on p. 952) and \mathcal{H} is a vector space of functions $\mathbf{x} \mapsto g(\omega, \mathbf{x}) \in \mathbb{R}_+$ for $\mathbf{x} \in \omega^\perp$. Here, the function $g(\omega, \cdot)$ represents the expected detector response distribution at the plane adjacent to the **CCD** (just prior to sampling and read-out) when the **TEM** image is acquired using incident electrons traveling along $\omega \in S^2$.

In order to derive an expression for the forward operator, we first observe that by (6), (19), and (26), the single electron intensity distribution is given as

$$I(U)(\omega, \mathbf{x}) = \mathcal{I} \circ \mathcal{T}^{\text{op}} \circ \mathcal{T}_{\omega}^{\text{sc}}(U)(\mathbf{x}) \quad \mathbf{x} \in \omega^{\perp}. \quad (40)$$

The forward operator corresponds to the expected detector response distribution, so by (36)–(37) we get

$$\begin{aligned} \mathcal{T}(U)(\omega, \mathbf{x}) &:= \mathcal{T}^{\text{det}}(I(U)(\omega, \cdot))(\mathbf{x}) \\ &\approx N_0(\omega) C_{\text{gain}} \left\{ I(U)(\omega, \cdot) \underset{\omega^{\perp}}{\otimes} \text{PSF}^{\text{det}} \right\}(\mathbf{x}) \quad \text{for } \mathbf{x} \in \omega^{\perp}. \end{aligned} \quad (41)$$

Here, $N_0(\omega)$ denotes the image dose used to acquire the micrograph, I is the corresponding single electron intensity distribution given by (40), and the last approximate equality follows from setting $I_b \equiv 0$ (Remark 13).

To get a more explicit expression for \mathcal{T} , we now consider various approximations of the single electron intensity distribution $I(U)$:

Lens-less imaging: This is the setting considered in section on p. 960 that results in the model (21) for \mathcal{T}^{op} , so (40) becomes

$$I(U)(\omega, \mathbf{x}) \approx \frac{k^2}{(2\pi)^4(p-q)^2} \left| \left\{ \text{PSF}_{p-q}^{\text{fsp}} \underset{\omega^{\perp}}{\otimes} \mathcal{T}_{\omega}^{\text{sc}}(U)(q\omega + \cdot) \right\}(\mathbf{x}) \right|^2 \quad (42)$$

where $\text{PSF}_{p-q}^{\text{fsp}}$ is given by (22b).

Single thin lens with an aperture: This is the setting considered in section on p. 960 that results in the model (23) for \mathcal{T}^{op} , so (40) becomes

$$I(U)(\omega, \mathbf{x}) \approx \frac{1}{(2\pi)^4 M^2} \left| \left\{ \text{PSF}_{\omega^{\perp}}^{\text{op}} \underset{\omega^{\perp}}{\otimes} \mathcal{T}_{\omega}^{\text{sc}}(U)(q\omega + \cdot) \right\} \left(\frac{\mathbf{x}}{M} \right) \right|^2. \quad (43)$$

where PSF^{op} is given by (24).

We conclude by providing the most common closed form expressions for \mathcal{T} relevant for combined phase and amplitude contrast modeling in HRTEM imaging. These are based on combining specific models of the scattered wave $\mathcal{T}_{\omega}^{\text{sc}}(U)$ with the above expressions of the single electron intensity distribution.

Standard Phase Contrast Model

For TEM imaging of thin weakly scattering specimens, such as cryo-fixated biological specimens, one can combine a series of approximations that ultimately result in an affine forward model. Currently this is the best trade-off between computational feasibility and accuracy for ET on HRTEM data.

The first step is to employ the weak phase object approximation (17), so

$$\mathcal{T}_{\omega}^{\text{sc}}(U)(\mathbf{x} + q\omega) \approx \psi_0(\mathbf{x} + q\omega) \left(1 + i\sigma \mathcal{P}(U)(\omega, \mathbf{x}) \right) \quad \text{for } \mathbf{x} \in \omega^{\perp}. \quad (44)$$

Next, assume the real and imaginary parts U_{re} and U_{im} of U are coupled like in (7). Insert (44) with (7) into (43), linearize the intensity as in (27), and use the fact that ψ_0 is a plane wave, so $|\psi_0|^2 \equiv 1$. Then, as worked out in [51, eqs.(37)–(38)], the single electron intensity distribution (43) becomes

$$I(U)(\omega, x) \approx \frac{1}{M^2} \left(1 - \frac{2\sigma}{(2\pi)^2} \left\{ \text{PSF}_{\text{tot}}^{\text{op}}(\omega, \cdot) \circledast_{\omega^\perp} \mathcal{P}(U_{\text{re}})(\omega, \cdot) \right\} \left(\frac{x}{M} \right) \right). \quad (45)$$

Here, $\text{PSF}_{\text{tot}}^{\text{op}}(\omega, z) := \text{PSF}_{\text{im}}^{\text{op}} + Q(\omega) \text{PSF}_{\text{re}}^{\text{op}}$, with $\text{PSF}_{\text{re}}^{\text{op}}$ and $\text{PSF}_{\text{im}}^{\text{op}}$ denoting the real and imaginary parts of PSF^{op} in (24), i.e.,

$$\begin{aligned} \text{PSF}_{\text{im}}^{\text{op}}(x) &= \mathcal{F}_{\omega^\perp} \left[A_\Sigma \left(\frac{f}{k} \cdot + f\omega \right) \sin \left[W(|\cdot|^2) \right] \right](x) \\ \text{PSF}_{\text{re}}^{\text{op}}(x) &= \mathcal{F}_{\omega^\perp} \left[A_\Sigma \left(\frac{f}{k} \cdot + f\omega \right) \cos \left[W(|\cdot|^2) \right] \right](x). \end{aligned}$$

Finally, inserting (45) into (41) gives the following expression for the forward operator:

$$\begin{aligned} \mathcal{T}(U)(\omega, x) &\approx \frac{N_0(\omega) C_{\text{gain}}}{M^2} \left[\left\{ \text{PSF}^{\text{det}} \circledast_{\omega^\perp} 1 \right\}(x) \right. \\ &\quad \left. - \frac{2\sigma}{(2\pi)^2} \left\{ \text{PSF}_{\text{tot}}^{\text{op}}(\omega, \cdot) \circledast_{\omega^\perp} \mathcal{P}(U_{\text{re}})(\omega, \cdot) \right\} \left(\frac{x}{M} \right) \right] \quad (46) \end{aligned}$$

where $\text{PSF}_{\text{tot}}^{\text{op}}(\omega, x) := \left\{ \text{PSF}^{\text{det}} \circledast_{\omega^\perp} (\text{PSF}_{\text{im}}^{\text{op}} + Q(\omega) \text{PSF}_{\text{re}}^{\text{op}}) \right\}(x)$ for $x \in \omega^\perp$.

Phase Contrast Model with Lens-Less Imaging

One can also consider the simpler lens-less imaging model (42) for the intensity. Combine the weak phase object approximation (44) with (7), and insert that into (42), linearize the intensity as in (27), and use the fact that ψ_0 is a plane wave, so $|\psi_0|^2 \equiv 1$. The end result is an expression of the type (46) but with a different PSF.

Phase Contrast Model with Ideal Detector Response and Optics

This is the case when $A_\Sigma \equiv 1$, $W \equiv 0$, and $\text{PSF}^{\text{det}} \equiv \delta_{\omega^\perp}$ in (46). Then, $\text{PSF}_{\text{im}}^{\text{op}} \equiv 0$ and $\text{PSF}_{\text{re}}^{\text{op}} = \text{PSF}^{\text{det}} \equiv \delta_{\omega^\perp}$, so

$$\mathcal{T}(U)(\omega, x) \approx \frac{N_0(\omega) C_{\text{gain}}}{M^2} \left(1 - \frac{2\sigma}{(2\pi)^2} Q(\omega) \mathcal{P}(U_{\text{re}})\left(\omega, \frac{x}{M}\right) \right). \quad (47)$$

Remark 14. If $Q(\omega) = 0$, then there is no detectable signal from the specimen. This is to be expected since the optics is needed to image phase contrast.

Forward Operator for Amplitude Contrast Only

Here we ignore the phase shift imposed by the specimen, so all the contrast in the micrograph is assumed to arise from electrons that are blocked from reaching the image plane (amplitude contrast). This is adequate for modeling essentially all medium-resolution contrast (beyond 2–3 nm) seen in micrographs, e.g., contrast from negatively stained specimens. Furthermore, all the early, successful attempts at 3D reconstruction relied on such a model [43, 97].

The Intensity

The starting point for modeling amplitude contrast is to consider electrons as particles and use a model similar to the Lambert–Beer law for the attenuation of X-rays in computed tomography. Thus, consider an incident beam of electrons traveling along $\omega \in S^2$ and let $\mu_\alpha: \mathbb{R}^3 \rightarrow \mathbb{R}_+$ denote the mass attenuation coefficient of the specimen for an angle α . Hence, $\mu_\alpha(x)$ is proportional to the probability that an incident electron traveling along ω scatters with an angle larger than α at x . A large value therefore implies that the electrons scatter with high angles and a small value means that the specimen is relatively transparent to the electron beam.

After interacting with the specimen, the incident beam gives rise to a (total) intensity distribution at the scintillator entrance surface $x \mapsto N_0 I(x)$ where N_0 is the incoming dose and I is the single electron intensity distribution defined in (28). The latter is now modeled as [176, p. 157]:

$$I(x) = I_0(x) \exp(-\mathcal{P}(\mu_\alpha)(\omega, x)) \quad \text{for } x \in \omega^\perp. \quad (48)$$

Here, \mathcal{P} is the ray transform in (1) and I_0 is the single electron intensity distribution one would obtain in the absence of a specimen.

The Forward Operator

The forward operator is obtained in the same way as (41) is obtained from (40), i.e.,

$$\mathcal{T}(\mu_\alpha)(\omega, x) \approx N_0(\omega) C_{\text{gain}} \left\{ I(\mu_\alpha)(\omega, \cdot) \otimes_{\omega^\perp} \text{PSF}^{\text{det}} \right\}(x) \quad \text{for } x \in \omega^\perp. \quad (49)$$

Here, $I(\mu_\alpha)(\omega, \cdot)$ is given by the left-hand side of (48), $N_0(\omega)$ is the image dose, and $\mu_\alpha: \mathbb{R}^3 \rightarrow \mathbb{R}_+$ fully characterizes the specimen for scattering with angles up to α . Hence, if (49) holds, one can pre-process data so that the corresponding forward operator equals the ray transform \mathcal{P} in (1).

Connection to Quantum Mechanics

The particle model in (48) can be related to the wave model based on the Schrödinger equation (5). To do this we need to take a closer look at μ_α .

First, in the amplitude contrast only model the phase contrast is ignored, so ψ_{sc} and ψ_0 have the same phase. Since $I = |\psi_{\text{sc}}|^2$, (48) yields

$$\psi_{\text{sc}}(\mathbf{x}) = \psi_0(\mathbf{x}) \exp\left(-\frac{1}{2} \int_{-\infty}^{\infty} \mu_\alpha(\mathbf{x} + s\boldsymbol{\omega}) ds\right).$$

Next, consider the projection approximation (16) for the ψ_{sc} . Equating the above expression for ψ_{sc} with the one in (16) yields $\mu_\alpha = 2\sigma U_{\text{im}}$ with $\sigma := me/k\hbar^2$. This relates the linear attenuation coefficient μ_α to the imaginary part U_{im} of the potential U in (2). This relation however only makes sense if one removes the explicit model for the aperture in the phase contrast model (simply set $A_\Sigma \equiv 1$ in (24)). Then, U_{im} acts as an attenuation term that accounts for both aperture and inelastic scattering.

Another connection is provided through the (elastic and inelastic) scattering cross-section. From [176, eq. (6.1)] we get that

$$\mu_\alpha(\mathbf{x}) = \frac{\rho(\mathbf{x})N_A}{M(\mathbf{x})}\sigma_\alpha\left(\frac{\mathbf{x}}{|\mathbf{x}|}\right) \quad \text{for } \mathbf{x} \in \mathbb{R}^3,$$

where $\sigma_\alpha: S^2 \rightarrow \mathbb{R}_+$ represents the local (elastic and inelastic) scattering cross-section, $\rho: \mathbb{R}^3 \rightarrow \mathbb{R}_+$ is the density, $M: \mathbb{R}^3 \rightarrow \mathbb{R}_+$ is the local molecular weight (in mol per unit volume), and N_A is Avogadro's constant (in mol per unit mass). Next, by [36, theorem 2.6], we can express the solution to (4a)–(4c) with $A \equiv \mathbf{0}$ as

$$\psi(\mathbf{x}) \approx \exp(i k \mathbf{x} \cdot \boldsymbol{\omega}) + \psi_\infty\left(\frac{\mathbf{x}}{|\mathbf{x}|}\right) \frac{\exp(i k |\mathbf{x}|)}{|\mathbf{x}|}.$$

The term $\psi_\infty: S^2 \rightarrow \mathbb{C}$ is called the far-field pattern and $i\psi_\infty$ is the complex scattering amplitude, which in turn is related to the local scattering cross section by [78, eq. (6)]

$$\sigma_\alpha(\mathbf{x}) = \int_{S^2 \setminus \Sigma_\alpha} \left| \psi_\infty\left(\frac{\mathbf{x}}{|\mathbf{x}|}\right) \right|^2 d\sigma(\mathbf{x}).$$

In the above, $\Sigma_\alpha \subset S^2$ is the region defined by the aperture (i.e., the angular range that is blocked by the aperture).

Summary

The model for the intensity depends on the type of contrast one seeks to model. The model presented in section “Forward Operator for Amplitude Contrast Only” for the amplitude contrast is only valid for thin specimens, e.g., unstained biological

specimens imaged using 100 keV electrons have to be thinner than 10 nm. If the specimen is thicker, this approach is only applicable to model low resolution image features.

At higher resolution, like in [HRTEM](#) imaging, one needs to account for the phase contrast, leading to the combined phase and amplitude contrast model (section “Forward Operator for Combined Phase and Amplitude Contrast”). This modeling framework depends highly on the model for the scattering operator $\mathcal{T}_\omega^{\text{sc}}$ defined in (6). In section “Electron–Specimen Interaction” we have presented several approximations to the scattering operator. The most accurate model is the one given by the multi-slice method that accounts for multiple scattering and does not assume weakly scattering specimen. The downside is that this results in a nonlinear model for image formation that is computationally challenging within an inverse problems setting. The first order Born approximation leads to an affine model that is more accurate than the geometrical optics approximation. It is valid whenever $k d \Delta U \ll \pi$ where d is the size of features one seeks to resolve and ΔU is the contrast (actually it is the ray transform of the contrast) [135]. Its implementation is however more complex requiring usage of nonuniform fast Fourier transform techniques for efficient evaluation of the scattering operator. Finally, for approaches based on geometrical optics approximation (13), only the weak phase object approximations (17) result in an affine model.

Currently there is no computationally feasible theory for modeling 2D image features in the micrographs at an intermediate resolution range (< 1 nm) in an amorphous specimen that is not ultra thin (thickness between 15 and 20 nm) [176, p. 157]. Models for simulation of such micrographs, see, e.g., [176, section 6.7], are computationally to demanding to be used within an 3D image reconstruction scheme. This is also confirmed by a recent study in [189] that considers cryo-electron microscopy (section on p. 942) of amorphous biological specimens. There, one concludes that the projection and weak-phase object approximations are satisfied for simulation of [TEM](#) image features not smaller than 0.5 nm, so higher resolution simulations require more advanced models for the scattering operator, see also [78]. In [ET](#) life-science applications one typically does not attempt to interpret 3D image features that are smaller than 3 nm, so a model for the scattering operator that is to be used within a tomographic reconstruction scheme can be based on the weak-phase object approximation.

5 Data Acquisition Geometry

The reconstruction problem in [ET](#) is an example of a tomographic inverse problem. Data naturally divides into sub-datasets, each containing data acquired when the object has undergone a specific Euclidean transformation (tomographic data). The associated *data acquisition geometry* is a specification of the Euclidean transformations that describe how the object moves in between the acquisition of the sub-datasets.

In **ET** each sub-dataset corresponds to a micrograph, a 2D **TEM** image, acquired using uniform illumination mode (Sect. 2). A *tilt-series* refers to the series of micrographs, and the *zero-tilt* micrograph is the one recorded when the specimen input plane is as orthogonal as possible to the optical axis. The specimen is only rotated (no translations) in-between sub-datasets, so the data acquisition geometry follows a *parallel beam geometry*, i.e., all electrons that generate an image travel along the same direction and the detector is planar and orthogonal to this incident direction of propagation.

Parallel Beam Geometries

For parallel beam geometry, continuum tomographic data is represented as a real-valued function defined on the tangent bundle $T(S^2)$:

$$T(S^2) := \{(\omega, x) \in S^2 \times \mathbb{R}^3 : x \in \omega^\perp\}.$$

$T(S^2)$ provides natural coordinates for tomographic data since $(\omega, x) \in T(S^2)$ represents data at x in the detector plane when the orientation of the detector is given by $\omega \in S^2$ (normal to the detector plane).

In **ET** data is given on a 3D subset of $T(S^2)$, typically by restricting $\omega \in S^2$ to a curve $S_0 \subset S^2$. Hence, the subsets of $T(S^2)$ we consider are of the following form:

Definition 1. A *parallel beam line complex* (also called Orlov's pencil) is a subset $\mathcal{M}_{S_0} \subset T(S^2)$ where

$$\mathcal{M}_{S_0} := \{(\omega, x) \in T(S^2) : \omega \in S_0\} \quad \text{for fixed } S_0 \subset S^2.$$

S_0 is sometimes called the *angular data collection aperture* [42]. Next, for a given region of interest $\Omega_0 \subset \mathbb{R}^3$, we define

$$\mathcal{M}_{S_0}(\Omega_0) := \{(\omega, x) \in \mathcal{M}_{S_0} : x = y - (y \cdot \omega)\omega \text{ for some } y \in \Omega_0\}.$$

For parallel beam geometries, continuum tomographic data is represented by a function $g: \mathcal{M}_{S_0} \rightarrow \mathbb{R}$ and the *data acquisition geometry* is a specification of the curve S_0 .

Examples Relevant for **ET**

Here we give some examples of parallel beam geometries that occur in **ET**. The corresponding curves S_0 are shown in Fig. 3. For single- and double-axis tilting, coordinates (x, y, z) in \mathbb{R}^3 are chosen so that the x -axis is parallel to the tilt-axis and the z -axis parallel to the electron beam when the specimen is in the zero-tilt position.

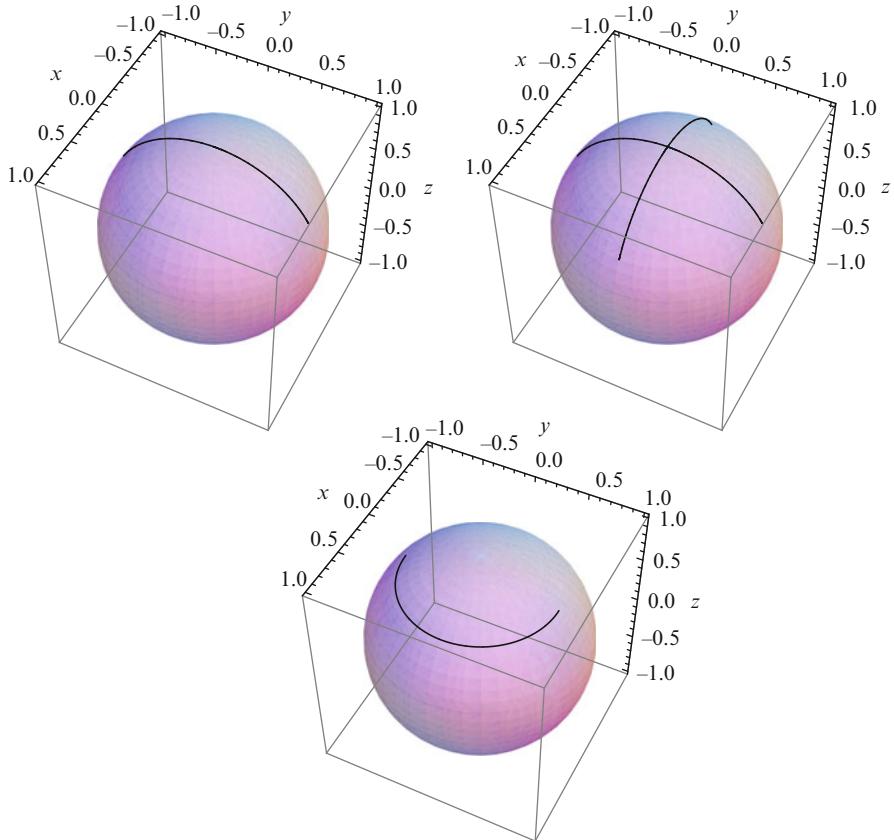

Fig. 3 Illustrating $S_0 \subset S^2$ for the three most common data collection geometries in ET, single-axis titling (*left*), double-axis titling (*middle*), and conical-axis titling (*right*). The z -axis is the electron beam direction, and in the case of single-tilting, the specimen is tilted around the x -axis

Single-axis titling: Here $S_0 := \{(0, \sin \theta, \cos \theta) : -\theta_{\max} < \theta < \theta_{\max}\}$ where a typical value of the tilt-angle is $\theta_{\max} = 60^\circ$.

Double-axis titling: S_0 is here the union of two single-axis titling geometries, one along the x - and the other along the y -axis. As for single-axis titling, a typical value for the tilt-angle is $\theta_{\max} = 60^\circ$.

Conical-axis titling: Fix β , typically $\beta = 45^\circ$, and define

$$S_0 := \{(\sin \beta \sin \theta, \sin \beta \cos \theta, \cos \theta) : 0 < \theta < 180^\circ\}.$$

In the ET community, the curve S_0 is often parametrized in terms of the Euler angles [143, p. 6] instead of describing it, like above, as a curve on S^2 . This is also the convention used by most software packages for ET.

6 The Reconstruction Problem in ET

Mathematical Formulation

We will state two variants of the 3D reconstruction problem in ET, one for continuum noise-free tomographic data and one for finitely sampled noisy tomographic data.

The Specimen

In the combined phase and amplitude contrast model (section “Forward Operator for Combined Phase and Amplitude Contrast”), the specimen is fully characterized by its 3D scattering potential $U_{\text{true}}: \mathbb{R}^3 \rightarrow \mathbb{C}_+$. In the amplitude contrast model (section “Forward Operator for Amplitude Contrast Only”), it is fully characterized by its 3D mass attenuation coefficient $\mu_a: \mathbb{R}^3 \rightarrow \mathbb{R}_+$. Since the mass attenuation coefficient can be identified with the imaginary part of the scattering potential (paragraph on p. 970), we will henceforth use the same notation, U_{true} , for both these functions and refer to them as the *signal*.

Next, the specimen is contained in an infinite slab $\Omega \subset \mathbb{R}^3$ given as an unbounded region enclosed between two parallel hyperplanes, Γ_{in} (specimen input plane) and Γ_{out} (specimen exit plane). We also introduce the region of interest $\Omega_0 \subset \Omega$, which is a bounded domain where we seek to recover the true signal U_{true} . Note that U_{true} has compact support in Ω , but its support is not necessarily contained in Ω_0 . In ET this is not the case (section “Incomplete Data, Uniqueness and Stability”). Finally, we introduce \mathcal{X} (reconstruction space), the vector space of feasible signals. Elements in \mathcal{X} are complex-valued functions with compact support in Ω with reasonable regularity (section on p. 952).

Continuum Tomographic Data

Here tomographic data is represented by a function $g: \mathcal{M}_{S_0}(\Omega_0) \rightarrow \mathbb{R}_+$ where $\mathcal{M}_{S_0}(\Omega_0) \subset T(S^2)$ given as in Definition 1. The data space \mathcal{H} is a suitable set of such functions, typically one requires that it is contained in $\mathcal{S}(\mathcal{M}_{S_0}(\Omega_0), \mathbb{R})$.

The inverse problem in ET is to recover the signal $U_{\text{true}} \in \mathcal{X}$ on Ω_0 from continuum tomographic data $g: \mathcal{M}_{S_0}(\Omega_0) \rightarrow \mathbb{R}_+$ where

$$g(\omega, x) = \mathcal{T}(U_{\text{true}})(\omega, x) \quad \text{for } (\omega, x) \in \mathcal{M}_{S_0}(\Omega_0). \quad (50)$$

Here $\mathcal{T}: \mathcal{X} \rightarrow \mathcal{H}$ is the forward operator associated with TEM imaging (section “Forward Operator for Combined Phase and Amplitude Contrast” for combined phase and amplitude contrast and section “Forward Operator for Amplitude Contrast Only” for amplitude contrast only). Finally, ET is local tomography problem, meaning that the support of U_{true} is not contained in Ω_0 .

Sampled Tomographic Data

Finitely sampled tomographic data directly corresponds to a tilt-series. To each micrograph in the tilt-series, we associate a directional vector $\omega_i \in S_0$ an image dose $N_0(\omega_i)$. The former is given by the angle between the incident beam and the specimen input plane Γ_{in} (zero-tilt is when $\omega_i \perp \Gamma_{\text{in}}$), and the latter is the total dose used to acquire the micrograph. Furthermore, there is a pixelization $\{\Delta_j\}_j$ associated with the **CCD** chip. If there are m_{slt} micrographs in the tilt-series and the **CCD** chip has n_{det} pixels, then tomographic data is represented as a vector in \mathbb{R}_+^m with $m = m_{\text{slt}}n_{\text{det}}$.

Next, we introduce the sampled forward operator $\mathcal{T}: \mathcal{X} \rightarrow \mathbb{R}^m$ as

$$\mathcal{T}(U)(i, j) := \mathbf{E} \left[\mathbf{C}^{\text{data}}(i, j) \right] \quad \text{for } i = 1, \dots, m_{\text{slt}} \text{ and } j = 1, \dots, n_{\text{det}} \quad (51)$$

where $\mathbf{C}^{\text{data}}(i, j)$ is the stochastic model in (33) for the measured value at the j :th pixel in the i :th micrograph (the dependency on U is suppressed in the notation). From (36) we can express the sampled forward operator in terms of the forward operator $\mathcal{T}: \mathcal{X} \rightarrow \mathcal{H}$ (section ‘‘Forward Operator for Combined Phase and Amplitude Contrast’’ for combined phase and amplitude contrast and section ‘‘Forward Operator for Amplitude Contrast Only’’ for amplitude contrast only):

$$\begin{aligned} \mathcal{T}(U)(i, j) &= \int_{\Delta_j} \mathcal{T}(U)(\omega_i, \mathbf{x}) d\mathbf{x} \approx |\Delta_j| \{ \mathcal{T}(U)(\omega, \cdot) \underset{\omega \perp}{\otimes} \text{PSF}_j^{\text{pix}} \}(\mathbf{x}_j) + \mu_j \\ &\approx |\Delta_j| \mathcal{T}(U)(\omega, \mathbf{x}_j). \end{aligned} \quad (52)$$

The last two approximations follow from (38) and (39), respectively.

The corresponding inverse problem is to recover the signal $U_{\text{true}} \in \mathcal{X}$ on Ω_0 from a tilt-series $\mathbf{g} \in \mathbb{R}_+^m$ where

$$\mathbf{g} = \mathcal{T}(U_{\text{true}}) + \mathbf{g}^{\text{noise}}. \quad (53)$$

In the above, \mathcal{T} is the sampled forward operator and $\mathbf{g}^{\text{noise}}(i, j)$ (noise component of data) is a sample of the random variable $\mathbf{C}^{\text{data}}(i, j) - \mathcal{T}(U_{\text{true}})(i, j)$.

Fully Discrete Setting

This is the case when the reconstruction space \mathcal{X} is discretized by mapping an element in \mathcal{X} to a vector in \mathbb{R}_+^n . The inverse problem is to recover the n -vector $U_{\text{true}} \in \mathbb{R}^n$ from sampled tomographic data $\mathbf{g} \in \mathbb{R}_+^m$ where

$$\mathbf{g} = \mathbf{T}(U_{\text{true}}) + \mathbf{g}^{\text{noise}}. \quad (54)$$

In the above, $\mathbf{T}: \mathbb{R}^n \rightarrow \mathbb{R}^m$ is the fully discretized forward operator that corresponds to \mathcal{T} .

Notion of Solution

An issue that often arise when dealing with inverse problems with noisy data and/or uncertain forward operator, like in ET, is that data is not in the range of the forward operator (inconsistent data). For such cases, (53) (or its fully discretized version (54)) will not have a solution (non-existence). A common approach to address this issue is to introduce a relaxed notion of solution by considering

$$\operatorname{argmin}_{U \in \mathcal{X}} \mathcal{D}(\mathcal{T}(U), \mathbf{g}) \quad \text{for given } \mathcal{D}: \mathbb{R}^m \times \mathbb{R}^m \rightarrow \mathbb{R}_+. \quad (55)$$

In the above, \mathcal{D} is the *data discrepancy* that quantifies the goodness-of-fit. Choosing it as the 2-norm in \mathbb{R}^m yields least-squares solutions, and more generally, deriving it from the data likelihood yields Maximum-Likelihood (ML) solutions. Existence for (53) with the above notion of a solution translates into existence of solutions to (55), see [196] for an overview of such results. In general, such results are highly dependent on the (i) space \mathcal{X} , (ii) data discrepancy \mathcal{D} , and (iii) forward operator $\mathcal{T}: \mathcal{X} \rightarrow \mathbb{R}^m$.

Besides existence, one also has the issue of uniqueness. As with most inverse problems involving function spaces and finite data, if the inverse problem (53) has a solution, it will not be unique. Furthermore, in ET the number of data points is almost always less than the number of 3D voxels, so the same also holds for the fully discretized version (54). Hence, assuming (55) has solutions, there are infinitely many of them (non-uniqueness). Handling the issue of non-uniqueness is the art of regularization, where the basic idea is to make use of a priori knowledge about $U_{\text{true}} \in \mathcal{X}$.

Expressions for the Data Discrepancy

Choosing \mathcal{D} as a suitable affine transformation of the negative log-likelihood of the random variable in (51) (that models measured data \mathbf{g}) allows one to interpret (55) as Maximum-Likelihood (ML) estimation of (53).

Retaining the above interpretation of (55), data with additive Gaussian noise (with zero mean and known covariance matrix Σ) leads to choosing \mathcal{D} as the Mahalanobis distance. It weights the usual 2-norm with the covariance matrix Σ of data to make the distance metric scale-invariant:

$$\mathcal{D}(\mathcal{T}(U), \mathbf{g}) := \frac{1}{2} (\mathcal{T}(U) - \mathbf{g})^t \cdot \Sigma^{-1} \cdot (\mathcal{T}(U) - \mathbf{g}).$$

On the other hand, for Poisson data, \mathcal{D} is given by the Kullback–Leibler divergence in the data space:

$$\mathcal{D}(\mathcal{T}(U), \mathbf{g}) := \sum_{i=1}^m (g_i \log \mathcal{T}(U)_i - \mathcal{T}(U)_i).$$

Now, the [ET](#) noise model in (34) is more complex. Deconvolving the detector noise leads to data that is Poisson with additive Gaussian noise. It turns out that the corresponding log-likelihood has a closed form expression [16]. If one insists on a closed form expression for the data discrepancy \mathcal{D} , this is probably the most accurate noise model for images acquired using a low photon/electron count and high detector noise. A difficulty however is that \mathcal{D} becomes non-convex and non-smooth. Therefore, a variety of approximations have been suggested, like [15, 32] and [67, 110], the latter two based on formulating a Mahalanobis distance that approximates the log-likelihood.

7 Specific Difficulties in Addressing the Inverse Problem

The inverse problem in [ET](#) is associated with a number of difficulties that make it a challenging problem.

The Dose Problem

This is *the single most important* factor limiting the usefulness of [ET](#) in life sciences. As explained below, the dose problem arises due to damage induced by the electron–specimen interaction and limits the total number of micrographs that can be recorded.

When a specimen is irradiated by an electron beam, it gets progressively damaged due to ionization. The actual mechanisms underlying specimen damage are more complex and outside the scope of this review, the reader may consult [9, 46] and the references therein for further information. For our purposes, the implication of specimen damage is that the number of electrons used to irradiate the specimen need to be low enough to preserve the structural integrity of the specimen. For biological materials, the total dose varies between 1,000 and 10,000 e⁻/nm² [148, section 3.2], depending on the size of image features that are of interest, the type of specimen, and the sample preparation method. Similar thresholds are presented by [103, section 3.2] and [19]. Hence, we are roughly dealing with a *total* of 300–3,000 e⁻/pixel (at 25,000× magnification using a detector with a pixel-size of 14 μm) distributed over 60 or 120 images, so micrographs have very low signal-to-noise ratio with significant influence of shot noise, see also Fig. 4.

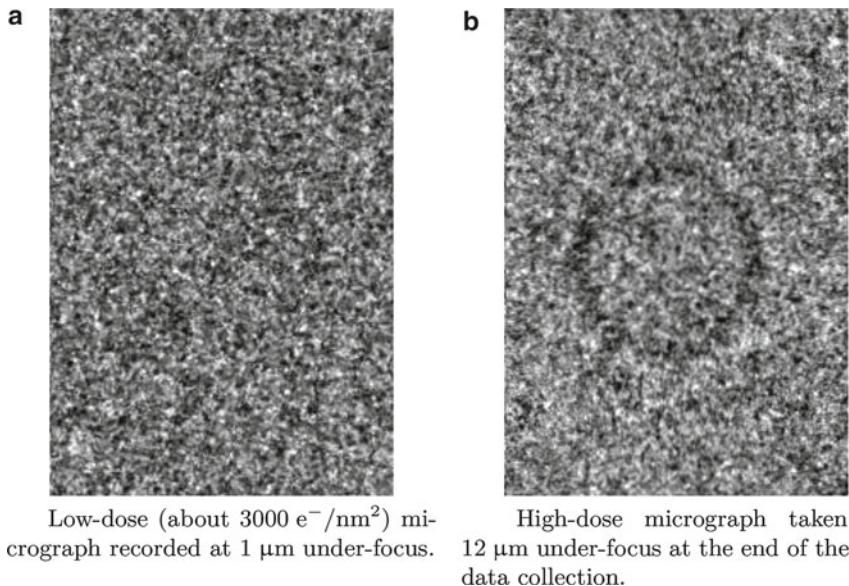

Fig. 4 Micrographs of an *in vitro* specimen containing microsomes (small spherical shells with diameter $\sim 60 \text{ nm}$) recorded using a 200 kV TEM. Both micrographs represent the same rectangular subregion ($H \times W: 150 \times 106 \text{ nm}$) of a zero-tilt micrograph. Note that the microsome, which is visible in the high-dose micrograph (b), is not visible in the low-dose micrograph (a). The high-dose micrograph is not used for reconstruction due to specimen damage. (a) Low-dose (about $3,000 \text{ e}^-/\text{nm}^2$) micrograph recorded at $1 \mu\text{m}$ under-focus. (b) High-dose micrograph taken at $12 \mu\text{m}$ under-focus at the end of the ET data collection

As a final note, the dose problem is less of an issue for ET applied to material sciences since those specimens are not as sensitive to damage induced by the electron–specimen interaction as biological specimens.

Incomplete Data, Uniqueness, and Stability

Mathematical uniqueness and stability results are only meaningful for inverse problems with continuum data (50) or in the fully discrete setting (54). For both cases, results are highly dependent on the forward operator, the data collection geometry, and the choice of the reconstruction and data spaces. Here we focus on (50), the case with continuum data.

It is easy to see that the inverse problem (50) cannot have a unique solution. One source for non-uniqueness is the phase problem (section “Phase Retrieval”), another is the fact that tomographic data is local, e.g., the support of U_{true} is not contained in Ω_0 whereas data is given only on $\mathcal{M}_{S_0}(\Omega_0)$. Furthermore, even if one can address the issue of non-uniqueness, there are strong indications that the inverse problem is severely ill-posed due to limitations in the data acquisition geometry (limited angle

data). These claims are supported by first considering the situation in a simplified setting, namely the standard phase contrast and the amplitude contrast models.

Standard Phase Contrast Model

The forward operator is given by (46), i.e., a ray transform followed by convolutions. Since the real and imaginary parts of the potential are related as in (7), any non-uniqueness issues associated with the phase problem are resolved. Hence, uniqueness rests upon the ability to uniquely invert the ray transform on $\mathcal{M}_{S_0}(\Omega_0)$, and stability refers to the aforementioned inversion and the deconvolution of the optics and detector PSFs.

Uniqueness

If the support of U_{true} is contained in the region of interest Ω_0 , then uniqueness for inversion of the ray transform follows from [122, theorem 3.144] whenever S_0 is infinite (uncountable), no matter how small it is. On the other hand, there is non-uniqueness for any finite set of directions, no matter how many [122, corollary 3.147]. As already mentioned on p. 974, ET is a local tomography problem. Hence, without additional prior information about U_{true} , the ray transform is not uniquely invertible [134, section VI.4]. One option is then to reconstruct features that are uniquely recoverable (section on p. 994).

Stability

Even when U_{true} is supported in Ω_0 (so there is uniqueness), we still have the issue of stability. Uniqueness is by analytic continuation, a non-constructive method that is highly vulnerable to noise in the data. Hence, this approach cannot be used to give reliable information about U_{true} from data.

Now, any reasonable form of stability is based on the possibility to obtain stability estimates in Sobolev spaces, analogous to those for the complete data case $S_0 = S^2$, which in turn requires that $S_0 \subset S^2$ fulfills Orlov's criteria (every great circle on S^2 has a nonzero intersection with S_0) [42, section 2.3] [134, chapter VI] [141, chapter 6]. This does not hold for the parallel beam data collection geometries that occur in ET (section “Examples Relevant for ET”), leading to severe ill-posedness. The ill-posedness is easy to see in the single-axis tilting scheme, where the inversion of the ray transform reduces to inversion of the 2D Radon transform in planes orthogonal to the tilt-axis. The limitation on the tilt-angle means that each such 2D Radon inversion problem is a limited angle problem, which is known to be severely ill-posed [40, 114]. Finally, the deconvolution in ET of the optics and detector PSFs are unstable operations, further adding to the ill-posedness of the inverse problem (50).

Amplitude Contrast Model

The forward operator is (49), and the deconvolution of the detector response PSF^{det} does not affect uniqueness. Hence, just as for the standard phase contrast model above, the issue of uniqueness/stability reduces to inversion of the ray transform on $\mathcal{M}_{S_0}(\Omega_0)$.

General Inverse Scattering

Here we consider the case when the intensity in (37) is given by the general scattering operator in (6). Since deconvolution of the detector response does not impair upon uniqueness, we can without loss of generality assume that $\text{PSF}^{\text{det}} = \delta_{\omega \perp}$.

Uniqueness

As already argued for, we cannot expect uniqueness from local data, so we first assume U_{true} is supported in Ω_0 . Next, non-uniqueness from phase retrieval can be resolved by making two measurements, or assuming the imaginary and real parts of the complex valued scatterer are related (section “Phase Retrieval”). Hence, a reasonable conjecture is that uniqueness holds for (50) under the same conditions as for the standard phase contrast model (section on p. 979). More precisely, U_{true} in (50) can be recovered uniquely whenever the real and imaginary parts of U_{true} are related as in (7) and micrographs are acquired at nonzero defocus (for a single thin lens section on p. 960) or at fixed distance form the specimen exit plane (for lens-less imaging section on p. 960). These assumptions are needed for phase retrieval (section “Phase Retrieval”), so another formulation is that U_{true} is uniquely determined from scattering data $\psi_{\text{sc}}(\omega, \cdot) = \mathcal{T}_{\omega}^{\text{sc}}(U_{\text{true}})$ for $\omega \in S_0$ whenever S_0 is infinite.

What mathematical results support the above conjecture? For full scattering data, there are uniqueness results for determining the far field pattern for (5) from a single measurement [35, theorem 10] (see chapter ▶ [Inverse Scattering](#)). One can also prove uniqueness for the inverse scattering problem with the magnetic Schrödinger operator in a slab geometry from a single scattered wave field, but this requires full knowledge of the Dirichlet-to-Neumann operator [104]. None of these results apply to our setting of tomographic data. The result closest to our setting is perhaps the one in [66] where one proves uniqueness for the inverse scattering problem when measurements are made on the reflected (backscattered) wave. For phase-less scattering data, [88] clearly states that uniqueness cannot hold for the problem of recovering U_{true} from the modulus of the far field pattern for (5) associated with a single direction ω . Here, Ω is assumed to be a bounded domain, and the scattered wave fulfills (4c) and an impedance boundary condition at $\partial\Omega$. A similar setting is studied in [95, 96], but this time data is the modulus of the scattered wave ψ_{sc} (that solves the direct scattering problem) acquired using wavelengths that vary continuously in an interval. A uniqueness result that is closest to our setting is the one in [90], which considers (5) with lens-less imaging. It turns out that for uniqueness one needs two micrographs for each direction, whereas stability requires four images. The results are however only proved when $S_0 \subset S^2$ is the equator and the scattering operator $\mathcal{T}_{\omega}^{\text{sc}}$ is approximated by the first order Born (paragraph on p. 956) or the paraboloid approximations. Nevertheless, it is highly probable that

the same result also holds when $\mathcal{T}_\omega^{\text{sc}}$ is not approximated and when S_0 an infinite set. Furthermore, if the imaginary part of the scatterer is related to the real part, one measurement should be enough for formal uniqueness.

Stability

All results cited here deal with stability in recovering U_{true} from full scattering data $\psi_{\text{sc}}(\omega, \cdot) = \mathcal{T}_\omega^{\text{sc}}(U_{\text{true}})$ for $\omega \in S_0$.

There are various stability results for (4a) that assume full knowledge of the Dirichlet-to-Neumann map. Results closer to our setting consider the inverse scattering problem (5) with boundary conditions (4b)–(4c), $S_0 = S^2$, and Ω a bounded domain with smooth boundary. One can, e.g., show that stability increases as the wave number k increases [131, Theorem 1.1 and eq. (1.4)]. Similarly, [4] establishes Lipschitz stability for determining the low-frequency component of the potential. In [140] one considers the case when $U_{\text{true}} = U_0 + \delta U$ where U_0 is known (typically representing some background) and δU is the (small) perturbation that is to be recovered. The result is that the perturbation can be stably reconstructed up to a certain frequency.

Stability in the context of phase contrast tomography is studied in [90], which considers (5) with lens-less imaging and $S_0 \subset S^2$ being the equator. They observe that numerical stability requires four measurements for each direction. A similar result is given in [130], which studies the same inverse scattering problem. If the real and imaginary parts of U_{true} are proportional (a special case of (7)) and two micrographs per direction are acquired, then the inversion is stable with respect to high-frequency noise. The arguments are however based on the projection assumption, but the result is interesting as it differs from situation in conventional tomography, which is known to be mildly ill-posed. This observation that phase contrast tomography is more stable than conventional tomography (assuming one can handle the phase problem) might also extend to the setting when $S_0 \subset S^2$ does not fulfill Orlov's criteria (section on p. 979). Hence, we expect wave imaging problems to be less influenced by limited angle data than ray imaging problems. The intuitive reason is that waves can “probe objects around corners” whereas rays cannot, and Fig. 5 illustrates this. There are however no formal mathematical results supporting this observation.

Nuisance Parameters

The formal statement of the inverse problem in ET in section “Mathematical Formulation” leaves out an important difficulty, namely the presence of nuisance parameters. These are parameters whose values need to be recovered alongside the potential U . We next list some of these parameters and indicate how they can be determined.

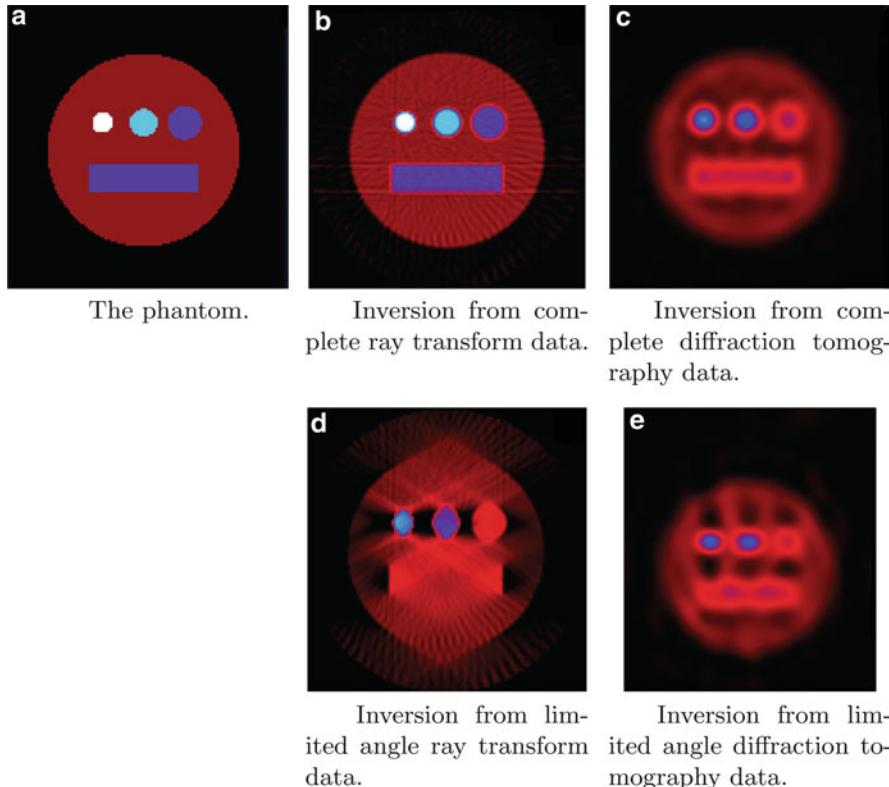

Fig. 5 Sensitivity of wave and ray tomography in 2D against limited angle data (angular range is $\pm 60^\circ$). Wave tomography is when data is restrictions of $\psi(\omega, \cdot)$ for $\omega \in S_0$ to a line orthogonal to ω and where $\psi(\omega, \cdot)$ solves (5) with (4b)–(4c). The wavelength of the incident wave equals the diameter of small white disc in the phantom in (a). It is clear that the limited angle artifacts (bottom row) are much more severe for ray tomography than for wave tomography. (a) The phantom. (b) Inversion from complete ray transform data. (c) Inversion from complete diffraction tomography data. (d) Inversion from limited angle ray transform data. (e) Inversion from limited angle diffraction tomography data (images courtesy of Frank Natterer)

Detector Parameters

The detector model outlined in (29) involves a detector response PSF^{det} , the overall gain C_{gain} , and the distribution of the background signal. None of these are nuisance parameters in the true sense since they can be determined by separate calibration experiments in a way independent of the tilt-series.

The overall gain C_{gain} can be calculated from a detector specification and/or from off-line data that has undergone basic pre-processing (section “Basic Pre-processing”), see, e.g., [146, pp. 380–381]. The detector response PSF^{det} is rotationally symmetric and positive since the spreading of the signal due to the scintillator and fiber-optic/lens coupling is rotationally symmetric. Thus, PSF^{det} is fully characterized by the Modulation Transfer Function (MTF), which is the modulus of its

Fourier transform: $\mathcal{F}_{\omega \perp}[\text{PSF}^{\det}](\xi) = \text{MTF}(|\xi|)$, Here, MTF: $\mathbb{R} \rightarrow \mathbb{R}_+$ measures how the signal amplitude is transferred for different spatial frequencies, and for slow-scan CCD sensors it is commonly parametrized as [176, p. 279], [146, p. 394]:

$$\text{MTF}(q) := \frac{a}{1 + \alpha q^2} + \frac{b}{1 + \beta q^2} + c. \quad (56)$$

The above parameters can be estimated from off-line calibration measurements, see, e.g., [188], which in turn yields the detector response PSF^{\det} . Finally, the background signal can also be estimated from similar calibration measurements.

Illumination and Optics Parameters

These are parameters associated with the illumination and optics. They are independent of the specimen but they can be unique for a tilt-series. Some, like the wavenumber k and magnification M , are considered constant and known to sufficient degree of accuracy. On the other hand, the image dose and a number of electron-optical parameters have nominal values that must be adjusted, either by an analysis of the recorded micrographs and/or by performing additional measurements after the ET data collection.

Image Dose

The image dose $N_0(\omega)$ in (37) plays an important role in the interpretation of data since it enters into the forward models in (41) and (49). It gives the number of electrons per pixel in the absence of a specimen.

One way to estimate the image dose is based on assuming a constant electron-current density J_0 (number of electrons per unit area and unit time). This quantity can be calculated by a Faraday cage and converted into the number of electrons per second. From the exposure time $t(\omega)$ we then get the actual dose used for the imaging by the relation $N_0(\omega) = J_0 t(\omega)$. Another option is to set $N_0(\omega) = C_{\max}(\omega)/C_{\text{gain}}$ where C_{gain} is the overall gain (see section on p. 982 for how it is estimated) and $C_{\max}(\omega)$ is the maximum pixel value in the micrograph. This will always underestimate the image dose. To account for the specimen, consider a linear absorption model where the specimen is a continuum medium in the slab Ω with thickness h . Hence, if $C(\omega)$ is the average detector response, then $C(\omega) = C_0(\omega)(1 - \mu h(\omega))$ in which $C_0(\omega)$ is the image dose, μ is characterized by the specimen, and $h(\omega) > 0$ is the thickness along ω (section “Forward Operator for Amplitude Contrast Only”). If the image dose is the same, say C_0 , for two images, then it is easy to see that it is given by $C_0 = (N_0(\omega) - N_0(\omega'))/(2 - 2h(\omega)/h(\omega'))$. A more general approach is to use least-squares to fit a quadratic function to points on $\omega \mapsto C_{\max}(\omega)$. This uses all data in the tilt-series and also allows one to estimate the shape of the specimen boundaries (a slab is the simplest shape but a “meniscus” type of membrane is more natural).

Remark 15. In experimental protocols, one typically reports the total dose at the object plane Γ_{obj} (Fig. 2). It roughly corresponds to the number of electrons per unit area at the specimen input plane Γ_{in} . This is an important number as it directly relates to the dose sensitivity of the specimen. The corresponding image dose is obtained by first dividing with the number of micrographs in the tilt-series, and then dividing by the magnification.

Optics Parameters

These parameters are only relevant for reconstruction methods based on forward models that account for the TEM optics, like the standard phase contrast model (section on p. 967).

First, we have parameters that describe the set-up for the optics (section “The Optical Set-Up”) illustrated in Fig. 2. This set-up does not correspond to a physical optical system. The parameters f , p , and q can be selected freely as long as (20) holds. It is however wise to use the convention that f in (20) equals the focal length of the actual objective lens. The two relations will then give the values for p and q . An advantage of this convention is that the size of the aperture in the focal plane Γ_{focal} matches the size of the physical objective aperture. This convention provides the parameter $d := p - q$ associated with lens-free imaging, the simplest model for the optics (section on p. 960).

Next, a more advanced TEM optics model, like the one in section on p. 960, requires values for electron-optical parameters (CTF estimation). These enter into the definition of PSF^{op} in (24) with defocus being the most important one. In ET applications that do not require interpretation of 3D features smaller than 4 nm, there is no need for CTF estimation since nominal values of the electron-optical parameters are good enough. This is however not the case for high-magnification/resolution applications [57]. In general, CTF estimation is based on identifying shape and position of the so-called Thon rings in the power spectrum density. These are resolution-dependent amplitude modulations caused by the optics PSF [79, section 77.2]. This identification is an ill-posed problem [175] and a variety of estimation techniques have been developed, mainly for single particle applications, see [60, sections 2.37–2.38] and [51, section 8.5] for a more detailed overview. Unfortunately, most of these approaches are not applicable to ET since micrographs have too low contrast and/or are too noisy. One approach is based on strip-based periodogram averaging, extended throughout the tilt-series to overcome the low contrast conditions found in ET [57, 191]. Another alternative, that better respects the true Poisson characteristics of the noise, is outlined in [186].

Remark 16. For material sciences applications, CTF estimation is important due to the high resolution/magnification. The estimation problem is in part simpler since micrographs have better contrast and signal-to-noise ratio, but more CTF parameters

have to be estimated as well. The reader may consult [176, chapter 10] for a survey of approaches.

Specimen-Dependent Parameters

In ET there are also parameters that depend on the specimen. One such parameter relates to local data (p. 974). Since the support of U is not contained in $\Omega_0 \subset \Omega \subset \mathbb{R}^3$, pixels in all micrographs (besides the zero-tilt image) will have contribution from outside Ω_0 (local tomography artifacts), see, e.g., [123, section 4]. These artifacts become more pronounced when there is strongly scattering material outside Ω_0 , as for biological in situ specimens and material sciences. A typical approach is to “pad” the data, which here means removing contributions from Ω_0 (long-object compensation). The simplest padding is based on assuming U equals some constant average value outside Ω_0 (constant continuation), which then becomes a specimen-dependent parameter. One can also consider smooth continuation in order to avoid introducing edge effects, but that results in introducing further specimen-dependent parameters. Yet another approach is to consider a low-resolution reconstruction from a larger region of interest, and use that to pad data.

Another parameter is the scaling factor Q associated with the assumption in (7) that relates the real and imaginary part of the potential. Current methods for estimating the amplitude contrast ratio are based on performing additional measurements, such as taking a defocus series. This is unfortunately not possible for most biological specimens.

8 Data Pre-processing

This section describes data processing steps that are commonly applied to micrographs in a tilt-series before they are used within a reconstruction method.

Basic Pre-processing

The degree of pre-processing of micrographs depends on how much one seeks to include in the forward operator. For all ET applications it is highly recommended to work with data that has been flat-fielded. Flat-fielding refers to the process of compensating for different gains and dark currents in a detector, so a uniform signal corresponds to a uniform output. This process also includes gain normalization that removes image features associated with the structure of the scintillator crystal and fiber-couplings (section on p. 963), see an example of this effect in [146, p. 393]. In addition, it is customary to remove high frequency peaks (X-ray peaks) based on a local mean value calculations.

Alignment

Acquiring a tilt-series corresponds to sampling a real valued function defined on $\mathcal{M}_{S_0}(\Omega_0)$ (Definition 1). The nominal specification for this sampling is unfortunately not accurate enough since the specimen undergoes unintentional movements during in between the acquisition of the micrographs. These movements result in shifts, rotations, and other types of image distortions.

Alignment is the procedure that corrects for these distortions and determines how $\mathcal{M}_{S_0}(\Omega_0)$ is sampled. Most alignment procedures follow a common four-step scheme:

Initial processing: In addition to basic pre-processing (section “Basic Pre-processing”), micrographs in tilt-series often also undergo further processing that involves denoising and feature extraction specifically tailored for alignment. These micrographs are only used during the alignment; to avoid losing information, they are not used for reconstruction.

Coarse alignment: Despite high-precision mechanics, raw tilt series might contain large shifts and rotations. Cross-correlation is used to coarsely align adjacent images. After coarse alignment, we can assume a smooth trajectory of features across images, facilitating subsequent alignment steps.

Feature tracking: The most common technique for feature detection is to define a patch around the feature as a template, and cross-correlate this template with other micrographs to search for the feature of interest. Due to high noise in images, one often have many false positive detections.

Determine the geometric relation: Once the 2D location of each feature is established and tracked across multiple images, epipolar geometry can be used to establish the geometric relation between the various images.

The choice of alignment method is based on the type of feature one seeks to track. Cryo-fixed specimens, especially *in vitro* specimens, lack visible features. Hence, one has to add fiducial markers to align tilt-series of such specimens. These are spherical gold beads that appear as high contrast point-like features in the micrographs. Techniques from epipolar geometry can then be used to elucidate the geometric relation between the micrographs, see [3] and the references therein for more details.

Deconvolving Detector Response

The Fourier transform of the detector response is strictly positive (section on p. 982), so it is fairly straightforward to deconvolve it, e.g., using a Wiener filter or the Richardson–Lucy algorithm [197]. A benefit of deconvolving the detector response, instead of including it into the forward model, is that the noise model for (deconvolved) data (section on p. 964) becomes much simpler.

Deconvolving Optics PSF

Deconvolving the optics response is only relevant for tilt-series from [HRTEM](#) imaging where phase contrast is important.

For lens-free imaging (section on p. [960](#)), this corresponds to deconvolving the effect of free-space propagation. Several approaches exist for this within the X-ray phase contrast imaging community, see [22] for a survey.

Optics models that are based on the single thin lens with an aperture model (section on p. [960](#)) are more involved to deconvolve since the [CTF](#) (the Fourier transform of the [PSF](#)) in (24) has multiple zeros. As an example, for the standard phase contrast model (section “Standard Phase Contrast Model”), one has to deconvolve $\text{PSF}_{\text{tot}}^{\text{op}}$ given in (45). If $Q(\omega) = 0$, then $\text{PSF}_{\text{tot}}^{\text{op}}(\mathbf{0}) = \text{PSF}_{\text{im}}^{\text{op}}(\mathbf{0}) = 0$, i.e., low-frequency image information is lost. Hence, the optics deconvolution is more challenging for [HRTEM](#) imaging specimens that act as “pure phase” objects. In general, the challenge in regularizing the optics deconvolution is the difficulty in specifying reasonable a priori information about the “true” signal, which here would be the micrograph one would obtain without perfect optics.

The optics is on the other hand needed to make phase contrast visible, so its deconvolution is only sensible if it is coupled with phase retrieval (section “Phase Retrieval”). In conclusion, it is highly dubious to first deconvolve the optics and then try 3D reconstruction if one does not couple that with some kind of phase retrieval. Thus, one either ignores the optics or include it into the forward model, so optics deconvolution is performed simultaneously with 3D reconstruction.

Phase Retrieval

For each direction $\omega \in S_0$, we have a phase retrieval problem (also called exit-wave reconstruction problem) which amounts to inverting the intensity operator in (26). In general this problem does not have a unique solution.

A common approach is to record two, or more, micrographs of the specimen using different imaging conditions (like different defocus values). From such data one can then reconstruct the phase of the wave [58]. This principle is put into action in electron holography and approaches based on the transport-of-intensity equation [99]. None of these approaches are however applicable to [ET](#) in life sciences since they require multiple micrographs for each direction $\omega \in S_0$, which is often not possible due to the specimen dose sensitivity (section “The Dose Problem”). Thus, we are left with considering “in-line” approaches that use only one micrograph at each direction.

Let us first consider the simplest model for the optics (lens-less imaging, section on p. [960](#)), i.e., free-space propagation. In this setting, phase retrieval within [ET](#) is identical to the corresponding problem in in-line X-ray phase contrast tomography. A variety of methods have been developed for the former, all based on relating the real and imaginary parts of the complex refractive index as in (7). The idea is to make use of the optics operator \mathcal{T}^{op} , which in this case is given by free-space

propagation (21), and perform the phase retrieval and optics deconvolution in one step by inverting $\mathcal{I} \circ \mathcal{T}^{\text{op}}$. The resulting phase retrieval operation is expressible as a convolution, see [22] for a nice survey. For ET, there is no obvious relation between the electrostatic and the absorption potentials. Nevertheless, it is common to assume that the latter is a multiple times the former, as discussed in section on p. 949. Thus, the aforementioned approaches from in-line X-ray phase contrast tomography should be applicable also on ET data as a pre-processing step for phase retrieval. A similar approach should also be applicable when the optics model is more complex, such as in (23).

Finally, one also has the option to include the intensity into the forward operator. In that context, phase retrieval is performed jointly as part of 3D reconstruction. If one seeks an affine forward operator, then one must linearize the intensity as in (26).

9 Reconstruction Methods

Before we describe the various reconstruction methods for ET, we state assumptions and procedures that are common for all current methods in use.

Type of Forward Operator

Unless otherwise stated, all reconstruction methods assume the forward operator is given by either the amplitude contrast (section “Forward Operator for Amplitude Contrast Only”) or the standard phase contrast (section on p. 967) models. For data that has undergone basic pre-processing (section “Basic Pre-processing”), both these lead to affine forward operators expressible as

$$\mathcal{T}(U)(\omega, x) = C(\omega) - C_0 \left\{ \underset{\omega^\perp}{\text{PSF}}(\omega, \cdot) \circledast \mathcal{P}(U_{\text{re}})(\omega, \cdot) \right\}(x) \quad \text{for } x \in \omega^\perp. \quad (57)$$

The specific expression for the PSF depends on the model but the overall structure remains the same for the amplitude and standard phase contrast models. In this context, the term $C(\omega)$ represents data one would record if there would be no specimen. It can be, together with C_0 , estimated from data (section “Nuisance Parameters”), in which case the inverse problem in ET can be recast to a setting with a linear forward operator.

Local Data

In ET we have local data (see p. 974), i.e., the support of U_{true} is not contained in Ω_0 . Hence, each micrograph contains the contribution of a larger or smaller extent of the specimen, so (53) becomes inconsistent. This is not an issue for reconstruction methods that are not sensitive to such issues, like ELT (section on p. 994). Other reconstruction methods should either pre-process data as to remove contributions from outside Ω_0 , or adapt the evaluation of the forward operator and its adjoint to account for this contribution (section on p. 985). This is referred to as long-object compensation and is based on assumptions about U_{true} outside Ω_0 , see [192] for

artifacts that arise in ET when such compensation is not performed in iterative methods (section “Iterative Methods with Early Stopping”).

Handling Nuisance Parameters

A reconstruction method for ET must handle how to assign values to nuisance parameters (section “Nuisance Parameters”), like $\omega \mapsto C(\omega)$ and C_0 in (57). Unless otherwise stated, all reconstruction methods in ET assume these are determined before reconstruction.

One can in principle consider the nuisance parameters as part of the signal that is to be recovered and attempt at reconstructing these alongside the initial signal. This is theoretically possible when using iterative and variational approaches. On the other hand, the forward operator might be nonlinear w.r.t. the nuisance parameters, the stability of the inversion w.r.t. the nuisance parameters could vary considerably when compared to inversion of the original signal, it is unclear which data discrepancy to use, etc. Hence, in practice one adopts an intertwined approach in which the signal is first reconstructed keeping the nuisance fixed, then the nuisance parameters are recovered keeping the signal fixed [165].

Type of Mathematical Results

From a strict mathematical point of view, a regularization involves a reconstruction operator that is well-posed (unique and stable solution) when reconstruction parameter(s) are chosen accordingly. Next, regularized solutions must converge to a ML/least-squares solution as the data error $\|\mathbf{g}^{\text{noise}}\| \rightarrow 0$. Besides these two requirements, one often also studies convergence rates (estimate of the difference between the regularized solution and a ML/least-squares solution) and stability estimates (bounds to the difference between the regularized solution with noise-free data and noisy data).

Analytic Methods

Overview

Analytic methods are applicable to inverse problems where the forward operator has an inverse that has an analytic formula, which is a concatenation of “simple” mathematical operators (such as finite number of differentiations to any order and integrations, whereas analytic continuation or summation of infinite series is not simple). The starting point is the reconstruction problem with continuum data given in (50). Assuming this problem has a unique solution, one can define the *reconstruction operator* as the inverse of the forward operator (*exact reconstruction*). On the other hand, if there is instability and/or non-uniqueness, like in ET (section “Incomplete Data, Uniqueness and Stability”), then an appropriate reconstruction operator should recover a feature, such as an approximate identity, of the signal. The actual implementation is given by an appropriate discretization of the reconstruction operator.

In summary, analytical methods lead to algorithms in which the signal is directly calculated from the measurements in a single step, without resorting to more time-

consuming, iterative methods. In tomographic applications, the numerical analysis basically employs filtering, backprojection, and summation operations, as well as discrete Fourier transforms.

Backprojection-Based Methods

The Filtered Back-Projection (**FBP**) and Weighted Back-Projection (**WBP**) methods are examples of backprojection-based methods that constitute the standard approach within the **ET** community for solving the reconstruction problem, see [143] for a recent survey.

Data Pre-processing

All backprojection-based methods assume data is (noisy) samples of the ray transform, i.e., the forward operator is (57) with $C(\omega) = 0$, $C_0 = 1$, and $\text{PSF}(\omega, \cdot) = \delta_{\omega^\perp}$. Hence, data should be pre-processed so that it fits this assumption, i.e., nuisance parameters $C(\omega)$ and C_0 need to be estimated and the **PSF** needs to be deconvolved.

A Priori Information

The assumption is that noise is high frequency whereas relevant features of U_{true} are low frequency. Thus, by providing an approximate inverse, these relevant features of U_{true} are recovered while noise is suppressed.

Reconstruction Operator

The starting point for both **FBP** and **WBP** is an equality that relates the ray transform to its back-projection. Let $S_0 \subset S^2$ be an infinite measurable set and $U \in \mathcal{S}(\mathbb{R}^3, \mathbb{R})$. A simple modification to the arguments used in proving [136, eq. (2.34)] allows us to prove the following identity on $\mathcal{M}_{S_0}(\Omega_0)$:

$$U * H = \mathcal{P}_{S_0}^*(h \circledast_{\omega^\perp} \mathcal{P}(U)) \quad \text{for } h \in \mathcal{S}(\mathcal{M}_{S_0}(\Omega_0), \mathbb{R}) \text{ and } H := \mathcal{P}_{S_0}^*(h). \quad (58)$$

Here, \mathcal{P} is the ray transform in (1) and $\mathcal{P}_{S_0}^*$ is the (*parallel beam*) *back-projection* defined as follows:

Definition 2 (Back-Projection). Let $g \in \mathcal{S}(T(S^2), \mathbb{R})$ and $S_0 \subset S^2$ is a measurable set. The (*parallel beam*) *back-projection* of g is then defined as

$$\mathcal{P}_{S_0}^*(g)(x) := \int_{S_0} g(\omega, x - (x \cdot \omega)\omega) d\omega \quad \text{for } x \in \mathbb{R}^3, \quad (59)$$

with $d\omega$ denoting the surface measure on S_0 .

Remark 17. $\mathcal{S}(T(S^2), \mathbb{R})$ is the Schwarz space for real-valued functions defined on $T(S^2)$, see [136, section 2.2] for the formal definition. $\mathcal{P}_{S_0}^*$ maps such functions to functions on \mathbb{R}^3 . Furthermore, if the \mathcal{L}^2 -inner product is considered for both the domain and range of $\mathcal{P}_{S_0}^*$, then $\mathcal{P}_{S_0}^*$ is the adjoint of \mathcal{P} .

The reconstruction operator for the **FBP** method is now defined as the right-hand side of the equality in (58):

$$\mathcal{R}_{\text{FBP}}(g) := \mathcal{P}_{S_0}^*(h_{\omega^\perp} \otimes g) \quad \text{for } g \in \mathcal{S}(\mathcal{M}_{S_0}, \mathbb{R}). \quad (60)$$

Hence, by (58) we get that $\mathcal{R}_{\text{FBP}}(g) = U_{\text{true}} * H$ whenever $g = \mathcal{P}(U_{\text{true}})$ on $\mathcal{M}_{S_0}(\Omega_0)$. In this context, $h: \mathcal{M}_{S_0} \rightarrow \mathbb{R}$ is called the *reconstruction kernel* and H is the corresponding *filter*. The idea in **FBP** is now to choose h such that $H \approx \delta$, since this implies that $\mathcal{R}_{\text{FBP}}(g) \approx U_{\text{true}}$.

The **WBP** method is mathematically equivalent to **FBP**. It is based on taking $h = \delta_{\omega^\perp}$ in (58). This means, of course, that the corresponding filter H will not be an approximation of δ , so (60) does not directly yield a reconstruction of U_{true} . However, if one can derive an expression for the Fourier transform of $H \approx \mathcal{P}_{S_0}^*(\delta_{\omega^\perp})$, then one can use this to recover U_{true} by dividing the Fourier transform of $\mathcal{P}_{S_0}^*(g)$ by the Fourier transform of H , and then apply the inverse Fourier transform. This leads to the following reconstruction operator:

$$\mathcal{R}_{\text{WBP}}(g) := \mathcal{F}^{-1} \left[\frac{\mathcal{F}[\mathcal{P}_{S_0}^*(g)]}{\mathcal{F}[H]} \right].$$

For **FBP**, in order to get a useful reconstruction operator one must choose the reconstruction kernel h such that convolution with $\mathcal{P}_{S_0}^*(h)$ represents extracting some feature of U . The idea is to first derive the reconstruction kernel h for exact reconstruction from ideal data, i.e., $\mathcal{P}_{S_0}^*(h) = \delta$. The regularized variant that provides an approximative inverse for noisy data is then given as a band-limited variant of the aforementioned reconstruction kernel. Similarly, in **WBP** we seek H such that it approximately equals the backprojection of a Dirac delta.

Adaptation to **ET**

The adaptation to **ET** lies in finding an appropriate reconstruction kernel h for the **FBP** method. The corresponding problem of finding H for **WBP** is discussed in [143, 156].

For single-axis tilting (section “Examples Relevant for **ET**”), the entire 3D ray transform inversion problem reduces to a sequence of 2D inversion problems that can be handled separately. Hence, in that sense, single-axis tilting does not lead to a truly 3D inversion problem. Likewise, the current approach for **FBP/WBP** reconstruction from double-axis tilting data is to split such a data set into two single-axis data sets, perform 3D reconstruction for each of these, and then combine the two 3D reconstructions by some averaging. This might give the impression that reconstruction from double-axis tilting is also not a “true 3D problem”. This is however not the case. The two 3D reconstructions will have different limited angle artifacts, so it is clear that a spatially dependent averaging will perform better than just a regular average. One can derive a partition of unity to use for such a spatially

dependent averaging by considering the reconstruction kernel for the 3D problem in double axis tilting.

Let us now consider the reconstruction kernel for general parallel beam line complexes in which S_0 is a curve. To derive an equation for the reconstruction kernel (filter equation), we first consider the following relation [136, theorem 2.17]:

$$\mathcal{F}[H](\xi) = \frac{1}{|\xi|} \int_{S_0 \cap \xi^\perp} \mathcal{F}_{\omega \perp}[h(\omega, \cdot)](\xi) d\omega \quad \text{for } h \in \mathcal{S}(\mathcal{M}_{S_0}, \mathbb{R}),$$

where $H := \mathcal{P}_{S_0}^*(h)$. Exact reconstruction requires $H = \delta$, i.e., $\mathcal{P}_{S_0}^*(h) \equiv 1$, so

$$\int_{S_0 \cap \xi^\perp} \mathcal{F}_{\omega \perp}[h(\omega, \cdot)](\xi) d\omega = |\xi|.$$

Hence, an obvious choice of reconstruction filter h , independent of ω , is

$$\mathcal{F}_{\omega \perp}[h(\omega, \cdot)](\xi) := \frac{|\xi|}{|S_0 \cap \xi^\perp|} \quad \text{where} \quad |S_0 \cap \xi^\perp| := \int_{S_0} \delta(\omega \cdot \xi) d\omega. \quad (61)$$

This is fine as long as S_0 satisfies Orlov's criteria (section ‘‘Incomplete Data, Uniqueness, and Stability’’), which ensures that $|S_0 \cap \xi^\perp| \neq 0$. Unfortunately, in ET this is not the case. A natural modification to (61) is to set the Fourier transform of $h(\omega, \cdot)$ to zero at points ξ where $|S_0 \cap \xi^\perp| = 0$. With this choice of reconstruction filter, the FBP reconstruction operator in (60) provides a least-squares solution with minimal 2-norm instead of an exact solution.

To get a more explicit expression for h , let A_{S_0} be the set of all $\xi \neq 0$ in \mathbb{R}^n such that ξ^\perp is not tangent to S_0 and intersects it at a finite number of points, with N_ξ denoting the number of such intersection points. Also, parametrize the curve S_0 by $s \mapsto \gamma(s)$ where $s \in I$ is an interval and $d\omega = |\gamma(s)| ds$. From a direct modification of the proof of [136, theorem 2.17], we get

$$\mathcal{F}[H](\xi) = 2\pi \sum_{i=0}^{N_\xi} \frac{|\gamma(s_i)|}{|\xi \cdot \dot{\gamma}(s_i)|} \mathcal{F}_{\omega \perp}[h(\gamma(s_i), \cdot)](\xi) \quad \text{for } \xi \in A_{S_0},$$

where $s_1, \dots, s_{N_\xi} \in I$ are such that $\xi \cdot \gamma(s) = 0$. The above immediately gives us a necessary condition for h (filter equation) if $H = \delta$ is to hold:

$$2\pi \sum_{i=0}^{N_\xi} \frac{|\gamma(s_i)|}{|\xi \cdot \dot{\gamma}(s_i)|} \mathcal{F}_{\omega \perp}[h(\gamma(s_i), \cdot)](\xi) = 1 \quad \text{for all } \xi \in A_{S_0}. \quad (62)$$

Thus, a natural choice of h is to define it as the inverse Fourier transform of

$$\xi \mapsto \begin{cases} \frac{|\xi \cdot \dot{\gamma}(s)|}{2\pi N_\xi |\gamma(s)|} & \text{whenever } N_\xi \neq 0, \\ 0 & \text{otherwise.} \end{cases} \quad (63)$$

Note that there are multiple choices for h whenever $N_\xi > 1$ for some ξ . Furthermore, the filter equation (62) is a necessary condition for $H = \delta$, so an interesting question is to find sufficient conditions.

Remark 18. There is a great deal of literature in the tomography community for constructing filter equations, i.e., designing reconstruction kernels h for 3D FBP methods such that $H = \delta_0$. Most of these results are not applicable to ET since they deal with data collection geometries (cone-beam or helical cone-beam) that arise in medical X-ray tomography and therefore are not parallel beam. Some work on filter equations in the parallel beam context can be found in early work on positron emission tomography [42]. These results are not applicable to ET since they assume $S_0 \subset S^2$ is an open set.

Remark 19. In the 3D electron microscopy literature there are several publications devoted to deriving reconstruction kernels when S_0 is not a curve, but rather some irregular subset of S^2 . This is motivated from the needs in single particle analysis when one seeks to invert the ray transform on a parallel beam line complex in which S_0 is an open set and the sampling is irregular/random within S_0 . These results are nicely surveyed in [143].

Comments and Discussion

The main advantage of FBP/WBP is that it is fairly easy to implement, so most software packages for ET have at least one of these methods implemented as listed in [143]. The methods are furthermore efficient enough to allow for large scale 3D reconstructions in short time. Next, the reconstruction quality is sufficient for answering biological questions that only require interpretation of 3D structural details larger than 60–80 nm.

There are several disadvantages that comes with using FBP/WBP. First, one assumes a forward model given by the ray transform, so data should be pre-processed accordingly to reflect that assumption. Next is to choose a reconstruction kernel to yield an approximative inverse, which in FBP is governed by the band-limit that becomes the regularization parameter. Techniques from sampling theory can now be used to identify efficient sampling schemes, provide qualitative understanding of certain artifacts, and provide guidelines for how to band-limit given a sampling scheme. This is well understood in the planar setting (i.e., in \mathbb{R}^2) for complete and moderately noisy fan or parallel beam data [52, 53, 134], but the situation is less clear in 3D and/or when data is incomplete. Guidelines, like Crowther's criterion [145, p. 316], that relate the “resolution” to the sampling scheme are therefore not applicable to ET even when data is collected by single-axis tilting. Finally, FBP/WBP are not really based on a model of the stochasticity

of the data. Both methods are essentially a discretization of an inversion formula. Therefore, it is difficult (if not impossible) to devise schemes for selecting the filter h that takes into account the specific stochasticity of the data, which in the [ET](#) setting is essentially Poisson distributed.

A common approach when using [FBP/WBP](#) in [ET](#) is to post-process reconstructions to remove speckle, enhance features, and reduce limited angle streak artifacts. The simplest approach for single-axis data is to average over slices. Most software packages offer this possibility to reduce the influence of noise. Other post-process approaches seek to reduce the well-known streak artifacts, see, e.g., [62, 133] in which the latter uses microlocal analysis to explain the appearance of the aforementioned artifacts.

Electron Λ -Tomography ([ELT](#))

[ET](#) data are local so the corresponding inverse problem does not have a unique solution even for continuum noise-free data (section “Incomplete Data, Uniqueness, and Stability”). A natural question is to determine what features that are uniquely recoverable from such local data and to provide stable means for their recovery.

As we shall see, one such feature is the “visible singularities” that provide location of certain edges of objects in the specimen. The visibility depends on the data collection geometry. Furthermore, it turns out that the recovery of the visible singularities is only mildly ill-posed (comparable to inversion of the ray transform on complete data). [ELT](#) is a local reconstruction method that recovers these visible singularities that is based on Λ -tomography. The description given here is based on [151, 155], see also chapter ▶ [Microlocal Analysis in Tomography](#).

Data Pre-processing

Same as for backprojection-based methods (section “Backprojection-Based Methods”).

A Priori Information

Relevant edge information can be recovered by suppressing high-frequency phenomena.

Uniquely Recoverable Signal Features

The analysis of signal features that are uniquely recoverable from local tomographic data relies heavily on microlocal analysis. Microlocal analysis was initially introduced to study how singularities propagated in solutions of partial differential equations [86, 168], and its application to integral geometry was first given in [76]. Somewhat later, microlocal analysis was used in a series of papers for studying the admissibility problem for various restricted generalized ray transforms (integrating over families of geodesics) [73–75]. Further applications in integral geometry came with [20] (support theorems) and [150] (limited data problems for the ray transform in \mathbb{R}^2 and \mathbb{R}^3), see chapter ▶ [Microlocal Analysis in Tomography](#) for a more detailed description.

The central idea in microlocal analysis is that singularities are characterized not only by their location, but also by the high frequencies that cause them. To make this more precise, one makes use of the well-known Fourier characterization of smoothness, i.e., U is smooth if and only if its Fourier transform decays faster than any power of $1/|\xi|$ as $|\xi| \rightarrow \infty$. Localizing this characterization yields a description of the singular support (location of the singularity). The formal definition of a wavefront set is given by a further localization, microlocalization, that characterizes those directions in Fourier space where we lack smoothness (i.e., direction of those high frequencies causing the singularities):

Definition 3 (The Wavefront Set). Let $x_0 \in \mathbb{R}^n$ and $\xi_0 \in \mathbb{R}^n \setminus \{\mathbf{0}\}$. We say that U is smooth near x_0 in the direction ξ_0 if there is a smooth cut-off function ϕ near x_0 (i.e. ϕ has compact support and $\phi(x_0) \neq 0$) such that $\mathcal{F}[U\phi]$ is rapidly decaying in some open conical neighborhood of ξ_0 . The wave front set, $\text{WF}(U)$, of U are those points (x_0, ξ_0) where U is not smooth near x_0 in the direction ξ_0 .

A simple example might aid the intuitive understanding. If U has a jump discontinuity along a smooth hyper-surface $\Gamma \subset \mathbb{R}^n$, then $\text{WF}(U)$ consists of (x_0, ξ_0) where $x_0 \in \Gamma$ and ξ_0 is normal to Γ .

Remark 20. The above definition skips some mathematical technicalities, e.g., ξ_0 is actually a cotangent vector and not an element in the same space as x_0 . This distinction becomes important when one defines the wavefront set for functions (or distributions) defined on smooth manifolds. Furthermore, one can also introduce Sobolev wavefront sets that encodes Sobolev regularity, see [151] and chapter ▶ [Microlocal Analysis in Tomography](#) for details.

Next, for inverse problems it is natural to seek to characterize singularities of the signal that are detectable in data. In the context of inverting the ray transform, a singularity $(x, \xi) \in \text{WF}(U)$ is said to be *visible* from ray transform data $g = \mathcal{P}(U)$ if it corresponds to a singularity in $\text{WF}(g)$. Thus, visible singularities are those that leave traces in data, and these can be characterized if data g is given on a parallel beam line complex:

Theorem 1 (Microlocal Regularity Principle). A singularity $(x, \xi) \in \text{WF}(U)$ is visible from ray transform data $g = \mathcal{P}(U)$ on $\mathcal{M}_{S_0}(\Omega_0)$ if and only if there is a line in $\mathcal{M}_{S_0}(\Omega_0)$ through x to which ξ is co-normal (with a few exceptions). Furthermore, the recovery of the visible singularities is mildly ill-posed in the sense that the singularities in the data g are weaker than those of U by $1/2$ Sobolev order (good enough to allow stable detection in practice).

An important special case is when U , as in the example following Definition 3, is smooth except for a jump discontinuity along a smooth hyper-surface Γ . Then, a singularity at $x \in \Gamma$ is visible if and only if there is a line in $\mathcal{M}_{S_0}(\Omega_0)$ that goes through x and is tangent to $\mathcal{M}_{S_0}(\Omega_0)$ (with a few exceptions).

Remark 21. In order to simplify the presentation, we have left out an array of technicalities in the formulation of Theorem 1, see, e.g., [151, theorem 6.3] for a rigorous formulation in the single-axis tilting case. Note also that this theorem is not dealing with a specific reconstruction method. It is more analogous to a “uniqueness” result describing what is possible to recover (assuming one has no further a priori information) irrespective of the reconstruction method.

Reconstruction Operator

We have seen that visible singularities are signal features that are uniquely recoverable from continuum ray transform data on $\mathcal{M}_{S_0}(\Omega_0)$. **ELT** is a reconstruction method that recovers such singularities from **ET** data. It is an adaptation of Λ -tomography, which was developed independently of microlocal analysis and first introduced in [173, 178] as a local tomographic reconstruction method.

To describe **ELT**, we start off by considering $S_0 = S^2$. Then, [52, eqs.(4–6)] yields the following generalization of (58) for $m \geq -1$:

$$\Lambda^m(U) * H = \mathcal{P}_{S_0}^*(h \otimes \mathcal{P}(U)) \quad \text{on } \mathcal{M}_{S_0}(\Omega_0) \text{ for } H := \mathcal{P}_{S_0}^* \Lambda^{-m}(h). \quad (64)$$

Here, $\mathcal{P}_{S_0}^*$ is the backprojection operator given in (59) and Λ is Calderón’s operator that is defined in terms of the Fourier transforms as $\mathcal{F}[\Lambda(U)](\xi) := |\xi| \mathcal{F}[U](\xi)$ for $U \in \mathscr{S}(\mathbb{R}^3, \mathbb{C})$. Now, we proceed like in the **FBP** method, i.e., we first derive a reconstruction kernel h for exact recovery of $\Lambda^m(U)$ by selecting h so that $H = \delta$ in (64). The regularized variant is obtained by band-limiting the aforementioned reconstruction kernel, which in turn provides an approximative inverse of $\Lambda^m(U)$. The case $m = 1$ is of specific interest since $\Lambda(U)(x)$ is unaffected by local tomography artifacts (section on p. 985) as its calculation by (64) only involves lines passing through a small neighborhood of x .

In **ET**, $S_0 \subset S^2$ is a curve. For simplicity, consider the case when S_0 is the equator in the (x, y) -plane. Then $\mathcal{P}_{S_0}^* \mathcal{P} U = k * U$ where

$$k(x) := c \delta(z) \frac{1}{|x'|} \quad \text{with } x' = (x, y).$$

Let Λ' and Δ' denote the 2D variants of Λ and the Laplacian restricted to the (x, y) -plane, i.e., $\Lambda' := \sqrt{-\partial_1^2 - \partial_2^2}$ and $\Delta' := \partial_1^2 + \partial_2^2$. Then,

$$\Lambda' \mathcal{P}_{S_0}^* \mathcal{P} U = c U \quad \text{so} \quad \Delta' \mathcal{P}_{S_0}^* \mathcal{P} U = c \Lambda' U. \quad (65)$$

Since the tangent to the great circle $\omega_3 = 0$ is contained in ω_3 -plane and is orthogonal to ω , we can write (65) as

$$\Lambda' \mathcal{P}_{S_0}^* \mathcal{P} U = \mathcal{P}_{S_0}^* \sqrt{-\mathcal{D}_{S_0}^2} \mathcal{P} U = c U \quad \text{and} \quad \Delta' \mathcal{P}_{S_0}^* \mathcal{P} U = \mathcal{P}_{S_0}^* \mathcal{D}_{S_0}^2 \mathcal{P} U = c \Lambda' U$$

where $\mathcal{D}_{S_0}^2 := (-\omega_2 \partial_1 + \omega_1 \partial_2)^2$. To summarize, we obtain

$$c \Lambda' U = \mathcal{P}_{S_0}^* \mathcal{D}_{S_0}^2 \mathcal{P}(U). \quad (66)$$

Generalizing the above calculation to arbitrary curves $S_0 \subset S^2$ provides the Λ -term for the reconstruction operator in [ELT](#) [151]:

$$\mathcal{R}_{\text{ELT}}(g) := -\mathcal{P}_{S_0}^* (\mathcal{D}_{S_0}^2(g)). \quad (67)$$

Here, $\mathcal{D}_{S_0}^2$ is a second order differentiation in ω^\perp -plane along the tangential direction to the curve S_0 , i.e.

$$\mathcal{D}_{S_0}^2(g)(\omega, y) := \frac{d^2}{ds^2} g(\omega, y + s\sigma) \Big|_{s=0} \quad (68)$$

with σ denoting the unit tangent to S_0 at $\omega \in S_0$. Analogous to (66), it is shown in [56, theorem 5.1]. that if S_0 fulfills Orlov's criterion, then $\mathcal{R}_{\text{ELT}}(g)$ recovers a singular pseudodifferential operator acting on U_{true} (the cited theorem does not hold for single-axis data but the result is true also for that case as shown in [151]). When Orlov's criterion is not fulfilled, then for single-axis data it turns out that the visible singularities of U_{true} correspond to singularities of $\mathcal{R}_{\text{ELT}}(g)$ whenever $g = \mathcal{P}(U_{\text{true}})$, see [151] and chapter ▶ [Microlocal Analysis in Tomography](#).

Adaptation to [ET](#)

The actual reconstruction operator in [ELT](#) is given as

$$\mathcal{R}_{\text{ELT}}(g) := \mathcal{P}_{S_0}^* (\mu - \mathcal{D}_{S_0}^2(g)). \quad (69)$$

This represents a local inversion method that recovers two important signal features. The pure Λ term defined in (67) emphasizes differences in data that occur at boundaries, i.e., this term picks up visible singularities. However, it does not distinguish interiors from exteriors since the derivative in these areas is typically small. The pure backprojection term (μ term) adds an averaged version of U that introduces contour to the reconstruction and allows one to distinguish objects from their surrounding.

In the implementation of [ELT](#), the $\mathcal{D}_{S_0}^2$ operator in (69) is evaluated using a filter that is a smoothed version of the second derivative (a smoothed central second difference), and the half-width of the filter is determined by the signal-to-noise characteristics of the data. Hence, [ELT](#) has two regularization parameters, μ and the width of the derivative kernel. A method for choosing μ is given in [54] where the idea is to pick μ so that the \mathcal{R}_{ELT} reconstruction is as flat as possible inside a pre-specified feature. Furthermore, like in [FBP](#), one can also convolve in the detector plane along the direction perpendicular to σ (see (68)), which for single-axis tilting is just averaging over slices.

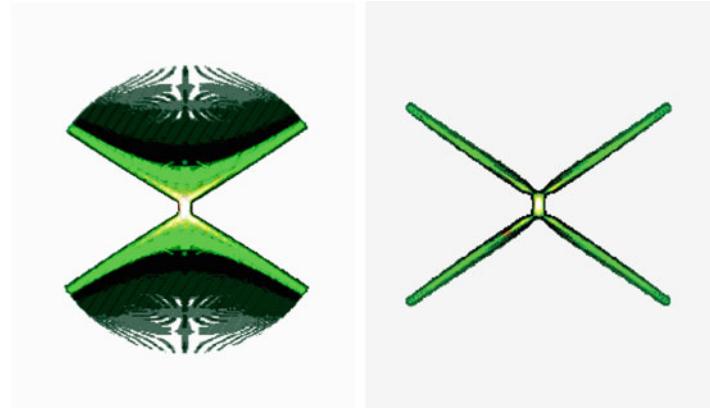

Fig. 6 A three-dimensional surface plot of the point response of **FBP** and **ELT** ($\mu = 0$) for single axis tilting (beam direction is vertical, and the tilt-axis is perpendicular to the plane) with maximum tilt-angle is 60° . Point response is more localized in **ELT** (right) than in **FBP** (left) (image from [155])

Comments and Discussion

There are several advantages in using **ELT** as compared to **FBP/WBP**. First, let us compare the convolution kernels for **ELT** and **FBP** as done in [151, Figure 1]. The **ELT** kernel is local, so it is zero away from the origin whereas the **FBP** kernel is not. In fact, the oscillations of the **FBP** kernel on the interval where the **ELT** kernel is zero are about 7 % of the maximum amplitude.

Next, **ELT** reconstruction operator has a more localized point response than **FBP** as shown in Fig. 6. The “X”-like wings at the end of the angular range in both point responses are expected in any limited angle backprojection algorithm. The point response is however less localized in the **FBP** case, so the artifacts spread out causing a dilution of the actual signal relative to the background. This renders the **FBP** more noisy than the **ELT** and there is a higher chance to lose a weak signal using **FBP**.

Generalized Ray Transform

Illuminating larger fields of view (regions that extend about 8,000 nm from the optical axis) requires using wider electron beams. Then we must account for the fact that electrons, especially those farther from the central axis, travel along helical curves. Hence, the scattering operator is better modeled by (15) instead of (16), i.e., the ray transform \mathcal{P} in (57) is replaced by a generalized ray transform that integrates over curves $s \mapsto \gamma(s)$ that are solutions to (12).

The **FBP** approach is extended in [106] to handle such generalized ray transforms that integrate over curved electron trajectories. This paper also considers alignment, which in this new setting is far more complex, see also [3, section 4.1.2]. In a similar manner, **ELT** has also been extended to the above setting. This involves

characterizing visible singularities analogous to theorem 1, and deriving local inversion methods [152, 154].

Approximative Inverse

Overview

The method of approximate inverse was originally developed in [118] for solving ill-posed integral equations of first kind. It has since then been extended to a more general setting. The starting point is, as with analytic methods, the reconstruction problem with continuum data (50). The idea is to derive a reconstruction kernel that is independent of data (so it can be pre-computed), and reconstruction is obtained by applying the kernel to data. The kernel is given as a solution of an adjoint equation that involves a mollifier. The regularizing property of approximate inverse comes from the choice of mollifier and robustness of the kernel against noise in data.

The approximative inverse method is by now a well-established approach for regularization with applications to a wide range of inverse problems, see the survey by [170]. Recent developments include extending the framework to a Banach space setting and to handle certain nonlinearities in the forward problem [171, part V]. See also [115] for an interesting unification concept for general regularization methods based on approximate inverse. The application to ET is given in [101, 102].

A Priori Information

As the name suggests, the original formulation of approximate inverse seeks provide an approximative inverse solution to the inverse problem. In this setting, the prior information is the same as for backprojection-based methods (section “Backprojection-Based Methods”). The approximate inverse method is in some sense the natural generalization of the FBP/WBP method to the setting where the forward operator is a general affine operator, like in (57).

Data Pre-processing

Computationally feasible implementations require an affine forward operator, which in particular includes operators of the type in (57).

Reconstruction Operator

We describe the reconstruction operator for linear operators in the Hilbert space setting and refer to [170] for its extensions to more general settings.

Consider a linear forward operator $\mathcal{T}: \mathcal{X} \rightarrow \mathcal{H}$ between Hilbert spaces \mathcal{X} and \mathcal{H} , each with inner products $\langle \cdot, \cdot \rangle_{\mathcal{X}}$ and $\langle \cdot, \cdot \rangle_{\mathcal{H}}$, respectively. Next, let $E_{\gamma}: \mathbb{R}^3 \times \mathbb{R}^3 \rightarrow \mathbb{C}$ be a mollifier for \mathcal{X} . The formal definition in the Hilbert space setting is given on [170, p. 26], but for our purposes it is enough to think of E_{γ} as a smoothing operator that converges to a δ -distribution as $\gamma \rightarrow 0$:

$$\langle E_{\gamma}(x, \cdot), U \rangle_{\mathcal{X}} \rightarrow U(x) \quad \text{as } \gamma \rightarrow 0 \text{ for all } U \in \mathcal{X}.$$

Fix a point \mathbf{x} and a mollifier and define the reconstruction kernel $\phi_x^\gamma \in \mathcal{H}$ as the solution to the adjoint equation

$$\mathcal{T}^*(\phi_x^\gamma) = E_\gamma(\mathbf{x}, \cdot). \quad (70)$$

Note that the above calculation does not depend on data. Moreover, if the above equation lacks a solution, we consider the minimal norm solution, i.e., ϕ_x^γ is the element in \mathcal{X} that minimizes the \mathcal{X} -norm of $\phi \mapsto \mathcal{T}^*(\phi) - E_\gamma(\mathbf{x}, \cdot)$. The reconstruction operator $\mathcal{R}_{\text{AI}}: \mathcal{H} \rightarrow \mathcal{X}$ is now defined as

$$\mathcal{R}_{\text{AI}}(g)(\mathbf{x}) := \langle g, \phi_x^\gamma \rangle_{\mathcal{H}} \quad \text{for } g \in \mathcal{H}. \quad (71)$$

The rationale for (71) is that it provides a mollified solution to our inverse problem. To see this, let $g = \mathcal{T}(U_{\text{true}})$, so

$$\begin{aligned} \mathcal{R}_{\text{AI}}(g)(\mathbf{x}) &= \langle g, \phi_x^\gamma \rangle_{\mathcal{H}} = \langle \mathcal{T}(U_{\text{true}}), \phi_x^\gamma \rangle_{\mathcal{H}} \\ &= \left\langle U_{\text{true}}, \mathcal{T}^*(\phi_x^\gamma) \right\rangle_{\mathcal{X}} = \langle U_{\text{true}}, E_\gamma(\mathbf{x}, \cdot) \rangle_{\mathcal{X}}. \end{aligned}$$

Next, calculating the reconstruction kernel requires solving the adjoint equation (70), which can be done in three different ways: (1) By means of an inversion formula for \mathcal{T} , (2) through a singular value decomposition, and (3) to use a projection method that recasts the adjoint equation into the finite dimensional setting where it can be solved using numerical methods.

One issue is that the adjoint equation (70) needs to be solved for each evaluation point \mathbf{x} . This is clearly unfeasible for 3D tomographic reconstruction problems. If the inverse problem is translation invariant, then it is natural to use convolution type mollifiers that only depend on the difference of the argument: $E_\gamma(\mathbf{x}, \mathbf{y}) = e_\gamma(\mathbf{x} - \mathbf{y})$. Given such mollifiers, the structure of the adjoint equation (70) does not depend on the point \mathbf{x} :

$$\mathcal{T}^*(\phi^\gamma) = e_\gamma. \quad (72)$$

Hence, the reconstruction kernel ϕ^γ is independent of \mathbf{x} and the reconstruction operator yields $\mathcal{R}_{\text{AI}}(g) = U_{\text{true}} * e_\gamma$ whenever $g = \mathcal{T}(U_{\text{true}})$.

Adaptation to ET

The adaptation to ET lies in the computation of the reconstruction kernel which in turn depends on the mollifier and the forward operator. The choice of the mollifier should match the a priori information about U_{true} and choice of γ (regularization parameter) depends on the noise level in data. Since ET is a translation invariant inverse problem, the reconstruction kernel can be computed given these choices by solving (72).

In ET we consider \mathcal{T} as the linear part of (57), i.e., if \mathcal{A} convolves with PSF in (57) then (72) becomes $(\mathcal{P}_{S_0}^* \circ \mathcal{A}^*)(\phi^\gamma) = e_\gamma$. We can now first compute v^γ by solving $\mathcal{P}_{S_0}^* \circ v^\gamma = e_\gamma$, and then compute the reconstruction kernel ϕ^γ from

$\mathcal{A}^*(\phi^\gamma) = v^\gamma$. A common mollifier is to take $e_\gamma(x) := \gamma^{-1}\tau(x/\gamma)$ where τ is a scaling function. PSF(ω, \cdot) has a closed form expression in Fourier space, which provides a closed form expression for the reconstruction kernel in Fourier space for parallel beam geometries relevant for ET. Hence, in ET the convolution with ϕ^γ that defines the reconstruction operator is preferably computed in Fourier space, see [101, 102] for details. A special case is when the PSF(ω, \cdot) = $\delta_{\omega\perp}$ in (57), i.e., we consider the inversion of the ray transform. The corresponding adjoint equation reads as $\mathcal{P}_{S_0}^*(\phi^\gamma) = e_\gamma$, so $\mathcal{R}_{\text{AI}}(g) = \mathcal{R}_{\text{FBP}}(g)$ where h in (60) given by ϕ^γ .

Comments and Discussion

The benefit of approximative inverse, as compared to iterative (section “Iterative Methods with Early Stopping”) and variational (section “Variational Methods”) methods, lies in the combination of computational efficiency and flexibility regarding the type of forward operators it can handle, and to some extent, the type of a priori information it can encode. It is in fact easy, at a first glance, to underestimate the diversity of the a priori information that the approximate inverse method can encode.

First, it is possible to work with a mollifier that is not rotation invariant [116, section 3]. This can be beneficial for ET since resolution is anisotropic due to the limited angle problem. Another possibility is given in [117] where approximative inverse is used for combined reconstruction and feature detection. The feature detection is here represented by a linear operator $\mathcal{L}: \mathcal{X} \rightarrow \mathcal{Y}$ (\mathcal{Y} is the Hilbert space of features). To compute an approximate inverse to $\mathcal{L}(U_{\text{true}})$ requires us to modify the adjoint equation (70) that provides the reconstruction kernel. In this new setting, it becomes $\mathcal{T}^*(\phi_x^\gamma) = \mathcal{L}(E_\gamma(x, \cdot))$. If \mathcal{L} is translational invariant, the adjoint equation is again independent of the evaluation point x and it can be written as $\mathcal{T}^*(\phi^\gamma) = \mathcal{L}(e_\gamma)$. The case when \mathcal{L} is an edge detector is treated in [117]. One can also select $\mathcal{T} = \Lambda$ and thereby perform Λ -tomography (section on p. 994), so approximate inverse extends ELT to the setting where one also includes deconvolution of the PSF.

A drawback with the approximative inverse method is that it is difficult (if not impossible) to devise schemes for selecting the filter γ that takes into account the specific stochasticity of the data.

Iterative Methods with Early Stopping

Iterative methods are a broad class of well-studied methods, see [11, 50, 77] for good surveys of both theory and implementation. The idea is to construct an iterative scheme in \mathcal{X} that, in the limit, converges to a solution of (55), i.e., one of possibly infinitely many ML/least-squares solutions of (53).

Overview

There are three classes of iterative methods, *conjugate gradient*, *Maximum-Likelihood Expectation Maximization (ML-EM)*, and *iterative algebraic* methods. These have over the years been extended in various ways, e.g., to handle nonlinear

forward operators, to account for different types of a priori information (like positivity), and to handle more complex noise models for data. Surveys of these, and other developments, are provided in [25, 81] for iterative algebraic techniques, in [92] and chapter ▶ **Iterative Solution Methods** for conjugate gradient type of methods, and in chapter EM Algorithms for **ML-EM** type of methods.

In the context of **ET**, only iterative algebraic methods are used. Hence, we focus on this category following the excellent exposition in [136, section 5.3], see also chapter ▶ **Tomography**. The main idea is to split the inverse problem in (53) into a finite number of sub-problems. A cyclic iteration over these sub-problems is required to generate the next iterate. The specific choice of splitting leads to different iterative algebraic methods, such as the Algebraic Reconstruction Technique (**ART**) and the Simultaneous Iterative Reconstruction Technique (**SIRT**). The common theme is however to generate an iterative sequence that, in the limit, converges to a least-squares solution of (53).

Data Pre-processing

Same as for the approximate inverse method (section “Approximative Inverse”).

A Priori Information

Iterative methods with early stopping share a common a priori assumption, namely that the iterative scheme is *semi-convergent*. This means that initial iterates recover low-frequency components of the signal in (53). Now, assume noise from data mainly influences the high-frequency components of the signal. Then, an ill-posed problem can be regularized by stopping the iterates before too much of the data noise impairs the reconstruction, i.e., the number of iterates becomes a regularization parameter. Iterates are also often smoothed for further regularization.

One can also account for additional a priori information. A common case is to require that U_{true} is a positive function, or more generally, belongs to a convex set. Such constraints can be enforced by projecting iterates onto the said convex set, albeit at a significant computational cost.

Reconstruction Operator

Consider (53) and split the data (tilt-series) $\mathbf{g} \in \mathbb{R}^m$ into N subsets:

$$\mathbf{g} = (\mathbf{g}_1, \dots, \mathbf{g}_N) \quad \text{with } \mathbf{g}_j \in \mathbb{R}^{m_j} \text{ and } m = m_1 + \dots + m_N. \quad (73)$$

Next, let $\tau_j: \mathbb{R}^m \rightarrow \mathbb{R}^{m_j}$ be the projection onto the j :th data component, so $\tau_j(\mathbf{g}) := \mathbf{g}_j$, and introduce the partial forward operator $\mathcal{T}_j: \mathcal{X} \rightarrow \mathbb{R}^{m_j}$ as

$$\mathcal{T}_j(U) := (\tau_j \circ \mathcal{T})(U) \quad \text{for } j = 1, \dots, N.$$

Then (53) splits into the following set of N sub-problems:

$$\mathbf{g}_j := \mathcal{T}_j(U_{\text{true}}) + \mathbf{g}_j^{\text{noise}} \quad \text{where } \mathbf{g}_j^{\text{noise}} := \tau_j(\mathbf{g}^{\text{noise}}). \quad (74)$$

The k :th iterate in an iterative algebraic method is obtained by performing an inner N -step iteration:

$$\begin{cases} U_k^0 := U_{k-1} \\ U_k^j := U_k^{j-1} + \mu(\mathcal{T}_j^* \circ \mathbf{C}_j^{-1})(\mathbf{g}_j - \mathcal{T}_j(U_k^{j-1})), & j = 1, \dots, N \\ U_k := U_{k-1}^N. \end{cases} \quad (75)$$

Here, $\mathbf{C}_j: \mathbb{R}^{m_j} \rightarrow \mathbb{R}^{m_j}$ is a fixed linear positive definite operator, and a typical choice for linear \mathcal{T}_j is $\mathbf{C}_j := \mathcal{T}_j \circ \mathcal{T}_j^*$. The parameter $\mu > 0$ is a relaxation parameter that is needed for noisy problems, like the one in ET, to reduce the impact of noise in data and speed up convergence.

Remark 22. There is a geometric interpretation of the iterates in (75). Each can be seen as the result of performing N consecutive projections in reconstruction space \mathcal{X} . More precisely, the j -iteration in (75) can be written as $U_k^j := \pi_j^\mu(U_k^{j-1})$ where $\pi_j^\mu(U) := (1 - \mu)U + \mu \pi_j(U)$ with $\pi_j: \mathcal{X} \rightarrow \mathcal{X}$ denoting the projection operator

$$\pi_j(U) := U + (\mathcal{T}_j^* \circ \mathbf{C}_j^{-1})(\mathbf{g}_j - \mathcal{T}_j(U)) \quad \text{for } j = 1, \dots, N.$$

Note that when $\mathbf{C}_j := \mathcal{T}_j \circ \mathcal{T}_j^*$, then $\pi_j(U)$ is merely the projection of the residual $\mathbf{g}_j - \mathcal{T}_j(U)$ onto the solution space of $\mathcal{T}_j(U) - \mathbf{g}_j = \mathbf{0}$.

The specific choice of splitting and choice of \mathbf{C}_j determines the type of iterative algebraic method. The three most common ones are listed below:

Algebraic Reconstruction Technique (ART): This is when data (73) is split up so that \mathbf{g}_j is a scalar corresponding to a single data point, i.e., $N = m$, and $\mathbf{C}_j = \mathcal{T}_j \circ \mathcal{T}_j^*$. The iterative sequence in (75) is now easier to understand when expressed in the full discretized setting. The (fully discretized) linear forward operator is given by multiplication with a $(m \times n)$ -matrix whose rows are denoted by $\mathbf{a}_j \in \mathbb{R}^n$ for $j = 1, \dots, m$. The corresponding sub-problems (74) are now given as

$$g_j = \mathbf{a}_j \cdot \mathbf{U}_{\text{true}} + g_j^{\text{noise}} \quad \text{for } j = 1, \dots, m,$$

and the projection calculation in (75) is expressible as

$$U_k^j := U_k^{j-1} + \mu \frac{1}{\|\mathbf{a}_j\|^2} (g_j - \mathbf{a}_j \cdot U_k^{j-1}) \cdot \mathbf{a}_j \quad \text{for } j = 1, \dots, m.$$

The ART, first introduced in [70], is perhaps the first iterative algebraic technique used for tomographic reconstruction. Later it was recognized it as a special case of Kaczmarz's method.

Simultaneous Iterative Reconstruction Technique (**SIRT**): Compared to **ART**, **SIRT** is the other extreme in the sense that data is not slit, i.e., $N = 1$. Hence, **SIRT** reconstruction is given as

$$U_{k+1} := U_k + \mu \mathcal{T}^*(\mathbf{g} - \mathcal{T}(U_k)). \quad (76)$$

Thus, each iterate corresponds to a full update of the signal that involves a complete sweep through all the data points.

The **SIRT** was introduced to the scientific community in the context of tomography by [65] as an alternative to **ART**. It was later discovered that the **SIRT** is equivalent to Landweber iteration.

Simultaneous ART (**SART**): **SART**, also called block iterative **ART**, was first introduced to the imaging community by [5]. It is a compromise between **ART** and **SIRT** in the sense that N equals the number of views. For **ET** this means that N is the number micrographs in the tilt-series, i.e., $N = m_{\text{lt}}$ and $\mathbf{g}_j \in \mathbb{R}^{n_{\text{det}}}$ corresponds to the j :th micrograph.

The regularizing property of iterative algebraic techniques is far from resolved in the general setting. Most of the literature focuses on proving convergence properties, as reviewed in [25]. Such results are of less interest for ill-posed problems since iterates are stopped long before convergence (assuming the iterates do converge to some point). A fast convergence is nonetheless desirable since this would require fewer iterates before a “good” reconstruction is obtained. In general, the convergence of iterative algebraic methods depends on the splitting. For tomographic data, a good strategy is to do a splitting so that the directions are as orthogonal as possible to the previous ones. Curiously enough, a random choice of directions is almost as good as the optimal choice. This was also recently proved mathematically in [26].

Adaptation to **ET**

The adaptation of iterative algebraic methods to **ET** lies in the choice of forward operator and its adjoint, and in how to select the number of iterates k_{\max} and the relaxation parameter μ .

In **ET** it is rather natural to split the tilt-series into micrographs (2D **TEM** images), so current implementations of iterative algebraic methods are based on **SART** rather than **ART** (even though this is not explicitly mentioned). Modern implementations also include possibility for more involved projection schemes, like component and block component averaging.

As of writing, in the context of **ET** there is no theory that provides a practically useful criteria for how to choose the number of iterates k_{\max} . This is perhaps not that big of an issue since one can always run a couple of extra iterates. If one saves intermediate iterates, each such iterate corresponds to a specific choice of k_{\max} . Concerning μ , an analysis of how its choice influences the qualitative behavior of the iterates must exploit the specific structure of the forward operator. For the 2D ray transform one can show that a strong under-relaxation, i.e., small μ results in iterations that first determine the smooth parts of the signal, while the higher resolution details appear later [136, pp. 113–115]. It is reasonable to expect that the

same holds for a forward operator of the type (57), so the common suggestion in ET is $\mu = 0.01$ (recommended range between 0 and 0.1).

Yet another aspect is related to how the reconstruction space \mathcal{X} is discretized in an implementation. The straight-forward approach is to simply evaluate the function at each voxel center. In [64, 109] one claims that a discretization based on Kaiser-Bessel window functions (blobs) improves the robustness against noise.

Finally, we consider the issue of a priori information. A variety of a priori information relevant for ET can be incorporated into iterative algebraic methods. One can beforehand determine regions where the signal has to attain a given value (say zero), one can set upper and lower values for the signal, or only update parts of the signal. Such Projection Onto Convex Sets (**POCS**)-type of constraints, that can be formulated as the signal belonging to a convex set, can be enforced by projecting iterates. **POCS** was introduced to the electron microscopy community in [28], but convincing evidence of benefits is lacking in ET [145, p. 315]. Iterative algebraic methods can also be used to solve variational regularization methods (section “Variational Methods”) with quadratic energy functionals. A final development is the so-called discrete **ART** where one discretizes the range of the allowed reconstructions. This is obviously suitable for specimens that consist of only a few different materials (gray levels), like in material sciences, and results are encouraging [13, 72].

Comments and Discussion

Iterative algebraic methods offer flexibility regarding the type of forward operators it can handle, and to some extent, the type of a priori information it can encode. Compared to approximate inverse (section “Approximative Inverse”), the flexibility is greater, but so is the computational burden.

SIRT is considered to give smoother reconstructions, but converges more slowly. Still, it is now part of most software packages for ET in both life and material sciences. Both **SART** and **SIRT** perform better than **FBP/WBP** [120], even though the difference is not that dramatic. There are in fact few situations where the significantly longer run-time associated with **SART/SIRT** is worth the effort. The run-time of **SART/SIRT** is however becoming less of an issue thanks to recent parallel implementations that make use of hardware acceleration. These allow reconstructions within a reasonable time of regions as large as $2048 \times 2048 \times 512$ voxels from tilt-series of 60–80 micrographs, each with a size of 2048×2048 pixels [177]. We finally mention [72] where **SIRT**, total variation regularization (section on p. 1008), and the discrete algebraic reconstruction technique are compared for material sciences application of ET.

Variational Methods

Variational methods provide a flexible framework for regularization of (53). Here, the reconstruction is given as a solution to an optimization problem:

$$\min_{U \in \mathcal{X}} \mu \mathcal{S}(U) + \mathcal{D}(\mathcal{T}(U), \mathbf{g}) \quad \text{for } \mathbf{g} \in \mathbb{R}^m \text{ given as in (53).} \quad (77)$$

In the above, $\mathcal{T}: \mathcal{X} \rightarrow \mathbb{R}^m$ is the sampled forward operator, which for **ET** is given by (52), $\mathcal{S}: \mathcal{X} \rightarrow \mathbb{R}_+$ is the *regularization functional* that enforces uniqueness and stability by incorporating a priori knowledge about $U_{\text{true}} \in \mathcal{X}$, $\mathcal{D}: \mathbb{R}^m \rightarrow \mathbb{R}_+$ is the *data discrepancy functional* that quantifies the goodness-of-fit against measured data, and $\mu > 0$ is a *regularization parameter* quantifying the compromise between accuracy and stability. Its choice should depend on the model for the noise, as well as on estimates of the size of the error. Formally, without knowledge of the latter, it is not possible to guarantee a result with low error, neither absolutely nor as a percentage [10].

If (77) is to be a regularization of (53), then solving (77) must be well-posed. Such issues form a central part of the general theory, and current state of the art is nicely surveyed by [169] in the context of imaging.

In the fully discrete setting (54), there is also a nice connection to statistical regularization. If \mathcal{D} is chosen as an affine transformation of the negative log-likelihood of the random variable modeling \mathbf{g} , then (77) corresponds to a maximum a posteriori estimate where the prior probability distribution is given as a Gibbs measure with an energy \mathcal{S} [91, subsection 3.3.2]. Extending this analogy to (53) is more elaborate since it requires a notion of Gibbs measure on the Hilbert/Banach space \mathcal{X} .

Data Pre-processing

Same as for the approximate inverse method (section “Approximative Inverse”).

Entropy Regularization

Overview

Entropy regularization refers to the case when the regularization functional \mathcal{S} in (77) is given by an entropy type of functional. There are plenty of examples, mainly from astronomy, where entropy type of functionals are used for regularization.

Existence, uniqueness, stability, convergence, and convergence rate for the maximum entropy method are studied in [47] when the forward operator is a Fredholm integral operator, but most results seem to be valid for an arbitrary bounded linear operator from \mathcal{L}^1 to a Hilbert space. A similar setting is dealt with in [49], which obtains stability, convergence, and convergence rate results. A wider class of regularization functionals is considered in [159], where convergence rates and error estimates are proved when the forward operator is a compact linear operator between Banach spaces, see also [137] for the case when the forward operator is given by convolution. Likewise, [82] establishes existence and regularity of solutions for convolution type of forward operators and a wide range of entropy type of regularization functionals.

The application to **ET** is in [172] with a mathematical analysis in the language of regularization theory given in [165].

A Priori Information

It is clear that entropy type of functionals do penalize complexity in some sense, thereby acting as a regularization. Entropy type of functionals also measure information content [44], so many attempts to rationalize the usage of entropy for regularization are based on this principle. This motivation is artificial unless there is a natural probability distribution on \mathcal{X} . This leads us to the framework of statistical regularization in which entropy is applied to the set of probability measures on \mathcal{X} [119, Method 3], but that is an entirely different approach for reconstruction.

Another motivation is provided by [38, 174] that considers reconstruction methods (called selection rules) for linear inverse problems with exact data. One starts off by postulating a set of axioms (consistency, distinctness, continuity, locality, and composition consistency) that a reconstruction method should satisfy. Next, it is proved that the least squares method is the only reconstruction method consistent with these axioms when the signal to be reconstructed is a real-valued function, having both negative and positive values, and entropy regularization is the only reconstruction method consistent when the signal to be reconstructed is positive.

Reconstruction Operator

The case we consider here makes use of the relative entropy, so we are given a fixed prior $\rho \in \mathcal{X}$ and the regularization functional is

$$\mathcal{S}_\rho(U) := \int_{\Omega} \left(U(\mathbf{x}) \ln \left(\frac{U(\mathbf{x})}{\rho(\mathbf{x})} \right) - U(\mathbf{x}) + \rho(\mathbf{x}) \right) d\mathbf{x} \quad \text{for } U \in \mathcal{X}. \quad (78)$$

Then, $U \mapsto \mathcal{S}_\rho(U)$ is convex and $\mathcal{S}_\rho(U) \geq 0$. Note also that when $U, \rho \in \mathcal{X}$ represent probability measures, then $\mathcal{S}_\rho(U) = 0$ if and only if $U = \rho$ almost everywhere and $-\mathcal{S}_\rho(U)$ equals the Kullback–Leibler divergence.

Adaptation to ET

In [172] one regularizes the inverse problem in ET by (77) with (78) and a data discrepancy given by a Mahalanobis distance (section “Notion of Solution”). The forward operators are as in (57) and the regularization parameter is chosen according to the Morozov principle, so a user must supply an estimate of the data error.

The Morozov principle for choosing the regularization parameter is not usable for highly noisy data since it requires unreasonably accurate estimates of the data error. Furthermore, a higher reconstruction resolution requires one to estimate the nuisance parameters. Thus, the approach in [172] is extended in [165], which uses an iterated regularization scheme (not to be confused with iterative regularization in section “Iterative Methods with Early Stopping”) that generates a sequence of regularization problems. Within this sequence, the estimate of the data error is “updated.” The nuisance parameters $\omega \mapsto C(\omega)$ and C_0 are recovered by *intertwining* the iterates that update the signal $U \in \mathcal{X}$ with least-squares iterates that update the nuisance parameters and locality in tomographic data is accounted for by constant continuation (section on p. 985). To formulate the precise scheme, for given data $\mathbf{g} \in \mathbb{R}^m$ and nuisance parameters $c \in \mathcal{V}$ (the space of nuisance

parameters), we introduce

$$\epsilon_{\min}(\mathbf{g}, c) := \inf_{U \in \mathcal{X}} \left\| \mathcal{T}(U, c) - \mathbf{g} \right\|_{\mathbb{R}^m}^2.$$

Hence, $\epsilon_{\min}(\mathbf{g}, c)$ is the smallest possible data error (it is zero for exact data). Also, define \mathcal{A}_b as a smoothing operator whose degree of smoothing is regulated by a parameter $b > 0$, it can, e.g., be a low-pass filter where b is the cut-off threshold in the Fourier space. Finally, $0 \leq \delta \leq 1$ is the regularization parameter that governs the updating of the estimate of the data error. Then, for a user provided choice of regularization parameters $\delta, b > 0$, the iterates $(U_j, c_j) \in \mathcal{X} \times \mathcal{V}$ in [165] are defined recursively as

$$c_j := \operatorname{argmin}_{c \in \mathcal{V}} \left\| \mathcal{T}(U_{j-1}, c) - \mathbf{g} \right\|_{\mathbb{R}^m} \quad (79)$$

$$\rho_j := \begin{cases} \mathcal{A}_b(U_{j-1}) & \text{if prior is to be updated,} \\ \rho & \text{if prior is not updated,} \end{cases} \quad (80)$$

$$\epsilon_j := \epsilon_{\min}(\mathbf{g}, c_j) + \delta \left(\left\| \mathcal{T}(\rho_j, c_j) - \mathbf{g} \right\|_{\mathcal{H}} - \epsilon_{\min}(\mathbf{g}, c_j) \right) \quad (81)$$

$$U_j := \begin{cases} \operatorname{argmin}_{U \in \mathcal{X}} \mathcal{S}_{\rho_j}(U) \\ \left\| \mathcal{T}(U, c_j) - \mathbf{g} \right\|_{\mathbb{R}^m}^2 \leq \epsilon_j. \end{cases} \quad (82)$$

Comments and Discussion

Entropy type of regularization performs fairly well, especially on cryo-fixedated in vitro specimens that contain isolated particles in aqueous environment. The idea of updating the estimate of the data error through (81) by choosing $0 < \delta < 1$ is much more robust than directly specifying an estimate for it in (82). On the other hand, one has to be careful in updating of the prior (80). If the prior is updated, reconstructions appear de-noised and de-speckled, but there is a significant risk of creating structures that tend to grow as iterates proceed and therefore are erroneously interpreted as true structures. If the prior is to be updated, it is highly recommended that one uses an edge preserving filter as \mathcal{A}_b . Finally, the nuisance parameters can equally well be estimated off-line by a least-squares approach, removing the need for (79).

TV Type of Regularization

Overview

We use the term “TV type” of regularization for variational methods in which \mathcal{S} in (77) is chosen as

$$\mathcal{S}(U) := \left(\int_{\Omega_0} |\nabla U(\mathbf{x})|^p d\mathbf{x} \right)^{1/p}. \quad (83)$$

Standard **TV** regularization is when $p = 1$, see chapters ▶ [Total Variation in Imaging](#) and ▶ [Numerical Methods and Applications in Total Variation Image Restoration](#) for surveys of its role in imaging. The emphasis here is on its usage in **ET**.

A Priori Information

Standard **TV** regularization is based on the a priori assumption that the signal to be recovered has a sparse gradient, e.g., like a step function.

Reconstruction Operator

The reconstruction operator is given as the solution of (77) with \mathcal{S} as in (83) and \mathcal{D} a suitable data discrepancy functional (section “Notion of Solution”). If the forward operator is affine, and the data discrepancy is strictly convex, then (77) has a unique solution.

Adaptation to **ET**

The first usage of **TV** regularization in **ET** was [1]. The approach is specifically tailored towards single axis tilting data (section “Examples Relevant for **ET**”) since one performs a series of 2D reconstruction in slices orthogonal to the tilt-axis. The regularizing functional is an anisotropic variant of **TV** that accounts for the anisotropy in resolution due to limited angle data (section “Incomplete Data, Uniqueness and Stability”). Standard **TV** regularization has also been applied in [71] on **STEM** data of specimens from material sciences (nano-particles). Results are compared against **SIRT** and **TV** regularization performs significantly better.

Both publications above that deal with **TV** regularization for **ET** have a number of weaknesses. First, no guidance is offered on how to select the regularization parameter. Next, both publications unnecessarily assume a forward operator given as the ray transform, so **ET** data needs to be pre-processed in the same way as for backprojection-based methods (section “Backprojection-Based Methods”). This is not an issue when an amplitude contrast model (section “Forward Operator for Amplitude Contrast Only”) is good enough for modeling micrograph contrast, like for incoherent **STEM** imaging in material sciences, but it is inadequate for **ET** based on **HRTEM** data. Finally, the data discrepancy functional \mathcal{D} is the 2-norm, corresponding to the assumption of additive Gaussian noise whereas the actual noise is more complex. This is however probably not that big of an issue (paragraph on p. 976).

The first two points raised above are in fact addressed in [164] that considers variational regularization of (53) with an affine forward operator of the form (57). The data discrepancy functional \mathcal{D} in (77) is given by the 2-norm and the regularization functional \mathcal{S} is of the form

$$\mathcal{S}(U) := \lambda \left(\int_{\Omega_0} |\nabla U(\mathbf{x})|^p d\mathbf{x} \right)^{1/p} + \mu \left(\int_{\Omega_0} |U(\mathbf{x})|^q d\mathbf{x} \right)^{1/q}. \quad (84)$$

Hence, choosing $p = 1$ and $\mu = 0$ gives the usual **TV** regularization. The implementation works with a forward operator that models both amplitude and phase contrast for any parallel beam geometry. Nuisance parameters $\omega \mapsto C(\omega)$ and C_0 are estimated by least-squares from tilt-series data and locality in tomographic data is accounted for by constant continuation (section on p. 985). The main scientific contribution of [164] is however a method for choosing the regularization parameter that is specifically designed for highly noisy **ET** data.

Comments and Discussion

Variational methods, like **TV** regularization, often perform very well in reducing speckle and noise if the choice of regularization functional correctly encodes some of the a priori regularity properties of U_{true} . An issue is however their computational feasibility, and this is especially so for **TV** regularization in 3D imaging. The non-differentiability of the regularization functional in **TV** makes it difficult to directly use efficient gradient-based methods for solving (77). There are several iterative approaches for this purpose, see chapter ▶ [Numerical Methods and Applications in Total Variation Image Restoration](#) for further details. This issue of computational feasibility is also related to choosing the regularization parameter. In contrast to iterative methods (section “Iterative Methods with Early Stopping”), for variational approaches each choice of regularization parameter requires a new iterative sequence. Hence, a critical part of computational feasibility is the ability to choose the regularization parameter.

Another issue with **TV** regularization relates to the suitability of using the (83) with $p = 1$. This results in reconstructions that often have too narrow dynamic range and suffer from stair-casing. This might not be an issue for automated image analysis tasks, like segmentation, but biologists consider such reconstructions to have an “unnatural” appearance. As an alternative to standard **TV** regularization, one could consider using other **TV**-like energy (semi) norms, e.g., empirical tests show that using $1.1 \leq p \leq 1.5$ in (84) gives reconstructions that compare favorably to **TV** (the case $p = 1$) regarding noise/speckle reduction, while gray-scale variations are recovered better. One can also consider Besov norms that are discretization-invariant and better at recovering smoothly varying parts of the signal [105]. An interesting approach is to consider the norm parameter p as a nuisance parameters and try to estimate it from data, like in [182] for the Besov norm. Another is to combine **TV** regularization with Bregman iterates and/or use higher-order **TV** methods to better recover smoothly varying parts of the signal and reduce stair-casing [14]. An example, [193] considers a variant of Dirichlet regularization that makes use of geometric information. This corresponds to choosing the regularization functional \mathcal{S} in (77) as

$$\mathcal{S}(U) := \int_{\Omega_0} u(\sigma(U)(x), \kappa(U)(x)) |\nabla U(x)|^2 dx$$

where $\sigma(U)(x)$ denotes the mean Gaussian curvature of the level-set surface of U at x , and $u: \mathbb{R}^2 \rightarrow \mathbb{R}_+$ is a user specified function. The optimization problem is by

solving an L^2 -gradient flow using calculus of variations. The method is compared against **SART**, **SIRT**, and **WBP** on a tilt-series of a cryo-fixated in vitro specimen with isolated HIV virions in aqueous buffer.

Finally, one may also consider using a norm in a variable Lebesgue space (Theorem 2.15 and 2.17 in [36]). Already in [18] it was suggested that in image reconstruction, a smoother image could be obtained by an interpolation technique that uses a variable exponent that decreases monotonically from two to one as ∇U increases, see comments in pp. 7–8 in [36]. This however leads to a non-convex functional that is computationally difficult to handle. One approach is then use Λ -tomography to determine the variable exponent. More precisely, consider the regularization functional

$$\mathcal{S}(U) := \int_{\Omega_0} |\nabla U(x)|^{p(|\nabla \rho(x)|)} dx \quad (85)$$

where $p: \mathbb{R}_+ \rightarrow [1, 2]$ is monotonically decreasing, e.g., $p(t) = 2/(1 + 2t)$, and ρ is pre-computed from data. If the singularities of ρ are at the same location as U_{true} , then using (85) instead of (83) yields much smoother reconstructions in regions of moderate gradient and thus prevents stair-casing [33]. One can use **ELT** to calculate ρ and use microlocal analysis to characterize the singularities of ρ that coincide with those of U_{true} (section on p. 994). Albeit convex, the downside of using (85) is that it is not 1-homogenous, so multiplicative scaling might change the values of the regularization functional.

Sparsity Promoting Regularization

Overview

As we have seen, sampling theory is at the heart of many image reconstruction algorithms for tomography, like **FBP/WBP** (section “Backprojection-Based Methods”). These methods make the assumption that noise is predominantly a high frequency phenomena, whereas relevant image features occupy low frequencies of the signal. Most signals are however sparse (compressible) in some suitable representation. It turns out that this a priori knowledge, if properly utilized, allows one to recover the signal from relatively few and/or highly noisy measurements.

A straightforward way to take advantage of sparsity often leads to solving (77) with an 0-norm as regularization functional, which unfortunately is computationally unfeasible. Within geophysics and other scientific/engineering disciplines, it has been known since the late 1970s that one can use the computationally feasible 1-norm instead of the 0-norm in certain cases. This observation was put into a formal mathematical setting in 2004 with the advent of a new sampling theory, compressed sensing, which puts precise conditions on a linear inverse problem for when the 1-norm on $U \mapsto \rho(U)$ in (77) gives the sparsest solution [27]. The field has since then exploded with several remarkable and far-reaching results, see chapter ▶ **Compressive Sensing** and the recent book [59] for an up-to-date survey. Below we focus on the role of sparsity in **ET**.

A Priori Information

Let us start by formalizing the notion of sparsity. We say that $\rho: \mathcal{X} \rightarrow \mathcal{Y}$ is a sparsifying map for $U_{\text{true}} \in \mathcal{X}$ whenever $\rho(U_{\text{true}})$ is “well approximated” by a low-dimensional subspace of \mathcal{Y} (\mathcal{Y} is here some suitable vector space). A common example is when there is a fixed set $\{\phi_i\}_i \subset \mathcal{X}$ (dictionary) such that $U \sim \sum_i \alpha_i \phi_i$ with most $\alpha_i \approx 0$. In such case, \mathcal{Y} is the space of sequences and $\rho(U) := \{\alpha_i\}_i$. Another example is $\rho(U) := |\nabla U|$, which leads to **TV** regularization (section on p. 1008).

Reconstruction Operator

Assume that ρ is a sparsifying map for $U_{\text{true}} \in \mathcal{X}$ in (53) (or (54)). It is now natural to consider the most sparse **ML** solution (55) by solving (77) using a regularization functional given as the 0-norm of $U \mapsto \rho(U)$.

Much of the theoretical development in compressed sensing deals with when one can replace this 0-norm with a 1-norm, the latter being computationally feasible. Most of the mathematical results apply for linear finite dimensional reconstruction problems (54) where the noise in data is additive Gaussian. If the matrix representing the fully discretized forward operator (sensing matrix) fulfills certain mathematical criteria (restricted isometry property and coherence w.r.t. the sparsifying map), then the optimization below yields the sparsest solution to (54):

$$\min_{U \in \mathbb{R}^n} \mu \|\rho(U)\|_1 + \|\mathbf{T}(U) - \mathbf{g}\|_{\mathbb{R}^m}^2 \quad \text{for } \mathbf{g} \in \mathbb{R}^m \text{ given as in (54).}$$

Adaptation to **ET**

Ideas of applying compressed sensing to **ET** have been discussed in [17] for **STEM** data from material science specimens. The forward operator is the ray transform and the data discrepancy functional is based on additive Gaussian noise model. The paper discusses dictionaries, like blobs (p. 1005), but examples show **TV** regularization.

Comments and Discussion

A key step in using sparsity is to suggest a sparsifying map. There is a wide range of (possibly over-complete) dictionaries, both analytic and learned, to choose from for sparsely representing texture/gray scale and edge information in images [48, 163]. Which ones are suitable for a specific **ET** application? As an example, the sparsest representation of a molecule is simply given by listing its atoms and their positions, e.g., following the RCSB Protein Data Bank specification. The corresponding sparsifying map is however only applicable when the electrostatic potential (the real part of the signal) is resolved to a 3D resolution of about 0.1 nm, which is way beyond what is reachable in **ET** applications in biology. Still, there are several notions for describing 3D structural information in macromolecular assemblies that could be used in the design of dictionaries. As an example, tertiary and quaternary structure descriptions are resolvable in **ET**, but it is unclear what dictionaries to use for encoding such structural information.

The next key issue is to what extent we have a sensing matrix that fulfills the criteria for replacing the 0-norm with the 1-norm. Unfortunately, there are no efficient methods for determining whether a sensing matrix is coherent w.r.t. a dictionary and/or fulfills the restricted isometry property. As an example, it is an open problem to provide deterministic and explicit methods that yield matrices that fulfill the restricted isometry property. On the other hand, it is well known that a random matrix will satisfy the restricted isometry property with high probability if its entries are samples of any sub-gaussian distribution [39, section 1.4.4]. There are also results in this direction for certain deterministic sensing matrices [21], but none of these results are applicable to [ET](#).

Other Reconstruction Schemes

Here we very briefly mention other reconstruction methods used in [ET](#). In [2] one applies geometric tomography to [ET](#) on [STEM](#) data from material sciences specimens. A similar approach is discrete tomography that was applied in [29] to [ET](#) on [TEM](#) data from biological specimens. This did not bring any benefits, but the situation is different in material sciences [12], see also comments regarding discrete [ART](#) on p. 1005.

Another approach deals with simultaneous reconstruction and segmentation within the framework of variational methods. Here, the Mumford–Shah functional can be used, see chapter ▶ [Mumford and Shah Model and Its Applications to Image Segmentation and Image Restoration](#) for an extensive review. In [94] one applies this approach to simulated [ET](#) data, and results are encouraging.

Finally, there is the possibility of making use of a priori shape information in the regularization (shape-based regularization). Shapes constitute the most important a priori knowledge that biologists use in their analysis of 3D reconstructions. A difficulty is that shapes are complex objects that are difficult to precisely describe as mathematical entities in a way feasible for computational treatment. Next, in biology no two objects have identical shape. Hence, the notion of shape must incorporate some form of statistics. The first approach to demonstrate the importance of shape information in the context of [ET](#) was taken in [69]. Here, variational regularization is used with a regularization functional that is based on a spatial prior that encodes local shape related geometric information. The interesting outcome of this attempt is that prescribing shape information on a small sub-set of the region of interest sharpens the entire reconstruction. An entirely different approach, that is much more robust against misspecification in a priori shape information, is based on shape metrics from the Large Deformation Diffeomorphic Metric Mapping ([LDDM](#)) framework in [194], see also chapter ▶ [Shape Spaces](#). The idea is that one has shape information given as a set of regions $\mathfrak{O} := \{\Omega_j\}_{j=1,\dots,k} \subset \Omega_0$ with associated *shape templates* $\mathfrak{I} := \{I_j\}_{j=1,\dots,k}$ where $I_j: \Omega_j \rightarrow \mathbb{R}$ is such that

$$U_{\text{true}}|_{\Omega_j} \approx \phi_j \cdot I_j \quad \text{for some admissible diffeomorphism } \phi_j \in G.$$

Here, G is the group of admissible diffeomorphisms that acts by the natural group action on the set \mathcal{X} of potentials. The above simply encodes the assumption that shapes of certain substructures in the specimen, namely those contain in Ω_j , are known up to a deformation. Such information can be obtained from an initial 3D reconstruction, or by prior knowledge. Shape-based regularization is now defined as variational regularization (77) with \mathcal{S} given as

$$\mathcal{S}(U) := \mathcal{S}_{\text{reg}}(U) + \alpha \mathcal{S}_{\text{shape}}(U; \mathfrak{O}, \mathfrak{I}, \boldsymbol{\mu}) \quad (86)$$

where \mathcal{S}_{reg} encodes a priori regularity properties of U_{true} and $\mathcal{S}_{\text{shape}}$ is the *shape functional* accounting for shape information given by \mathfrak{O} and \mathfrak{I} :

$$\mathcal{S}_{\text{shape}}(U; \mathfrak{O}, \mathfrak{I}, \boldsymbol{\mu}) := \min_{\phi_1, \dots, \phi_k \in G} \sum_{j=1}^k \left[d_{\text{shape}}(U|_{\Omega_j}, I_j)^2 + \mu_j \left\| \phi_j \cdot I_j - U|_{\Omega_j} \right\|_2 \right].$$

In the above, d_{shape} is the shape metric given by LDDM [194] that measures the shape similarity between the shape template and U_{true} . Hence, one combines an energy functional for regularity (like TV or Dirichlet energy) with a shape metric against a shape template [138]. Initial tests on 2D tomography (see Fig. 7) show that it is clear that a priori shape information, even imperfect, has a great potential in improving the reconstruction.

10 Validation

A serious obstacle in the development of computational methods for ET is the lack of proper validation tools. None of the reconstruction methods mentioned in this review has been validated mathematically (e.g., proof of convergence and error estimates) in a context that is relevant for ET. Moreover, there are no theoretical results that give bounds on the best possible “resolution,” partly because it is unclear what notion of resolution to use. Hence, validation must be based on ET data from phantoms (specimens whose structure/potential is precisely known). Physical phantoms, i.e., physical specimens with a precisely known structure, only exist in material sciences. Hence, for many ET application one is confined to simulated data. To avoid committing an “inverse crime,” both the simulator and phantom generator need to be as accurate as possible. This is nontrivial as explained in [166, 187].

Finally, there is the issue of defining objective criteria for evaluating the quality of a reconstruction. This is closely related to the problem of defining a notion of resolution. Statistical approaches based on defining figures-of-merit are outlined in [30], but this approach only works for validation against simulate data.

Notion of Resolution

Intuitively one would expect that resolution *quantifies the size of the smallest features that can be reliably reconstructed*. Due to formal non-uniqueness (section “Incomplete Data, Uniqueness and Stability”) in ET, one needs a notion of resolution for the visible wavefront set. This in turn requires precise control of the

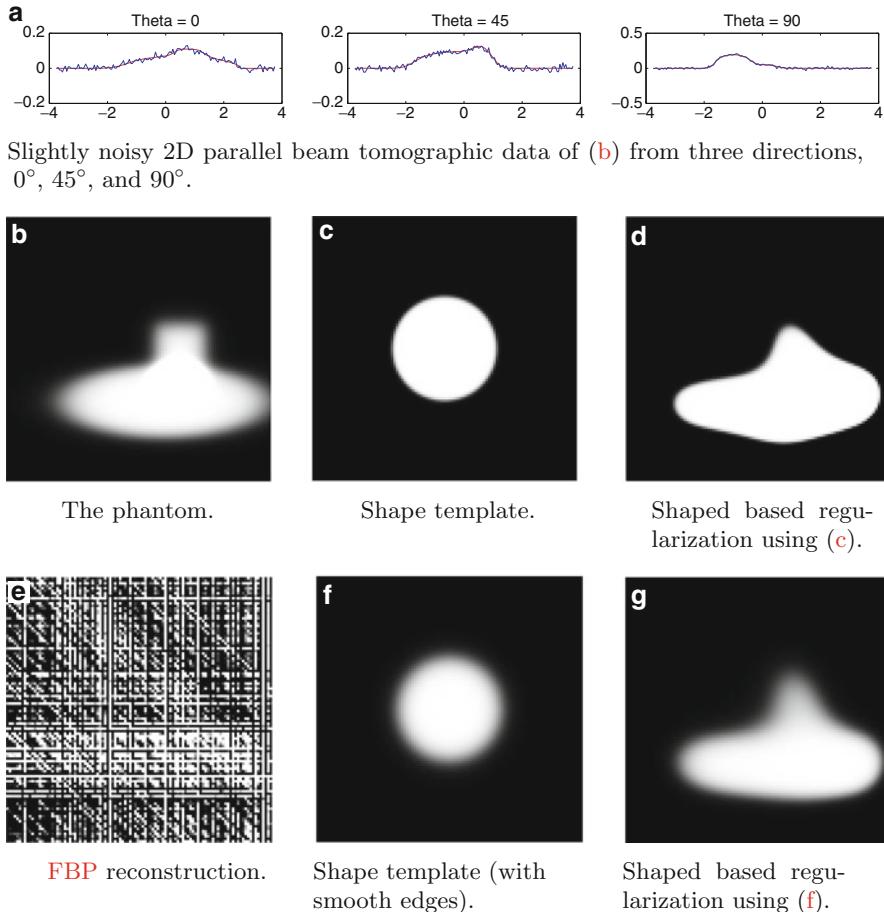

Fig. 7 Test of 2D tomography with imperfect shape information. All reconstructions are based on data in (a). It is interesting to see how edge smoothness of the shape template affects the reconstruction. (a) Slightly noisy 2D parallel beam tomographic data of (b) from three directions, 0° , 45° , and 90° . (b) The phantom. (c) Shape template. (d) Shape-based regularization using (c). (e) FBP reconstruction. (f) Shape template (with smooth edges). (g) Shape-based regularization using (f)

constants in the Sobolev estimates that characterize the visible wavefront set. Some work in this direction is pursued in [153]. Secondly, it would also be of interest to have the corresponding characterization of visible wavefronts when the PSFs for the TEM optics and detector are included, and/or when one considers the full inverse scattering problem (i.e., the scattering operator is given by (6)).

The notions of resolution used in ET are all essentially different ways of estimating the spectral signal-to-noise ratio [144]. A serious drawback is that these notions do not account for the main degrading factor, the influence of the shot noise (section “Characteristics of the Noise”). Thus, a notion of resolution in ET has to

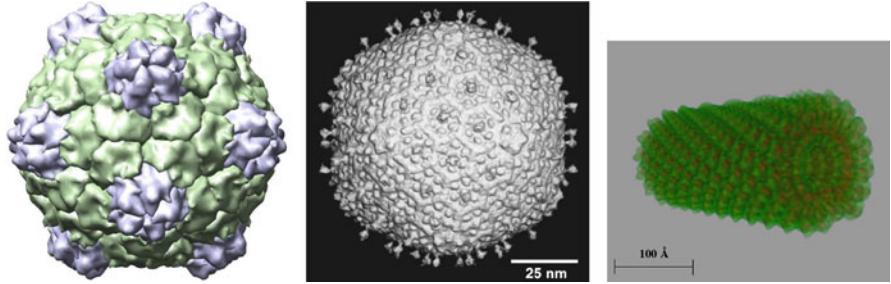

Fig. 8 Surface rendered electrostatic potentials calculated from atomic resolution models of a **CPMV** (left), a bacteriophage T4 head (middle), and a **TMV** (right) particle. The **CPMV** virion has a diameter of 28 nm [112], T4 bacteriophage head has a “diameter” of about 80 nm [108], and a **TMV** virion is about 300 nm long and 18 nm in diameter [132]. Hence, the diameter of the **CPMV** is about 1/3 of the diameter of the bacteriophage T4 head and 1.5 times the diameter of the **TMV**

include probabilistic concepts, see, e.g., [157, 180, 190] for ideas along these lines. To summarize, there is still no useful notion of resolution for **ET**.

11 Examples

This section shows results of different reconstruction methods applied to simulated and experimental single-axis tilt-series data, the latter courtesy of **FEI**. The **WBP** and **SIRT** reconstructions are obtained using **IMOD** v. 4.3.7 [124], the approximate inverse reconstructions are from Holger Kohr based on [102], and the variational regularization reconstructions are by software from Hans Rullgård based on [164].

Regularization Parameters

For **WBP**, it is the distance r (in pixels) of the radial reconstruction kernel in Fourier space before it is cut-off by a Gaussian with variance σ . For **SIRT** it is the number of iterations. For approximate inverse, it is the width γ of the Gaussian mollifier (paragraph on p. 999), and for variational methods, it is μ in (77).

Tilt-series data is not processed. **WBP** and **SIRT** assume data are samples of the ray transform, whereas the variational and approximate inverse methods implement (57) in which the **PSF** models the optics and the detector in the standard phase contrast model (section on p. 967).

Balls

This is a simulated single-axis tilt-series generated using the **TEM** simulation software in [166] of a phantom consisting of 40 balls with different size and contrast embedded in aqueous buffer.

Simulations represent a single-axis tilt-series acquired from a 300 keV conventional bright-field **TEM**. The tilt-angle ranges from -60° to 60° with one

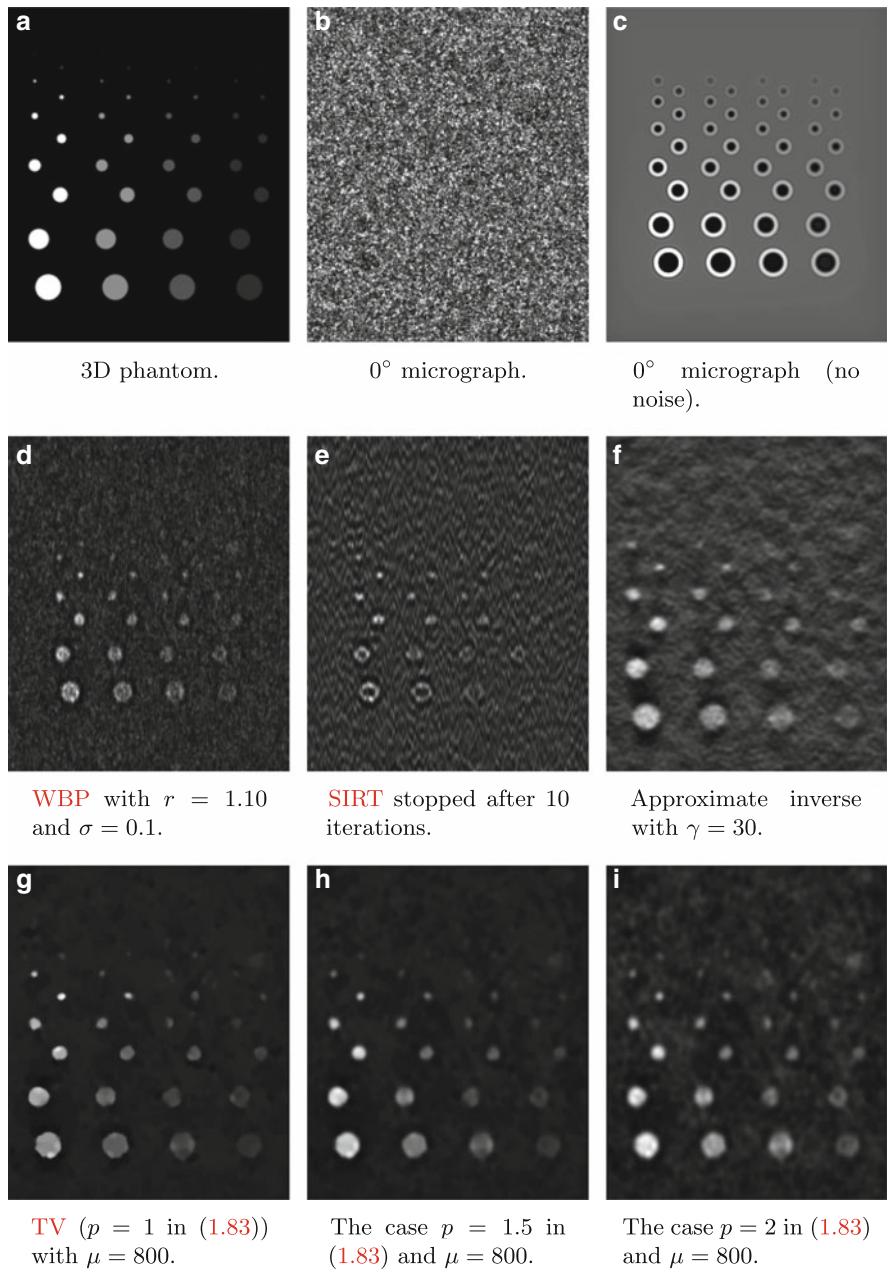

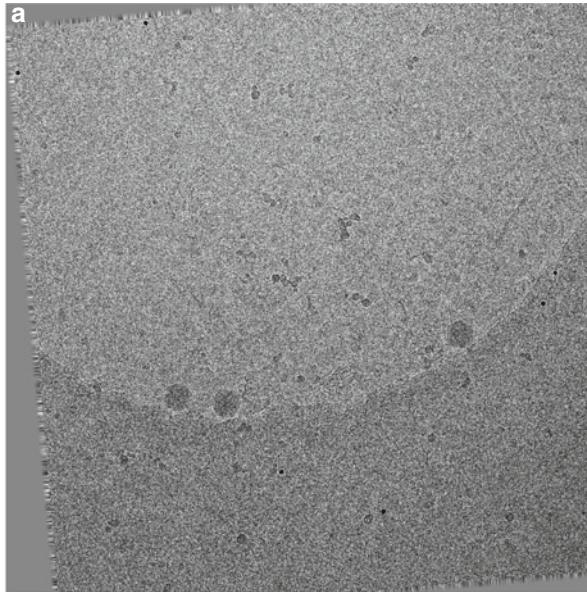

Fig. 9 Simulated data from a balls phantom. (a) shows a 2D cross-section of the phantom and (b) is the zero-tilt image, with (c) showing the noise-free version. micrograph every second degree, i.e., 61 micrographs in total. The 3D region of interest Ω_0 is a rectangular $210 \times 250 \times 40$ voxel region, with 0.5 nm voxels. Magnification is $25,000\times$, defocus is $3 \mu\text{m}$, $f = 2.7 \text{ mm}$ (focal length), $C_s = 2.1 \text{ mm}$ (spherical aberration), $C_c = 2.2 \text{ mm}$ (chromatic aberration), aperture diameter is $40 \mu\text{m}$, and $\alpha_c = 0.1 \text{ mrad}$ (condenser aperture angle). The detector has $16 \mu\text{m}$ pixels, $C_{\text{gain}} = 80$, and detector response follows (56) with $a = 0.7$, $b = 0.2$, $c = 0.1$, $\alpha = 10$, and $\beta = 40$. Finally, the total dose is $6,000 \text{ e}^-/\text{nm}^2$, which corresponds to $40 \text{ e}^-/\text{pixel}$ in each micrograph.

Virions and Bacteriophages in Aqueous Buffer

This is an experimental single-axis tilt series of a cryo-fixed in vitro specimen that contains a mixture of **TMV**, Keyhole Limpet Hemocyanin, **CPMV**, and T4 bacteriophage particles in aqueous buffer, see Fig. 8.

The single-axis tilt-series was acquired by **FEI** using a 300 keV conventional bright-field **TEM** (FEI Titan Krios with a Falcon direct electron detector). It consists of 81 micrographs that were aligned using IMOD software [124]. There are three regions of interest listed below (voxel size is 0.4767 nm):

Region 1: $512 \times 256 \times 200$ containing mainly **CPMV** virions, see Fig. 10b for corresponding cut-out from the zero-tilt micrograph.

Region 2: $512 \times 256 \times 350$ containing mainly a single bacteriophage T4 head, see Fig. 10c for corresponding cut-out from the zero-tilt micrograph.

Region 3: $512 \times 256 \times 350$ containing mainly portion of a single **TMV** virion, see Fig. 10d for corresponding cut-out from the zero-tilt micrograph.

Micrographs are acquired at $29,370\times$ magnification using a defocus of $6.0 \mu\text{m}$ and a detector with a pixel size of $14 \mu\text{m}$. The total dose is unknown. So are the parameters for the **TEM** electron optical elements and illumination (Figs. 9, 10, and 11).

12 Conclusion

Much of the development in **ET** has circled around new improved and sample preparation. There has been tremendous progress in increasing the resolving power in electron optical elements, which in turn is important for imaging in material sciences. Current state-of-the-art **TEMs** have an optical resolving power of 0.05 nm [93], which is to be compared to the “size” of an isolated neutral atom that ranges between 0.03 and 0.3 nm . There are also strong indications that we are reaching the physical limits for the optical resolving power of an electron microscope, and that is not due to imperfections in optics but rather “noise” from the specimen [158]. Thus, it is reasonable to assume that the optical resolving power will not improve much beyond 0.05 nm .

For **ET** in life sciences, the aforementioned development is not that relevant since the resolving power of the **TEM** optics does not limit the 3D “resolution.” Instead, the limitation here is due to the noise in image data, which in turn is due to the limited dose (section “The Dose Problem”). On the other hand, technological development regarding automation in sample preparation and data collection will have a big impact on **ET** in life sciences. **TEMs** are now stable enough to allow for automated recording of multiple tilt-series from multiple regions of interests within one or multiple specimens. Thus, the amount of available high-quality tilt-series is rapidly increasing and mathematics will have a key role in providing better 3D reconstructions as well as extracting useful information from such 3D reconstructions.

The inverse problem in **ET** also contains open mathematical problems, e.g., there are open problems related to uniqueness and stability (section “Incomplete Data, Uniqueness, and Stability”). Furthermore, the design of regularization methods need to better account for the regularity/sparsity that a specimen poses. An example is the variants of **TV** type of regularization which need to be analyzed carefully from this viewpoint. Notions of sparsity and shape that are applicable to flexible molecular assemblies and/or subcellular structures is a central theme. Yet another central topic is the regularization parameter selection in problems with highly noisy data and/or complex noise models (Poisson and Gaussian, or correlated Poisson and Gaussian). Another area where much remains to be done is to mathematically analyze intertwined reconstruction schemes. These are approaches for handling nuisance parameters (paragraph on p. 989) in the context of classical regularization that often work surprisingly well. Finally, the high level of noise in **ET** indicates that the best framework for reconstruction is offered by statistical regularization. This framework is yet to be applied to **ET** in the sense that one recovers not only a single estimator but also a measure of the uncertainty. Statistical regularization is computationally demanding, so it has had limited applications to imaging problems. Nevertheless, it can be successfully applied to real 3D tomography problems [182], so the approach should also be applicable to **ET**.

Acknowledgments The writing of this review chapter would not be possible without the help of several people. Jan Boman at the Department of Mathematics, Stockholm University and Todd Quinto at the Department of Mathematics, Tufts University provided valuable advice and help, especially regarding material in section “Analytic Methods.” Hans Rullgård at Comsol has provided advice and support regarding the usage of the **TEM** simulation and the **TV**-regularization softwares used in Sect. 11. Remco Schoenmakers at **FEI** generously provided the data used in section “Virions and Bacteriophages in Aqueous Buffer” as well as access to the image in Fig. 1. Milos Vulevic and Bernd Reiger in TU Delft provided valuable insight into the detector modeling in subsection on p. 963, Sergej Masich at the Department of Cell and Molecular Biology, Karolinska Institutet helped out in the alignment of the tilt-series in section “Virions and Bacteriophages in Aqueous Buffer” as well as in running the IMOD reconstructions in Sect. 11. Holger Kohr and Alfred Louis at the Department of Mathematics, Saarlands University contributed to the material on the approximate inverse method and phase contrast tomography. Kohr also provided the approximate inverse reconstructions in Sect. 11. Finally, Günther Uhlmann at the Department of Mathematics, Washington State University provided valuable insight into uniqueness and stability issues discussed in section “Electron–Specimen Interaction.”

Work on this chapter is financially supported by the Swedish Foundation for Strategic Research.

Abstract

This chapter discusses diffuse optical tomography. We present the origins of this method in terms of spectroscopic analysis of tissue using near-infrared light and its extension to an imaging modality. Models for light propagation at the macroscopic and mesoscopic scale are developed from the radiative transfer equation (RTE). Both time- and frequency-domain systems are discussed. Some formal results based on Green's function models are presented, and numerical methods are described based on discrete finite element method (FEM) models and a Bayesian framework for image reconstruction. Finally, some open questions are discussed.

1 Introduction

Optical imaging in general covers a wide range of topics. In this chapter, we mean techniques for *indirect* imaging using light as a method for obtaining observations of a subject. In a typical experiment, a highly scattering medium is illuminated by a narrow collimated beam, and the light that propagates through the medium is collected by an array of detectors. There are many variants of this basic scenario. For instance, the source may be pulsed or time harmonic, coherent, or incoherent, and the illumination may be spatially structured or multispectral. Likewise, the detector may be time or frequency resolved, polarization or phase sensitive, located in the near or far field, and so on. The inverse problem that is considered is to reconstruct the optical properties of the medium from boundary measurements. The mathematical formulation of the corresponding forward problem is dictated primarily by *spatial scale*, ranging from the Maxwell equations at the microscale to the radiative transport equation at the mesoscale and to the diffusion theory at the macroscale. In addition, experimental time scales vary from the femtosecond on which light pulses are generated, through the nanosecond on which diffuse waves propagate, to the millisecond scale on which biological activation takes place and still longer for pathophysiologic changes.

In this chapter, we concentrate primarily on the macroscopic scale and the diffusion model for light propagation. The derivation of this model and its limits of applicability are discussed in section “Radiative Transfer Equation.” Historically, a large amount of early development considered analytic forms for the Green's function of the diffusion equation and series expressions for the effect of perturbations of these propagators by inhomogeneities; usually, only first-order linear methods were considered. These are discussed in section “Green's Functions and the Robin to Neumann Map.” As computational methods become more readily available, more sophisticated approaches using optimization and Bayesian methods are becoming more accepted. We discuss these approaches in Sect. 4.

2 Background

Figure 1 schematically illustrates the two main types of measurement system: time resolved and intensity modulated. In the former, a short duration pulse $\sim 5\text{--}10\text{ ps}$ is employed, and in the latter, a steady-state intensity is created, modulated at a frequency in the range 100–1,000 MHz. Obviously, the spectrum of frequencies in the time domain is many orders higher than in the frequency-domain systems themselves, although the higher frequencies are very heavily damped and carry no information. A third domain is “DC” systems – these are the same as frequency domain, without the modulation. They are much simpler and cheaper, but without a complex wave, the inverse problem is nonunique [6].

Spectroscopic Measurements

Attenuation of light in the near infrared (NIR) is due to absorption and scattering. The parameter of most interest is absorption which is caused by chromophores of variable concentration such as hemoglobin in its oxygenated and deoxygenated states. In the absence of scattering, the change in light intensity obeys the Beer–Lambert law

$$-\ln \frac{I_{\text{in}}}{I_{\text{out}}} = \mu_a d = \alpha_c [c]d, \quad (1)$$

where d is the source-detector separation, which is equal to the optical path length, $[c]$ is the concentration of chromophore c , and α_c is the absorption coefficient per unit length per unit concentration of chromophore c and can usually be obtained in vitro. In the presence of scattering, the optical path length of transmitted photons

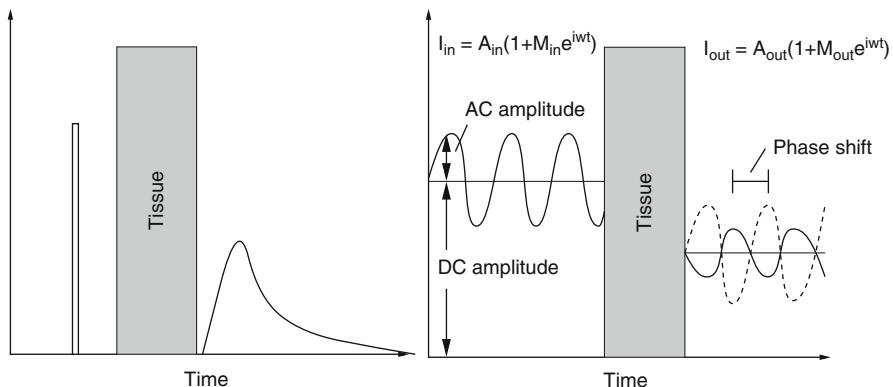

Fig. 1 Optical transillumination measurements made with a time-resolved system (*left*) or an intensity-modulated system (*right*)

follows a much more complex relationship. Hence, attenuation measurements alone do not allow quantification of chromophore concentration.

Continuous intensity (DC) instruments measure changes in the intensity of light leaving the tissue surface [56]. This is frequently done in a purely spectroscopic manner, i.e., to obtain only global changes in chromophore concentration. In order to quantify concentration changes, additional information is required. One approach is to derive an approximate *differential path length factor* (DPF), which restores the approximate Beer–Lambert law for small changes in concentration

$$-\delta \ln \frac{I_{\text{in}}}{I_{\text{out}}} = \text{DPF} \delta \mu_a d. \quad (2)$$

Since there are typically several contributing chromophores, light of different wavelengths in the NIR region is employed, and regression techniques are used to find their relative weightings [26]. It was shown empirically [29] that the DPF is simply the mean time of light multiplied by the speed of light in the tissue. In fact, this relationship follows naturally from the diffusion approximation of light transport [8]. Furthermore, it is equally well approximated by the change in phase of an intensity-modulated system, at least at low modulation frequencies.

Intensity-modulated measurements were first reported by [69]. Most systems use a heterodyne technique to mix the transmitted light with a reference beam of slightly different modulation frequency, thus producing a lower frequency envelope that is easier to detect using RF equipment. Time-resolved systems were first developed using a *streak camera* [29, 49, 73], an instrument with exceptionally high time resolution in the picosecond range but with high cost, relatively low dynamic range, and a significant inherent temporal nonlinearity due to a sinusoidal ramp voltage. Alternatively, *time-correlation single photon counting* (TCSPC) systems measure arrival times of individual photons by comparison with a reference pulse using a time-to-amplitude converter (TAC) device [20, 79, 83]. These systems have a high dynamic range and excellent temporal linearity.

Imaging Systems

Imaging methods can be divided into *direct* systems which seek to detect heterogeneities in tissue by analyzing the transmitted (or, in some cases, reflected) light and *indirect* systems which attempt to solve the inverse problem of image reconstruction. The latter is the main emphasis of this article although the former is historically the precedent, in a similar manner in which x-ray radiographs were the precursor to x-ray computed tomography (CT).

Transillumination of candle light for a patient suffering from hydrocephalus was reported as early as 1831, but the first significant attempt at diagnostic imaging using optical radiation was for breast lesions and was made by Cutler [27], who used a lamp held under the breast in a darkened room. However, even at this stage, multiple scattering effects caused a notable degradation in image quality. The recognition

of this fact led to many attempts to eliminate or minimize the degradation due to scattering ranging from collimation [55] and polarization discrimination [84] to coherence gating using holographic gating [90] or heterodyne detection [82].

With the introduction of time-resolved detectors came the natural attempt to use temporal gating to discriminate early arriving photons (which necessarily have the shortest optical path and therefore suffer the least number of scatterings) from later arriving photons which have undergone multiple scatterings and therefore have ill-determined photon paths. The early implementations of this idea used a Kerr gate as an ultrafast shutter [99]. However, this technique is limited to relatively low-scattering media due to the small dynamic range of the Kerr shutter. Other studies have been based on the streak camera [42] or TCSPC [19] systems described in section “Spectroscopic Measurements.”

The attempt to physically discriminate between photons that have undergone different numbers of scattering events is inherently limited by the statistical likelihood of the low scattering number photons arriving at the detector. For the relatively optically thick tissues that are of interest in breast cancer screening or brain imaging, these photons are overwhelmed by noise. For this reason, indirect methods that solve an inverse problem based on recovering the spatially varying optical parameters that provide the best fit of a photon transport model with the measured data are becoming more prevalent. Within this framework, the three basic strategies (time resolved, intensity modulated, and DC systems) have all been developed and reported. In addition, many different geometrical arrangements have been investigated. Initial studies have been on 2D slice-by-slice imaging, although it is apparent that the photon propagation must in reality be described by a 3D model. Fully 3D methods are now appearing.

In the remainder of this article, we will discuss the inverse problem and the strategies that have been adopted in order to solve it. In order to analyze this problem, we first have to consider the model of photon transport in dense media.

3 Mathematical Modeling and Analysis

Radiative Transfer Equation

In optical imaging, light transport through a medium containing scattering particles is described by transport theory [54]. In transport theory, the particle conservation within a small volume element of phase space is investigated. The wave phenomenon of particles is ignored. The transport theory can be modeled through stochastic methods and deterministic methods. In the stochastic approach, individual particle interactions are modeled as the particles are scattered and absorbed within the medium. The two stochastic methods that have been used in optical imaging are the Monte Carlo method and the random walk theory, of which two, the Monte Carlo is the most often used [5].

In deterministic approach, particle transport is described with integrodifferential equations which can be solved either analytically or numerically [5]. In optical

imaging, a widely accepted model for light transport is the radiative transport equation (RTE). The RTE is a one-speed approximation of the transport equation, and thus it basically assumes that the energy (or speed) of the particles does not change in collisions and that the refractive index is constant within the medium. For discussion of photon transport in medium with spatially varying refractive index, see, e.g., [16, 36, 62, 72].

Let $\Omega \subset \mathbb{R}^n$, $n = 2$ or 3 denote the physical domain where n is the dimension of the domain. The medium is considered isotropic in the sense that the probability of scattering between two directions depends only on the relative angle between those directions and not on an absolute direction. For discussion of light propagation in anisotropic medium, see, e.g., [44]. Furthermore, let $\partial\Omega$ denote the boundary of the domain and $\hat{s} \in S^{n-1}$ denote a unit vector in the direction of interest. The RTE is written in time domain as

$$\begin{aligned} & \frac{1}{c} \frac{\partial \phi(r, \hat{s})}{\partial t} + \hat{s} \cdot \nabla \phi(r, \hat{s}) + (\mu_s + \mu_a)\phi(r, \hat{s}) \\ &= \mu_s \int_{S^{n-1}} \Theta(\hat{s} \cdot \hat{s}') \phi(r, \hat{s}') d\hat{s}' + q(r, \hat{s}) \end{aligned} \quad (3)$$

and in frequency domain as

$$\begin{aligned} & \frac{i\omega}{c} \phi(r, \hat{s}) + \hat{s} \cdot \nabla \phi(r, \hat{s}) + (\mu_s + \mu_a)\phi(r, \hat{s}) \\ &= \mu_s \int_{S^{n-1}} \Theta(\hat{s} \cdot \hat{s}') \phi(r, \hat{s}') d\hat{s}' + q(r, \hat{s}), \end{aligned} \quad (4)$$

where c is the speed of light in the medium, i is the imaginary unit, ω is the angular modulation frequency of the input signal, and $\mu_s = \mu_s(r)$ and $\mu_a = \mu_a(r)$ are the scattering and absorption coefficients of the medium, respectively. The scattering coefficient represents the probability per unit length of a photon being scattered, and the absorption coefficient represents the probability per unit length of a photon being absorbed. Furthermore, $\phi(r, \hat{s})$ is the radiance, $\Theta(\hat{s} \cdot \hat{s}')$ is the scattering phase function, and $q(r, \hat{s})$ is the source inside Ω . The radiance can be defined such that the amount of power transfer in the infinitesimal angle $d\hat{s}$ in direction \hat{s} at time t through an infinitesimal area dS is given by

$$\phi(r, \hat{s}; t) \hat{s} \cdot \hat{v} dS d\hat{s},$$

where \hat{v} is the normal to the surface dS [54]. The scattering phase function $\Theta(\hat{s} \cdot \hat{s}')$ describes the probability that a photon with an initial direction \hat{s}' will have a direction \hat{s} after a scattering event. In optical imaging, the most usual phase function for isotropic material is the Henyey–Greenstein scattering function [47] which is of the form

$$\Theta(\hat{s} \cdot \hat{s}') = \begin{cases} \frac{1}{2\pi} \frac{1-g^2}{(1+g^2-2g\hat{s} \cdot \hat{s}')}, & n = 2, \\ \frac{1}{4\pi} \frac{1-g^2}{(1+g^2-2g\hat{s} \cdot \hat{s}')^{3/2}}, & n = 3, \end{cases} \quad (5)$$

where g is the scattering shape parameter that defines the shape of the probability density and it gets values between $-1 < g < 1$. With the value $g = 0$, the scattering probability density is a uniform distribution. For forward dominated scattering, $g > 0$, and for backward dominated scattering, $g < 0$. The time-domain and frequency-domain representations of the RTE are related through Fourier transform.

In order to obtain a unique solution for the RTE, the ingoing radiance distribution on the boundary $\partial\Omega$, that is, $\phi(r, \hat{s})$ for $\hat{s} \cdot \hat{v} < 0$, where \hat{v} is the outward unit normal, needs to be known [24]. Several boundary conditions can be applied to the RTE [1, 33, 57]. In optical imaging, the boundary condition which assumes that no photons travel in an inward direction at the boundary $\partial\Omega$ is used [5]

$$\phi(r, \hat{s}) = 0, \quad r \in \partial\Omega, \quad \hat{s} \cdot \hat{n} < 0. \quad (6)$$

This boundary condition, also known as the free surface boundary condition and the vacuum boundary condition, implies that once a photon escapes the domain Ω , it does not reenter it. The boundary condition (6) can be modified to include a boundary source $\phi_0(r, \hat{s})$ at the source position $\varepsilon_j \subset \partial\Omega$, and it can be written in the form [96]

$$\phi(r, \hat{s}) = \begin{cases} \phi_0(r, \hat{s}), & r \in \cup_j \varepsilon_j, \quad \hat{s} \cdot \hat{n} < 0 \\ 0, & r \in \partial\Omega \setminus \cup_j \varepsilon_j, \quad \hat{s} \cdot \hat{n} < 0. \end{cases} \quad (7)$$

In optical imaging, the measurable quantity is the exitance $J_n(r)$ on the boundary of the domain. It is defined as [5]

$$J_n(r) = \int_{S^{n-1}} (\hat{s} \cdot \hat{v}) \phi(r, \hat{s}) d\hat{s}, \quad r \in \partial\Omega. \quad (8)$$

Diffusion Approximation

In optical imaging, light propagation in tissues is usually modeled with the diffusion approximation (DA) to the RTE. The most typical approach to derive the DA from the RTE is to expand the radiance, the source term, and the phase function into series using the spherical harmonics and truncate the series [5, 24, 33]. If the spherical harmonics series is truncated at the N th moment, P_N approximation is obtained [5, 33]. The first-order spherical harmonics approximation is referred to as the P_1 approximation, and the DA can be regarded as a special case for that. The most typical approach for utilizing the P_N approximations in optical imaging has been to use them in angular discretization of the numerical solution of the RTE [14, 100].

An alternative to the P_N approximation is the Boltzmann hierarchy approach, in which moments of radiance are used to form a set of coupled equations that approximate the RTE [38]. Furthermore, the DA can be derived using asymptotic techniques [7, 17] leading to generalized diffusion equation or by using projection algebra [33, 57]. If the speed of light is not constant, a diffusion equation with spatially varying indices of refraction can be derived [16].

Here, a short review of the derivation of the DA is given according to [54, 57]. First, the P_1 approximation is derived, and then, the DA is formed as a special case for that. In the DA framework, the radiance is approximated by

$$\phi(r, \hat{s}) \approx \frac{1}{|S^{n-1}|} \Phi(r) + \frac{n}{|S^{n-1}|} \hat{s} \cdot J(r), \quad (9)$$

where $\Phi(r)$ and $J(r)$ are the photon density and photon current which are defined as

$$\Phi(r) = \int_{S^{n-1}} \phi(r, \hat{s}) d\hat{s} \quad (10)$$

$$J(r) = \int_{S^{n-1}} \hat{s} \phi(r, \hat{s}) d\hat{s}. \quad (11)$$

By inserting the approximation (9) and similar approximations written for the source term and phase function into Eq. 4 and following the derivation in [5, 54], the P_1 approximation is obtained

$$\left(\frac{i\omega}{c} + \mu_a \right) \Phi(r) + \nabla \cdot J(r) = q_0(r), \quad (12)$$

$$\left(\frac{i\omega}{c} + \mu_a + \mu'_s \right) J(r) + \frac{1}{n} \nabla \Phi(r) = q_1(r), \quad (13)$$

where $\mu'_s = (1 - g_1)\mu_s$ is the reduced scattering coefficient, $q_0(r)$ and $q_1(r)$ are the isotropic and dipole components of the source, and g_1 is the mean of the cosine of the scattering angle [5, 57]

$$g_1 = \int_{S^{n-1}} (\hat{s} \cdot \hat{s}') \Theta(\hat{s} \cdot \hat{s}') d\hat{s}. \quad (14)$$

In the case of the Henyey–Greenstein scattering function, Eq. 5, we have $g_1 = g$.

To derive the diffusion approximation, it is further assumed that the light source is isotropic, thus $q_1(r) = 0$, and that $\frac{i\omega}{c} J(r) = 0$. The latter assumption, which in time-domain case is of the form $\frac{1}{c} \frac{\partial J(r)}{\partial t} = 0$, is usually justified by specifying the condition $\mu_a \ll \mu'_s$ [5]. Utilizing these approximations, Eq. 13 gives the Fick's law

$$J(r) = -\kappa \nabla \Phi(r), \quad (15)$$

where

$$\kappa = \kappa(r) = (n(\mu_a + \mu'_s))^{-1} \quad (16)$$

is the diffusion coefficient. Substituting Eq. 15 into Eq. 12, the frequency-domain version of the DA is obtained. It is of the form

$$-\nabla \cdot \kappa \nabla \Phi(r) + \mu_a \Phi(r) + \frac{i\omega}{c} \Phi(r) = q_0(r). \quad (17)$$

The DA has an analogue in time domain as well. It is of the form

$$-\nabla \cdot \kappa \nabla \Phi(r) + \mu_a \Phi(r) + \frac{1}{c} \frac{\partial \Phi(r)}{\partial t} = q_0(r). \quad (18)$$

The time-domain and frequency-domain representations of the DA are related through Fourier transform, similarly as in the case of the RTE.

Boundary Conditions for the DA

The boundary condition (6) cannot be expressed in terms of variables of the diffusion approximation. Instead, there are a few boundary conditions that have been applied to the DA. The simplest boundary condition is the Dirichlet boundary condition which is also referred to as the zero-boundary condition. It sets the photon density to zero on the boundary; thus, $\Phi(r) = 0$, $r \in \partial\Omega$ [40, 87]. Alternatively, an extrapolated boundary condition can be used [33, 40, 87]. In the approach, the photon density is set to zero on an extrapolated boundary which is a virtual boundary outside the medium located at a certain distance from the real boundary. Both the zero-boundary condition and the extrapolated boundary condition are physically incorrect, and they have mostly been used because of their mathematical simplicity [40].

The most often used boundary condition in optical imaging is the Robin boundary condition which is also referred to as the partial current boundary condition [4, 24, 33, 40, 54, 87]. It can be derived as follows. Within the P_1 approximation framework (9), the total inward- and outward-directed photon fluxes at a point $r \in \partial\Omega$ are

$$J^-(r) = - \int_{\hat{s} \cdot \hat{n} < 0} (\hat{s} \cdot \hat{n}) \phi(r, \hat{s}) d\hat{s} = \gamma_n \Phi(r) - \frac{1}{2} \hat{v} \cdot J(r) \quad (19)$$

$$J^+(r) = \int_{\hat{s} \cdot \hat{n} > 0} (\hat{s} \cdot \hat{n}) \phi(r, \hat{s}) d\hat{s} = \gamma_n \Phi(r) + \frac{1}{2} \hat{v} \cdot J(r), \quad (20)$$

where γ_n is a dimension-dependent constant which obtains values $\gamma_2 = 1/\pi$ and $\gamma_3 = 1/4$ [57]. To derive the Robin boundary condition for the DA, it is assumed that the total inward-directed photon flux on the boundary is zero; thus,

$$J^-(r) = 0, \quad r \in \partial\Omega. \quad (21)$$

Utilizing Eq. 19 and the Fick's law (15), the Robin boundary condition can be derived. It is of the form

$$\Phi(r) + \frac{1}{2\gamma_n} \kappa \frac{\partial \Phi(r)}{\partial \hat{v}} = 0, \quad r \in \partial\Omega. \quad (22)$$

The boundary condition (22) can be extended to include the reflection on the boundary that is caused by different refractive indices between the object and the surrounding medium. In that case, Eq. 21 is modified to the form

$$J^-(r) = R J^+(r), \quad r \in \partial\Omega, \quad (23)$$

where $R = R(x)$ is the reflection coefficient on the boundary $\partial\Omega$, with $0 \leq R \leq 1$ [57]. Thus, if $R = 0$, no boundary reflection occurs, and Eq. 23 is reduced into Eq. 21. The parameter R can be derived from Fresnel's law [40] or, if the refractive index of the surrounding medium is $n_{\text{out}} = 1$, by an experimental fit

$$R \approx -1.4399 n_{\text{in}}^{-2} + 0.7099 n_{\text{in}}^{-1} + 0.6681 + 0.0636 n_{\text{in}}, \quad (24)$$

where n_{in} is the refractive index of the medium [87]. Utilizing Eqs. 19 and 20 and the Fick's law (15), the Robin boundary condition with mismatched refractive indices can be derived. It takes the form

$$\Phi(r) + \frac{1}{2\gamma_n} \kappa \zeta \frac{\partial \Phi(r)}{\partial \hat{v}} = 0, \quad r \in \partial\Omega, \quad (25)$$

where $\zeta = (1 + R)/(1 - R)$, with $\zeta = 1$ in the case of no surface reflection. The boundary conditions of the DA for an interface between two highly scattering materials have been discussed, for example, in [4].

The exitance, Eq. 8, can be written utilizing Eqs. 19 and 20, the Fick's law (15), and the boundary condition (25). In the DA framework, the exitance is of the form

$$\begin{aligned} J_n(r) &= J^+(r) - J^-(r) = \hat{v} \cdot J(r) \\ &= -\kappa \frac{\partial \Phi(r)}{\partial \hat{v}} = \frac{2\gamma_n}{\zeta} \Phi(r), \quad r \in \partial\Omega. \end{aligned} \quad (26)$$

Source Models for the DA

In the DA framework, light sources are usually modeled by two approximate models, namely, the collimated source model and the diffuse source model. In the case of the collimated source model, the source is modeled as an isotropic point source

$$q_0(r) = \delta(r - r_s), \quad (27)$$

where position r_s is located at a depth $1/\mu'_s$ below the source site [40, 87]. In the case of the diffuse source model, the source is modeled as an inward-directed diffuse boundary current I_s at the source position $\varepsilon_s \subset \partial\Omega$ [87]. In the case of the diffuse source model, Eq. 23 can be modified as

$$J^-(r) = RJ^+(r) + (1 - R)I_s, \quad r \in \cup_j \varepsilon_j. \quad (28)$$

Then, following the similar procedure as earlier, the Robin boundary condition with the diffuse source model is obtained. It is of the form

$$\Phi(r) + \frac{1}{2\gamma_n} \kappa \zeta \frac{\partial \Phi(r)}{\partial \hat{v}} = \begin{cases} \frac{I_s}{\gamma_n}, & r \in \cup_j \varepsilon_j \\ 0, & r \in \partial\Omega \setminus \cup_j \varepsilon_j. \end{cases} \quad (29)$$

Validity of the DA

The basic condition for the validity of the DA is that the angular distribution of the radiance is almost uniform. In order to achieve this, the medium must be scattering dominated; thus, $\mu_a \ll \mu_s$. Most of the tissue types are highly scattering and the DA can be regarded as a good approximation for modeling light propagation within them. The DA has been found to describe light propagation with a good accuracy in situations in which its assumptions are valid [63, 80] and it has been successfully applied in many applications of optical tomography.

However, the condition stating that the angular distribution of the radiance must be almost uniform is violated close to the highly collimated light sources. In addition, the condition cannot be fulfilled in strongly absorbing or low-scattering tissues such as the cerebrospinal fluid which surrounds the brain and fills the brain ventricles. Furthermore, in addition to the above conditions, the DA cannot accommodate realistic boundary conditions or discontinuities at interfaces. The diffusion theory has been found to fail in situations in which its approximations are not valid such as close to the sources [35, 87] and within the low-scattering regions [37, 48].

Numerical Solution Methods for the DA

The analytical solutions of the RTE and its approximations are often restricted to certain specific geometries, and therefore, their exploitability in optical imaging is limited. Therefore, the equations describing light propagation are usually solved with numerical methods. The most often applied numerical methods are the finite difference method and the finite element method (FEM). The latter is generally regarded as more flexible when issues of implementing different boundary conditions and handling complex geometries are considered, and therefore, it is most often chosen as the method for solving equations governing light transport in tissues.

The FE model for the time-varying DA was introduced in [9]. It was later extended to address the topics of boundary conditions and source models [80, 87] and the frequency-domain case of the DA [86]. It can be regarded as the most typical approach to numerically solve the DA.

Hybrid Approaches Utilizing the DA

To overcome the limitations of the diffusion theory close to the light sources and within low-scattering and non-scattering regions, different hybrid approaches and approximate models have been developed.

The hybrid Monte Carlo diffusion method was developed to overcome the limitations of the DA close to the light sources. In the approach, Monte Carlo simulation is combined with the diffusion theory. The method was introduced in [98] to describe light reflectance in a semi-infinite turbid medium, and it was extended for turbid slabs in [97]. In the hybrid Monte Carlo diffusion approach, Monte Carlo method is used to simulate light propagation close to the light source and the DA is analytically solved elsewhere in the domain. Monte Carlo is known to describe light propagation accurately. However, it has the disadvantage of requiring a long computation time. This has effects on computation times of the hybrid Monte Carlo approaches as well. A hybrid radiative transfer–diffusion model to describe light propagation in highly scattering medium was introduced in [93]. In the approach, light propagation is modeled with the RTE close to the light sources, and the DA is used elsewhere in the domain. The solution of the RTE is used to construct a Dirichlet boundary condition for the DA on a fictitious interface within the object. Both the RTE and the DA are numerically solved with the FEM.

Different hybrid approaches and approximate models have been applied for highly scattering media with low-scattering and non-scattering regions. Methods that combine Monte Carlo simulation with diffusion theory have been applied for turbid media with low-scattering regions. The finite element approximation of the DA and the Monte Carlo simulation was combined in [41] to describe light propagation in a scattering medium with a low-scattering layer. However, also in this case, the approach suffers from the time-consuming nature of the Monte Carlo methods. Moreover, the hybrid Monte Carlo diffusion methods often require iterative mapping between the models which increases computation times even more. The radiosity–diffusion model [10, 37] can be applied for highly scattering media with non-scattering regions. The method uses the FE solution of the DA to model light propagation within highly scattering regions and the radiosity model to model light propagation within non-scattering regions. A coupled transport and diffusion model was introduced in [18]. In the model, the transport and diffusion models are coupled, and iterative mapping between the models is used for the forward solution. Furthermore, a coupled radiative transfer equation and diffusion approximation model for optical tomography was introduced in [94] and extended for domains with low-scattering regions in [92]. In the approach, the RTE is used as the forward model in sub-domains in which the assumptions of the DA are not valid and the DA is used elsewhere in the domain. The RTE and DA are coupled through boundary conditions between the RTE and DA sub-domains and solved simultaneously using the FEM.

Green's Functions and the Robin to Neumann Map

Some insight into light propagation in diffusive media can be gained by examining infinite media. In particular, verification of optical scattering and absorption parameters is frequently made with source and detector fibers immersed in a large container and far from the container walls. In a finite domain, however, we will need to use boundary conditions. We will distinguish between solutions to the homogeneous equation with inhomogeneous boundary conditions and the inhomogeneous equation with homogeneous boundary conditions. In the latter case, we can use a Green's function acting on q_0 . In the former case, we use a Green's function acting on a specified boundary function.

We will use the notation G_Ω for the Green's function for the inhomogeneous form of (18) with homogeneous boundary conditions and $G_{\partial\Omega}$ for the Green's function for the homogeneous form of (18) with inhomogeneous boundary conditions, i.e., we have G_Ω solving

$$-\nabla \cdot \kappa(\mathbf{r}) \nabla G_\Omega(\mathbf{r}, \mathbf{r}', t, t') + \left(\mu_a(\mathbf{r}) + \frac{1}{c} \frac{\partial}{\partial t} \right) G_\Omega(\mathbf{r}, \mathbf{r}', t, t') = \delta(\mathbf{r}') \delta(t') \quad (30)$$

$$\mathbf{r}, \mathbf{r}' \in \Omega \setminus \partial\Omega, t > t'$$

$$G_\Omega(\mathbf{r}_d, \mathbf{r}', t, t') + 2\zeta\kappa(\mathbf{r}_d) \frac{\partial G_\Omega(\mathbf{r}_d, \mathbf{r}', t, t')}{\partial \nu} = 0 \quad (31)$$

$$\mathbf{r}_d \in \partial\Omega$$

and $G_{\partial\Omega}$ solving

$$-\nabla \cdot \kappa(\mathbf{r}) \nabla G_{\partial\Omega}(\mathbf{r}, \mathbf{r}_s, t, t') + \left(\mu_a(\mathbf{r}) + \frac{1}{c} \frac{\partial}{\partial t} \right) G_{\partial\Omega}(\mathbf{r}, \mathbf{r}_s, t, t') = 0 \quad (32)$$

$$\mathbf{r} \in \Omega \setminus \partial\Omega, t > t'$$

$$G_{\partial\Omega}(\mathbf{r}_d, \mathbf{r}_s, t, t') + 2\zeta\kappa(\mathbf{r}_d) \frac{\partial G_{\partial\Omega}(\mathbf{r}_d, \mathbf{r}_s, t, t')}{\partial \nu} = \delta(\mathbf{r}_s) \delta(t') \quad (33)$$

$$\mathbf{r}_s, \mathbf{r}_d \in \partial\Omega.$$

For a given Green's function G , we define the corresponding *Green's operator* as the integral transform with G as its kernel:

$$\mathcal{G}f := \int_{-\infty}^{\infty} \int_{\Omega} G(\mathbf{r}, \mathbf{r}', t, t') f(\mathbf{r}', t') d^n \mathbf{r}' dt.$$

For the measurable, we define the *boundary derivative operator* as

$$\mathcal{B} := -\kappa \frac{\partial}{\partial \nu},$$

where appropriate we will use the simplifying notation

$$G^{\mathcal{B}} := \mathcal{B}G$$

to mean the result of taking the boundary data for a Green's function.

Since (18) is parabolic, we must not simultaneously specify both Dirichlet and Neumann boundary conditions on the whole of $\partial\Omega$. The same is true if we convert to the frequency domain and use a complex elliptic equation to describe the propagation of the Fourier transform of Φ . Instead, we specify their linear combination through the Robin condition (25). Then, for any specified value q on $\partial\Omega$, we will get data y given by (26). The linear mapping $\Lambda q \rightarrow y$ is termed the *Robin to Neumann map* and can be considered the result of a boundary derivative operator \mathcal{B} acting on the Green's operator with kernel $G_{\partial\Omega}$

$$\Lambda_{\text{RtN}}(\kappa, \mu_a)q = \mathcal{B}\mathcal{G}_{\partial\Omega}q.$$

Since the Neumann data and Dirichlet data are related by (25), we may also define the Robin to Dirichlet map $\Lambda_{\text{RtD}}(\kappa, \mu_a)$ and specify the relationship

$$\Lambda_{\text{RtD}}(\kappa, \mu_a) - 2\zeta\Lambda_{\text{RtN}}(\kappa, \mu_a) - I = 0 \quad (34)$$

The Forward Problem

The Robin to Neumann map is a linear operator mapping boundary sources to boundary data. For the inverse problem, we have to consider a nonlinear mapping from the space of μ_a, κ coefficients to the boundary data.

When considering an incoming flux J^- with corresponding boundary term q , the data is a function of one variable

$$y_q = \mathcal{F}_q \begin{pmatrix} \mu_a \\ \kappa \end{pmatrix}, \quad (35)$$

which gives the boundary data for the particular source term $q = \mathcal{D}^-(J^-)$. Using this notation, we consider the forward mapping for a finite number of sources $\{q_j; j = 1 \dots S\}$ as a parallel set of projections

$$\mathbf{y} = \mathcal{F} \begin{pmatrix} \mu_a \\ \kappa \end{pmatrix}, \quad (36)$$

where

$$\mathcal{F} := (\mathcal{F}_1, \dots, \mathcal{F}_S)^T \quad (37)$$

$$\mathbf{y} := (y_1, \dots, y_S)^T. \quad (38)$$

We will consider (36) as a mapping from two continuous functions in solution space $\mu_a, \kappa \in X(\Omega) \times X(\Omega)$ to continuous functions in data space $y \in Y(\partial\Omega)$. If the data is sampled as well (which is the case in practice), then \mathcal{F} is sampled at a set of measurement positions $\{\mathbf{r}_d; i = 1, \dots, M\}$.

The inverse problem of diffusion-based optical tomography (DOT) is to determine κ, μ_a from the values of y for all incoming boundary distributions q . If κ, μ_a are found, we can determine μ'_s through (16).

Schrödinger Form

Problem (17) can be put into Schrödinger form using the Liouville transformation. We make the change of variables $U = \kappa^{1/2}\Phi$, by which (17) becomes

$$-\kappa\nabla^2\Phi - 2\kappa^{1/2}\nabla\kappa^{1/2} \cdot \nabla\Phi + \left(\mu_a + \frac{i\omega}{c}\right)\Phi = q_0.$$

Using

$$\nabla^2U = \kappa^{1/2}\nabla^2\Phi + 2\nabla\Phi \cdot \nabla\kappa^{1/2} + \Phi\nabla^2\kappa^{1/2}$$

leads to

$$-\nabla^2U(\mathbf{r}; \omega) + k^2(\mathbf{r}; \omega)U(\mathbf{r}; \omega) = \frac{q_0(\mathbf{r}; \omega)}{\kappa^{1/2}(\mathbf{r})} \quad (39)$$

$$\mathbf{r} \in \Omega/\partial\Omega \quad (40)$$

$$U(\mathbf{r}_d; \omega) + 2\xi\kappa(\mathbf{r}_d)\frac{\partial U(\mathbf{r}_d; \omega)}{\partial v} = \kappa^{1/2}(\mathbf{r}_d)q(\mathbf{r}_d; \omega) \quad (41)$$

$$\mathbf{r}_d \in \partial\Omega, \quad (42)$$

where

$$k^2 = \frac{\nabla^2\kappa^{1/2}}{\kappa^{1/2}} + \frac{\mu_a}{\kappa} + \frac{i\omega}{c\kappa}.$$

If k^2 is real (i.e., $\omega = 0$), there exist infinitely many κ, μ_a pairs with the same real k^2 , so that the measurement of DC data cannot allow the separable unique reconstruction of κ and μ_a [6]. For $\omega \neq 0$, the unique determination of a complex k^2 should be possible by extension of the uniqueness theorem of Sylvester and Uhlmann [91]. From the complex k^2 , it is in principle possible to obtain separable reconstruction of first κ from the imaginary part of k^2 and μ_a from the real part; see [74] for further discussion.

In a homogeneous medium, with constant optical parameters μ_a, κ , we can simplify (42) to

$$-\nabla^2\Phi(\mathbf{r}; \omega) + k^2\Phi(\mathbf{r}; \omega) = q_H(\mathbf{r}; \omega), \quad (43)$$

with the same boundary condition (25) and with

$$k^2 = \left(\frac{\mu_a c + i\omega}{c\kappa} \right); \quad q_H = \frac{q_0(\mathbf{r}; \omega)}{\kappa}. \quad (44)$$

This equation is also seen directly from (17) for constant κ .

The solution in simple geometries is easily derived using the appropriate Green's functions [8]. In an infinite medium, this is simply a spherical wave

$$\Phi(\mathbf{r}; \omega) \equiv G(\mathbf{r}, \mathbf{r}_s; \omega) = \frac{e^{\pm k|\mathbf{r}-\mathbf{r}_s|}}{|\mathbf{r}-\mathbf{r}_s|}, \quad (45)$$

where the notation $G(\mathbf{r}, \mathbf{r}_s; \omega)$ defines Green's function for a source at position \mathbf{r}_s . Due to the real part of the wave number k , this wave is damped. This fact is the main reason that results from diffraction tomography are not always straightforwardly applicable in optical tomography. In particular, for the case $\omega = 0$, the wave is *wholly non-propagating*. Even as $\omega \rightarrow \infty$, the imaginary part of the wave number never exceeds the real part. This is a simple consequence of the parabolic nature of the diffusion approximation. Although hyperbolic approximations can be made too, they do not ameliorate the situation.

Perturbation Analysis

An important tool in scattering problems in general is the approximation of the change in field due to a change in state, developed in a series based on known functions for the reference state. There are two common approaches which we now discuss.

Born Approximation

For the Born approximation, we assume that we have a reference state $\mathbf{x}_0 = (\mu_a, \kappa)^T$, with a corresponding wave Φ , and that we want to find the *scattered* wave Φ^δ due to a change in state $\mathbf{x}^\delta = (\alpha, \beta)^T$. We have

$$\kappa = \kappa + \beta, \quad \mu_a = \mu_a + \alpha. \quad (46)$$

Note that it is not necessary to assume that the initial state is homogeneous. Putting (46) into (17) gives

$$-\nabla \cdot (\kappa + \beta) \nabla \tilde{\Phi}(\mathbf{r}; \omega) + \left(\mu_a + \alpha + \frac{i\omega}{c} \right) \tilde{\Phi}(\mathbf{r}; \omega) = q_0(\mathbf{r}; \omega) \quad (47)$$

with

$$\tilde{\Phi} = \Phi + \Phi^\delta. \quad (48)$$

Equation 47 can be solved using the Green's operator for the reference state

$$\tilde{\Phi} = \mathcal{G}_0 [q_0 + \nabla \cdot \beta \nabla \tilde{\Phi} - \alpha \tilde{\Phi}]. \quad (49)$$

With G_0 , Green's function for the reference state, we have

$$\begin{aligned} \tilde{\Phi}(\mathbf{r}; \omega) &= \Phi(\mathbf{r}; \omega) + \int_{\Omega} (G_0(\mathbf{r}, \mathbf{r}'; \omega) \nabla_{r'} \cdot \beta(\mathbf{r}') \nabla_{r'} \tilde{\Phi}(\mathbf{r}'; \omega) - \alpha(\mathbf{r}') \tilde{\Phi}(\mathbf{r}'; \omega)) d^n \mathbf{r}' \\ &= \Phi(\mathbf{r}; \omega) - \int_{\Omega} (\beta(\mathbf{r}') \nabla_{r'} G_0(\mathbf{r}, \mathbf{r}'; \omega) \cdot \nabla_{r'} \tilde{\Phi}(\mathbf{r}'; \omega) \\ &\quad \alpha(\mathbf{r}') G_0(\mathbf{r}, \mathbf{r}'; \omega) \tilde{\Phi}(\mathbf{r}'; \omega)), \end{aligned} \quad (50)$$

where we used the divergence theorem and assumed $\beta(\mathbf{r}_d) = 0; \mathbf{r}_d \in \partial\Omega$.

If we define a “potential” as the differential operator

$$\mathcal{V}(\alpha, \beta) := \nabla \cdot \beta \nabla - \alpha, \quad (51)$$

we can recognize (49) as a Dyson equation and write it in the form

$$[I - \mathcal{G}_0 \mathcal{V}] \tilde{\Phi} = \mathcal{G}_0 q_0. \quad (52)$$

This may be formally solved by a Neumann series,

$$\frac{\mathcal{G}_0}{[I - \mathcal{G}_0 \mathcal{V}]} = \mathcal{G}_0 + \mathcal{G}_0 \mathcal{V} \mathcal{G}_0 + \mathcal{G}_0 \mathcal{V} \mathcal{G}_0 \mathcal{V} \mathcal{G}_0 + \dots \quad (53)$$

or, equivalently, by using (48) in (50) to obtain the Born series

$$\tilde{\Phi} = \Phi^{(0)} + \Phi^{(1)} + \Phi^{(2)} + \dots, \quad (54)$$

where

$$\begin{aligned} \Phi^{(0)} &= \Phi \\ \Phi^{(1)} &= \mathcal{G}_0 \mathcal{V} \Phi \\ \Phi^{(2)} &= \mathcal{G}_0 \mathcal{V} \mathcal{G}_0 \mathcal{V} \Phi \\ &\vdots \end{aligned}$$

Rytov Approximation

The Rytov approximation is derived by considering the logarithm of the field as a complex phase [54, 60]:

$$\Phi(\mathbf{r}; \omega) = e^{u(\mathbf{r}; \omega)} \quad (55)$$

so that, in place of (48), we have

$$\ln \tilde{\Phi} = \ln \Phi + u^\delta. \quad (56)$$

Putting $\Phi = e^{u_0}$ into (17), we get

$$-\Phi \nabla \cdot \kappa \nabla u_0 - \Phi \kappa |\nabla u_0|^2 + \tilde{\Phi} \left(\mu_a + \frac{i\omega}{c} \right) = q_0. \quad (57)$$

Putting $\Phi = \Phi e^{u^\delta}$ and (46) into (17), we get

$$-\tilde{\Phi} \nabla \cdot (\kappa + \beta) \nabla (u_0 + u^\delta) - \tilde{\Phi} (\kappa + \beta) |\nabla (u_0 + u^\delta)|^2 + \tilde{\Phi} \left(\mu_a + \alpha + \frac{i\omega}{c} \right) = q_0. \quad (58)$$

Subtracting (57) from (58) and assuming $\tilde{\Phi} = \Phi$ over the support of q_0 , we get

$$\begin{aligned} & -\kappa \left(2 \nabla u_0 \cdot \nabla u^\delta + |\nabla u^\delta|^2 \right) - \nabla \cdot \kappa \nabla u^\delta \\ &= \nabla \cdot \beta \nabla (u_0 + u^\delta) + \beta |\nabla (u_0 + u^\delta)|^2 - \alpha. \end{aligned} \quad (59)$$

We now make use of the relation

$$\nabla \cdot \kappa \nabla u^\delta \Phi = \Phi \nabla \cdot \kappa \nabla u^\delta + 2\kappa \nabla \Phi \cdot \nabla u^\delta + u^\delta \nabla \cdot \kappa \nabla \Phi \quad (60)$$

$$= \Phi \left(\nabla \cdot \kappa \nabla u^\delta + 2\Phi \kappa \nabla u_0 \cdot \nabla u^\delta \right) + u^\delta \nabla \cdot \kappa \nabla \Phi. \quad (61)$$

The last term on the right is substituted from (17) to give

$$\nabla \cdot \kappa \nabla u^\delta + 2\kappa \nabla u_0 \cdot \nabla u^\delta = \frac{\nabla \cdot \kappa \nabla u^\delta \Phi}{\Phi} + u^\delta \left(\mu_a + \frac{i\omega}{c} \right) - \frac{q_0}{\Phi}. \quad (62)$$

Substituting (62) into (59) and using

$$\Phi \nabla \cdot \beta \nabla u_0 + \Phi \beta |\nabla u_0|^2 = \nabla \cdot \beta \nabla (\Phi u_0)$$

we arrive at

$$\begin{aligned} & -\nabla \cdot \kappa \nabla u^\delta \Phi + \left(\mu_a + \frac{i\omega}{c} \right) u^\delta \Phi \\ &= \nabla \cdot \beta \nabla \Phi - \alpha \Phi + \Phi \nabla \cdot \beta \nabla u^\delta + \kappa |\nabla u^\delta|^2. \end{aligned} \quad (63)$$

The approximation comes in neglecting the last two terms on the right, which are second order in the small perturbation. The left-hand side is the unperturbed

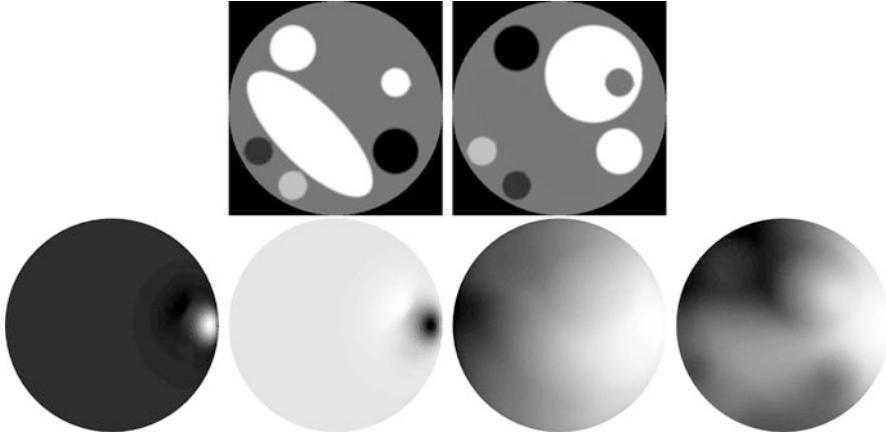

Fig. 2 *Top:* absorption and scattering images used to generate complex fields. Disk diameter 50 mm, absorption range $\mu_a \in [0.01\text{--}0.04] \text{ mm}^{-1}$, scatter range $\mu'_s \in [1\text{--}4] \text{ mm}^{-1}$. The complex field Φ was calculated using a 2D FEM for a δ -function source on the boundary at the 3 o'clock position. A reference field Φ was calculated for the same source and a homogeneous disk with $\mu_a = 0.025 \text{ mm}^{-1}$, $\mu'_s = 2 \text{ mm}^{-1}$. *Bottom:* the difference in fields $\Phi - \Phi$ (real and imaginary) and the difference of logs $\ln \Phi - \ln \Phi$ (real and imaginary)

operator, and so the formal solution for $u^\delta \Phi$ is again obtained through Green's operator with kernel G_0 . Thus, the first-order Rytov approximation becomes

$$u^\delta(\mathbf{r}; \omega) = \frac{\Phi^{(1)}(\mathbf{r}; \omega)}{\Phi(\mathbf{r}; \omega)} \quad (64)$$

$$= \frac{-1}{\Phi(\mathbf{r}; \omega)} (\beta(\mathbf{r}') \nabla_{r'} G_0(\mathbf{r}, \mathbf{r}'; \omega) \cdot \nabla_{r'} \Phi(\mathbf{r}'; \omega) \\ + \alpha(\mathbf{r}') G_0(\mathbf{r}, \mathbf{r}'; \omega) \Phi(\mathbf{r}'; \omega)). \quad (65)$$

The Rytov approximation is usually argued to be applicable for larger perturbations than the Born approximation, since the neglected terms are small as long as the gradient of the field is slowly varying. See [60] for a much more detailed discussion.

Illustrations of the scattered field in the Born and Rytov formulations are shown in Fig. 2. Since in the frequency domain the field is complex, so is its logarithm. The real part corresponds to the log of the field amplitude and its imaginary part to the phase. From the images in Fig. 2, it is apparent that perturbations are more readily detected in amplitude and phase than in the field itself. This stems from the very high dynamic range of data acquired in optical tomography which in turn stems from the high attenuation and attendant damping. It is the primary motivation for the use of the Rytov approximation, despite the added complications.

Linearization

Linearization is required either to formulate a linear reconstruction problem (i.e., assuming small perturbations on a known background) or as a step in an iterative approach to the nonlinear inverse problem. We will formulate this in the frequency domain. In addition, we may work with either the wave itself, which leads to the Born approximation, or its logarithm, which leads to the Rytov approximation.

Linear Approximations

In the Born approximation to the linearized problem, we assume that the difference in measured data is given just by the first term in the Born series (54)

$$\begin{aligned} \Phi^\delta(\mathbf{r}; \omega) &\equiv \Phi^{(1)}(\mathbf{r}; \omega) \\ &= - \int_{\Omega} (\beta(\mathbf{r}') \nabla_{r'} G_{\Omega,0}(\mathbf{r}, \mathbf{r}'; \omega) \cdot \nabla_{r'} \Phi(\mathbf{r}'; \omega) \alpha(\mathbf{r}') G_{\Omega,0}(\mathbf{r}, \mathbf{r}'; \omega) \Phi(\mathbf{r}'; \omega)) d^n \mathbf{r}'. \end{aligned} \quad (66)$$

From (26), we obtain for a detector at position $\mathbf{r}_d \in \partial\Omega$

$$y(\mathbf{r}_d; \omega) = y_0(\mathbf{r}_d; \omega) + \int_{\Omega} \mathbf{K}_q^T(\mathbf{r}_d, \mathbf{r}'; \omega) \begin{pmatrix} \alpha(\mathbf{r}') \\ \beta(\mathbf{r}') \end{pmatrix} d^n \mathbf{r}', \quad (67)$$

where \mathbf{K}_q is given by

$$\mathbf{K}_q(\mathbf{r}_d, \mathbf{r}'; \omega) = \begin{pmatrix} G_{\Omega,0}^B(\mathbf{r}_d, \mathbf{r}'; \omega) \Phi(\mathbf{r}'; \omega) \\ \nabla_{r'} G_{\Omega,0}^B(\mathbf{r}_d, \mathbf{r}'; \omega) \cdot \nabla_{r'} \Phi(\mathbf{r}'; \omega) \end{pmatrix}. \quad (68)$$

The subscript q refers to the incoming flux that generates the boundary condition for the particular field Φ .

Since the Rytov approximation was derived by considering the change in the logarithm of the field, we have in place of (68) simply

$$\mathbf{K}_q^{\text{Ryt}}(\mathbf{r}_d, \mathbf{r}'; \omega) = \frac{1}{y_0(\mathbf{r}_d; \omega)} \mathbf{K}_q(\mathbf{r}_d, \mathbf{r}'; \omega). \quad (69)$$

Assuming that we are given measured data g for a sufficient number of input fluxes, the linearized problem consists in solving for α, β from

$$y^\delta = \mathcal{K}_q \begin{pmatrix} \alpha \\ \beta \end{pmatrix}, \quad (70)$$

where \mathcal{K}_q is a linear operator with kernel given by (68) or (69) and

$$y^\delta = g - y_0, \quad (71)$$

where y_0 is the data that would arise from state \mathbf{x}_0 .

We can now distinguish between a linearized approach to the static determination of $\mathbf{x} = \mathbf{x}_0 + (\alpha, \beta)^T$ and a *dynamic imaging* problem that assumes a reference measurement g_0 . In the former case, we assume that our model is sufficiently accurate to calculate y_0 . In the latter case, we use the reference measurement to solve

$$y^\delta = g - g_0. \quad (72)$$

This in fact is where the majority of reported results with measured data are taken. By this mechanism, inconsistencies in the modeling of the forward problem (most notably using 2D instead of 3D) are minimized. However, for static or “absolute” imaging, we still require an accurate model, even for the linearized problem.

Sensitivity Functions

If we take q to be a δ -function at a source position $\mathbf{r}_s \in \partial\Omega$, then Φ is given by a Green’s function too, and we obtain the *Photon Measurement Density Function* (PMDF)

$$\rho(\mathbf{r}_d, \mathbf{r}', \mathbf{r}_s; \omega) = \begin{pmatrix} G_{\Omega,0}^B(\mathbf{r}_d, \mathbf{r}'; \omega) G_{\partial\Omega,0}(\mathbf{r}', \mathbf{r}_s; \omega) \\ \nabla_{r'} G_{\Omega,0}^B(\mathbf{r}_d, \mathbf{r}'; \omega) \cdot \nabla_{r'} G_{\partial\Omega,0}(\mathbf{r}', \mathbf{r}_s; \omega) \end{pmatrix} \quad (73)$$

with the Rytov form being

$$\rho^{\text{Ryt}}(\mathbf{r}_d, \mathbf{r}', \mathbf{r}_s; \omega) = \frac{1}{G_{\partial\Omega,0}^B(\mathbf{r}_d, \mathbf{r}_s; \omega)} \rho(\mathbf{r}_d, \mathbf{r}', \mathbf{r}_s; \omega).$$

It is instructive to visualize the various ρ -functions which exhibit notable differences for μ_a and κ and between the Born and Rytov functions, as seen in Fig. 3.

Clearly

$$\mathbf{K}_q = \int_{\partial\Omega} \rho(\mathbf{r}_d, \mathbf{r}', \mathbf{r}_s; \omega) q(\mathbf{r}_s) d\mathbf{r}_s = \mathcal{G}' q,$$

where \mathcal{G}' is a linear operator with kernel ρ .

We can also define the linearized Robin to Neumann map

$$\Lambda'_{\text{RtN}}(\mu_a, \kappa) \begin{pmatrix} \alpha \\ \beta \end{pmatrix} = \int_{\partial\Omega} H(\mathbf{r}_d, \mathbf{r}_s; \omega) q(\mathbf{r}_s) d\mathbf{r}_s = \mathcal{H} q,$$

where \mathcal{H} is a linear operator with kernel H given by

$$H(\mathbf{r}_d, \mathbf{r}_s) = \int_{\Omega} \rho^T(\mathbf{r}_d, \mathbf{r}', \mathbf{r}_s; \omega) \begin{pmatrix} \alpha(\mathbf{r}') \\ \beta(\mathbf{r}') \end{pmatrix} d^n \mathbf{r}.$$

Fig. 3 Top row: sensitivity function ρ for μ_a ; left to right: real, imaginary, amplitude, and phase; bottom row: the same functions for κ

Note that there are no equivalent Rytov forms. This is because the log of the Robin to Neumann map is not linear.

Adjoint Field Method

A key component in the development of a reconstruction algorithm is the use of the adjoint operator. The application of these methods in optical tomography has been discussed in detail by Natterer and coworkers [31, 74].

Taking the adjoint of \mathcal{K}_q defines a mapping $Y(\partial\Omega) \rightarrow X(\Omega) \times X(\Omega)$

$$\mathcal{K}^* q b = \int_{\partial\Omega} \bar{\mathbf{K}}_q(\mathbf{r}_d, \mathbf{r}'; \omega) b(\mathbf{r}_d; \omega) dS \quad (74)$$

$$= \int_{\partial\Omega} \left(\nabla_{r'} \bar{G}_{\Omega,0}^B(\mathbf{r}_d, \mathbf{r}'; \omega) \cdot \nabla_{r'} \bar{\Phi}(\mathbf{r}'; \omega) \right) b(\mathbf{r}_d; \omega) dS. \quad (75)$$

Consider the reciprocity relation

$$\bar{G}_{\Omega,0}^B(\mathbf{r}_d, \mathbf{r}; \omega) = -G^*_{\partial\Omega,0}(\mathbf{r}, \mathbf{r}_d; \omega) \quad (76)$$

with $G^*_{\partial\Omega,0}$, Green's function that solves the adjoint problem

$$-\nabla \cdot \kappa(\mathbf{r}) \nabla G^*_{\partial\Omega,0}(\mathbf{r}, \mathbf{r}_d; \omega) + \left(\mu_a(\mathbf{r}) - \frac{i\omega}{c} \right) G^*_{\partial\Omega,0}(\mathbf{r}, \mathbf{r}_d; \omega) = 0 \quad (77)$$

$\mathbf{r} \in \Omega \setminus \partial\Omega$

$$G^*_{\partial\Omega,0}(\mathbf{r}, \mathbf{r}_d; \omega) + 2\xi\kappa(\mathbf{r}_d) \frac{\partial G^*_{\partial\Omega,0}(\mathbf{r}, \mathbf{r}_d; \omega)}{\partial\nu} = \delta(\mathbf{r}_d; \omega) \quad (78)$$

$\mathbf{r}_d \in \partial\Omega.$

Now, we can define a function Ψ by applying the adjoint Green's operator to the function $b \in Y(\partial\Omega)$ to give

$$\Psi(\mathbf{r}; \omega) = - \int_{\partial\Omega} \overline{G}_{\Omega,0}^B(\mathbf{r}_d, \mathbf{r}; \omega) b(\mathbf{r}_d; \omega) dS \quad (79)$$

$$= \int_{\partial\Omega} G^*_{\partial\Omega,0}(\mathbf{r}, \mathbf{r}_d; \omega) b(\mathbf{r}_d; \omega) dS. \quad (80)$$

By using (78), we have that Ψ solves

$$-\nabla \cdot \kappa(\mathbf{r}) \nabla \Psi(\mathbf{r}; \omega) + \left(\mu_a(\mathbf{r}) - \frac{i\omega}{c} \right) \Psi(\mathbf{r}; \omega) = 0 \quad \mathbf{r} \in \Omega \setminus \partial\Omega \quad (81)$$

$$\Psi(\mathbf{r}_d; \omega) + 2\xi\kappa(\mathbf{r}_d) \frac{\partial\Psi(\mathbf{r}_d; \omega)}{\partial\nu} = b(\mathbf{r}_d; \omega) \quad \mathbf{r}_d \in \partial\Omega \quad (82)$$

and therefore, \mathcal{K}_q^* is given by

$$\mathcal{K}_q^* b = \begin{pmatrix} -\bar{\Phi}\Psi \\ -\nabla\bar{\Phi} \cdot \nabla\Psi \end{pmatrix}. \quad (83)$$

Finally, we have an adjoint form for the PMDF (73)

$$\rho(\mathbf{r}_d, \mathbf{r}', \mathbf{r}_s; \omega) = \begin{pmatrix} -\overline{G}_{\partial\Omega,0}^*(\mathbf{r}', \mathbf{r}_d; \omega) G_{\partial\Omega,0}(\mathbf{r}', \mathbf{r}_s; \omega) \\ -\nabla_{r'} \overline{G}_{\partial\Omega,0}^*(\mathbf{r}', \mathbf{r}_d; \omega) \cdot \nabla_{r'} G_{\partial\Omega,0}(\mathbf{r}', \mathbf{r}_s; \omega) \end{pmatrix} \quad (84)$$

Time-Domain Case

In the time domain, we form the *correlation* of the propagated wave and the back-propagated residual. Equation 83 becomes

$$\mathcal{K}_q^* b = \begin{pmatrix} \int_0^T -\Phi(t) \Psi(t) dt \\ \int_0^T -\nabla\Phi(t) \cdot \nabla\Psi(t) dt \end{pmatrix}, \quad (85)$$

where $\Psi(t)$ is the solution to the adjoint equation

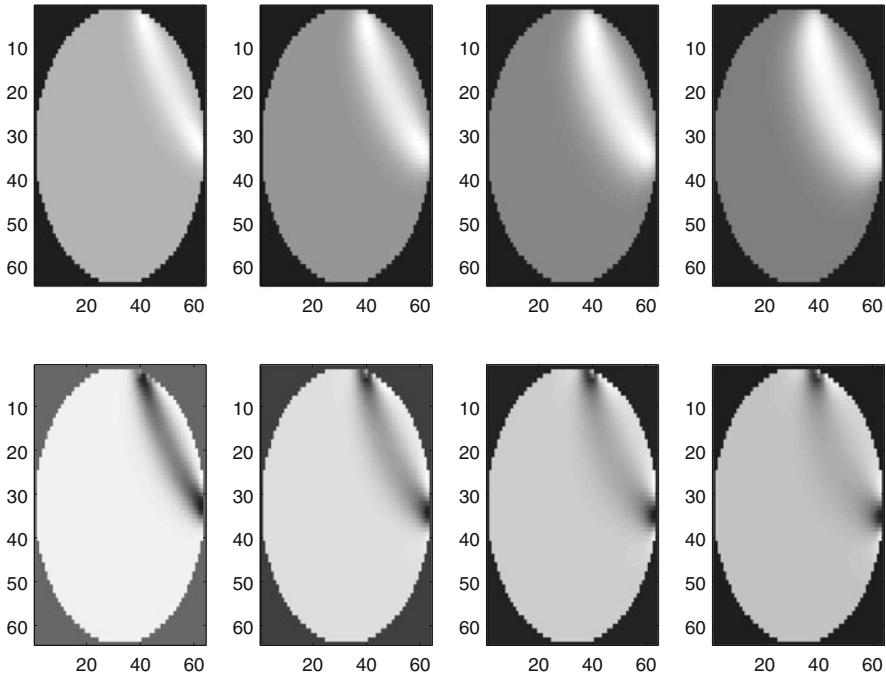

Fig. 4 Top row: time-window sensitivity function ρ for μ_a – left to right: time gates 500–1,000, 1,500–2,000, 2,500–3,000, 3,500–4,000 ps. Bottom row: the same functions for κ

$$\left(-\frac{1}{c} \frac{\partial}{\partial t} - \nabla \cdot \kappa(\mathbf{r}) \nabla + \mu_a(\mathbf{r}) \right) \Psi(\mathbf{r}, t) = 0 \quad \mathbf{r} \in \Omega \setminus \partial\Omega, t \in [0, T] \quad (86)$$

$$\Psi(\mathbf{r}, T) = 0, \quad \mathbf{r} \in \Omega \quad (87)$$

$$\Psi(\mathbf{r}_d, t) + 2\zeta\kappa(\mathbf{r}_d) \frac{\partial\Psi(\mathbf{r}_d, t)}{\partial\nu} = b(\mathbf{r}_d, t) \quad \mathbf{r}_d \in \partial\Omega, t \in [0, T]. \quad (88)$$

This is much more expensive, although it allows to apply temporal domain filters to optimize the effect of “early light” (that light that has undergone relatively few scattering events). In Fig. 4, the sensitivity functions over a sequence of time intervals are shown. Notice that the functions are more concentrated along the direct line of propagation for early times and become more spread out for later times.

Light Propagation and Its Probabilistic Interpretation

In time-domain systems, the source is a pulse in time which we express as a δ -function

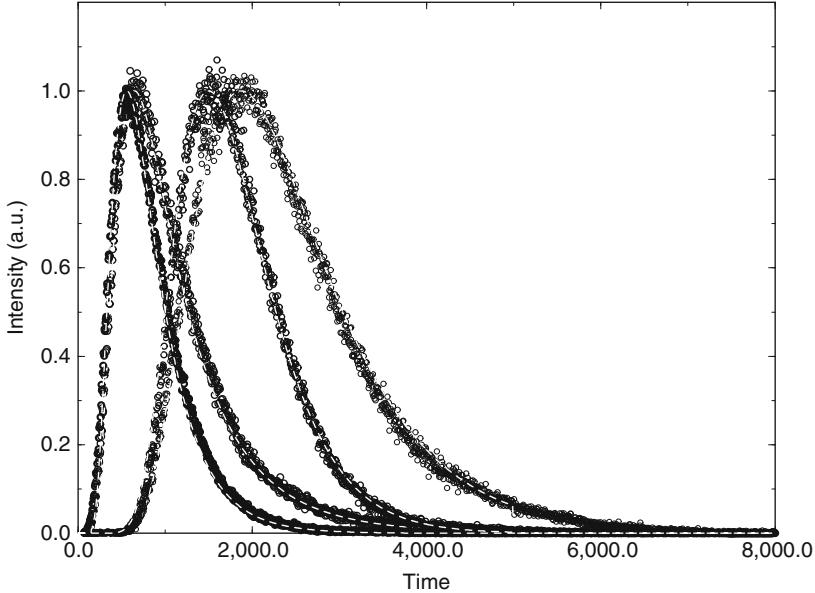

Fig. 5 Example of temporal response functions for different source-detector spacings. *Circles* represent measured data and *dashed lines* are the modeled data using a 3D finite element method. Each curve is normalized to a maximum of 1 (Data courtesy of E. Hillman and J. Hebden, University College London)

$$q(\mathbf{r}_d, t) = q(\mathbf{r}_d)\delta(t), \quad (89)$$

where $q(\mathbf{r}_d)$ is the source distribution on $\partial\Omega$. Furthermore, if the input light fiber is small, the spatial distribution can be considered a δ -function too, located at a source position $\mathbf{r}_{s_j} \in \partial\Omega$

$$q(\mathbf{r}_d, t) = \delta(\mathbf{r}_d - \mathbf{r}_{s_j})\delta(t). \quad (90)$$

For this model, the measured signal $y(\mathbf{r}_d, t)$ is the impulse response (Green's function) of the system, restricted to the boundary. When measured at a detector $\mathbf{r}_{di} \in \partial\Omega$, it is found to be a unimodal positive function of t with exponential decay to zero as $t \rightarrow \infty$. Some examples are shown in Fig. 5, showing measured data from the system described in [83] together with modeled data using a 3D finite element method. The function can be interpreted as a conditional probability density of the time of arrival of a photon, given the location of its arrival.

Consider the Green's functions for (18) in infinite space:

$$G(\mathbf{r}, \mathbf{r}', t, t') = \frac{e^{-\mu_a t - \frac{|\mathbf{r}-\mathbf{r}'|^2}{4\kappa(t-t')}}}{(4\pi\kappa t)^{3/2}} \quad t > t'. \quad (91)$$

Equation 91 has the form of the *Probability Density Function* (PDF) for a lossy random walk; for a fixed point in time, the distribution is spatially a Gaussian; for a fixed point in space, the distribution in time shows a sharp rise followed by an asymptotically exponential decay. In the probabilistic interpretation, we assume

$$\frac{G(\mathbf{r}, t, \mathbf{r}', t')}{\int G(\mathbf{r}, t, \mathbf{r}', t') dt} \equiv P_{\mathbf{r}', t'}(t | \mathbf{r}) \quad (92)$$

as a *conditional* PDF in the sense that a photon that has arrived at a given point does so in time interval $[t, t + \delta t]$ with probability $P_{\mathbf{r}', t}(t | \mathbf{r})\delta t$. Furthermore, the absolute PDF for detecting a photon at point \mathbf{r} at time t is given by

$$G(\mathbf{r}, t, \mathbf{r}', t') \equiv P_{\mathbf{r}', t'}(\mathbf{r}, t) = P_{\mathbf{r}'}(\mathbf{r})P_{\mathbf{r}', t'}(t | \mathbf{r}).$$

Here, $P_{\mathbf{r}'}(\mathbf{r})$ is interpreted as the relative intensity $I(\mathbf{r})/I_0$ of the detected number of photons relative to the input number.

For most PDFs based on physical phenomena, there exists a *Moment-Generating Function* (MGF)

$$M(s) = \mathbb{E}[P(t)e^{st}], \quad (93)$$

where $\mathbb{E}[\cdot]$ is the expectation operator, whence the moments (around zero) are determined by

$$m_n = \left. \frac{\partial^n M(s)}{\partial s^n} \right|_{s=0} \quad (94)$$

and in principle the PDF $P(t)$ can be reconstructed via a Taylor series for its MGF

$$M(s) = m_0 + m_1 s + \cdots m_n \frac{s^n}{n!} + \quad (95)$$

However, explicit evaluation of this series is impractical. Furthermore, we may assume that only a small number of independent moments exist, in which case we reconstruct the series implicitly given only the first few moments. In the results presented here, only the first three moments m_0 , m_1 , and m_2 are used. They have the physical interpretations

$$\begin{aligned} m_0 &\quad \text{Total intensity } I(\mathbf{r}) \\ \frac{m_1}{m_0} &\quad \text{Mean time } \langle t \rangle(\mathbf{r}) \\ \frac{m_2}{m_0} - \left(\frac{m_1}{m_0} \right)^2 &\quad \text{Variance time } \sigma_t^2(\mathbf{r}). \end{aligned}$$

In order to test the validity of the moment method to construct the time-varying solution, we created a finite element model of a $4 \times 7 \times 4$ cm slab. The optical

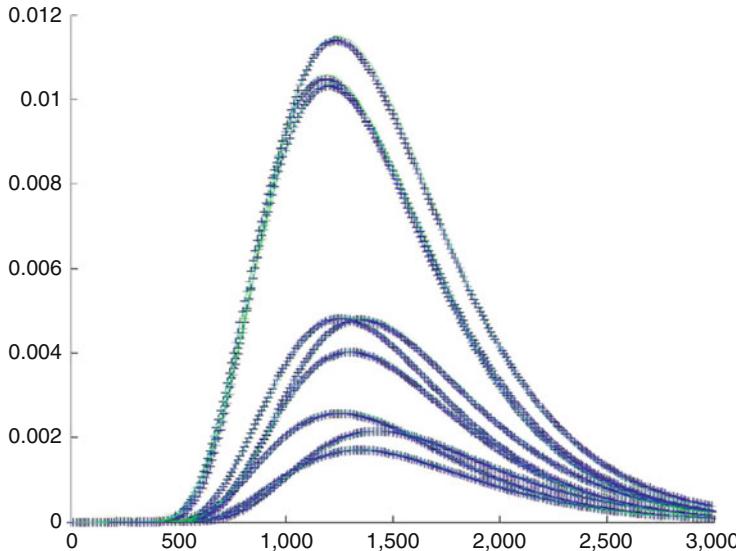

Fig. 6 An example of the output time-of-flight histograms at each of nine detectors on the transmission surface of a slab. Solid curves are computed from (95) using the zeroth, first, and second moments and implicit extrapolation; crosses are computed using finite differencing in time of the system (18) and 300 steps of size 10 ps

parameters were set to an arbitrary heterogeneous distribution by adding a number of Gaussian blobs of different amplitude and spatial width in both μ_a and κ to a background of $\mu_a = 0.1 \text{ cm}^{-1}$, $\kappa = 0.03 \text{ cm}$. A source was placed at the center of one face of the slab and nine detectors placed in a rectangular array on the opposite face of the slab. The time-of-flight histogram of transmitted photons at each detector was calculated in two ways: (1) by solving the time-dependent system (18) using a fully implicit finite differencing step in time (2) by solving for the moments m_0, m_1, m_2 using (94) and deriving the time-varying solution via (95).

One case is shown in Fig. 6. The comparison is virtually perfect despite the grossly heterogeneous nature of the example which precludes the exact specification of a Green's function. The moment-based method is several hundred times faster.

4 Numerical Methods and Case Examples

Image Reconstruction in Optical Tomography

Optical tomography is generally recognized as a nonlinear inverse problem; linear methods can certainly be applied (e.g., [85]) but are limited to the case of small perturbations on a known background.

The following is an overview of the general approach: we construct a physically accurate model that describes the progress of photons from the source optodes

through the media and to the detector optodes. This is termed the *forward problem* (section “The Forward Problem”). This model is parameterized by the spatial distribution of scattering and absorption properties in the media. We adjust these properties iteratively until the predicted measurements from the forward problem match the physical measurements from the device. This is termed the *inverse problem*.

The model-based approach is predicated on the implicit assumption that there exists in principle an “exact model” given by the physical description of the problem, and the task is to develop a computational technique that matches measured data within an accuracy below the expected level of measurement error. In other words, we assume that model inaccuracies are insignificant with respect to experimental errors. However, the computational effort in constructing a forward model of sufficient accuracy can be prohibitive at best. In addition, the physical model may have shortcomings that lead to the data being outside the range of the forward model (nonexistence of solution).

In the *approximation error method* [57], we abandon the need to produce an “exact model.” Instead, we attempt to determine the statistical properties of the modeling errors and compensate for them by incorporating them into the image reconstruction using a Bayesian approach (section “Approximation Error Approach”). The steps involved in using the approximation error theory are (1) the construction and sampling of a prior, (2) the construction of a mapping between coarse and fine models, (3) calculation of forward data from the samples on both coarse and fine models, and (4) statistical estimation of the mean and covariance of the differences between data from the coarse and fine models. In [11], this technique was shown to result in reconstructed images using a relatively inaccurate forward model that were of almost equal quality to those using a more accurate forward model; the increase in computational efficiency was an order of magnitude.

Reconstruction from optical measurements is difficult because it is fundamentally ill posed. We usually aim to reconstruct a larger number of voxels than there are measurements (which results in *nonuniqueness*), and the presence of noisy measurements can result in an exponential growth in the image artifacts. In order to stabilize the reconstruction, *regularization* is required. Whereas such regularization is often based on ad hoc considerations for improving image quality, the Bayesian approach provides a rigorous framework in which the reconstructed images are chosen to belong to a distribution with principled characteristics (the prior).

Bayesian Framework for Inverse Optical Tomography Problem

In the Bayesian framework for inverse problems, all unknowns are treated and modeled as random variables [57]. The measurements are often considered as random variables also in non-Bayesian framework for inverse problems. The actual modeling of the measurements as random variables is, however, often implicit, which is most manifest when least squares functionals are involved in the formulation of the problem. In the Bayesian framework, however, both the measurements

and the unknowns are *explicitly* modeled as random variables. The construction of the *likelihood (observation) models* and the *prior models* is the starting point of the Bayesian approach to (inverse) problems.

Once the probabilistic models for the unknowns and the measurement process have been constructed, the *posterior distribution* $\pi(x | y)$ is formed, which distribution reflects the uncertainty of the interesting unknowns x given the measurements y . This distribution can then be explored to answer all questions which can be expressed in terms of probabilities. For general discussion of Bayesian inference, see, for example, [21].

Bayesian inverse problems are a special class of problems in Bayesian inference. Usually, the dimension of a feasible representation of the unknowns is significantly larger than the number of measurements, and thus, for example, a maximum likelihood estimate is either impossible or extremely unstable to compute. In addition to the instability, the variances of the likelihood model are almost invariably much smaller than the variances of the prior models. The posterior distribution is often extremely narrow and, in addition, may be a nonlinear manifold.

Bayesian Formulation for the Inverse Problem

In the following, we denote the unknowns with the vector x , the measurements with y , and all probability distributions (densities) by π . Typically, we would have $x = (\mu_a, \mu_s)$, with μ_a and μ_s identified with the coordinates in the used representations.

The complete statistical information of all the random variables is given by the joint distribution $\pi(x, y)$. This distribution expresses all the uncertainty of the random variables. Once the measurements y have been obtained, the uncertainty in the unknowns x is (usually) reduced. The measurements are now reduced from random variables to numbers, and the uncertainty of x is expressed as the posterior distribution $\pi(x | y)$. This distribution contains all information on the uncertainty of the unknowns x when the information on measurements y is utilized.

The conditional distribution of the measurements given the unknown is called the *likelihood distribution* and is denoted by $\pi(y | x)$. The marginal distribution of the unknown is called the *prior (distribution)* and is denoted by $\pi(x)$. By the definition of conditional probability, we have

$$\pi(x, y) = \pi(y | x)\pi(x) = \pi(x | y)\pi(y). \quad (96)$$

Furthermore, the marginal distributions can be obtained by marginalizing (integrating) over the remaining variables, that is, $\pi(x) = \int \pi(x, y) y$ and $\pi(y) = \int \pi(x, y) x$. The following rearrangement is called Bayes' theorem

$$\pi(x | y) = \pi(y)^{-1}\pi(y | x)\pi(x). \quad (97)$$

If we were given the joint distribution, we could simply use the above definitions to compute the posterior distribution. Unfortunately, the joint distribution is practically never available in the first place. However, it turns out that in many cases,

the derivation of the likelihood density is a straightforward task. Also, a feasible probabilistic model for the unknown can often be obtained. Then, one can use Bayes' theorem to obtain the posterior distribution. The demarcation between the Bayesian and frequentist paradigms is that, here, the posterior is obtained by using a (prior) model for the distribution of the unknown rather than the marginal density, which cannot be computed since the joint distribution is not available in the first place. We stress that all distributions have to be interpreted as models.

Inference

Point estimates are the Bayesian counterpart of the “solutions” suggested by regularization methods. The most common point estimates are the *maximum a posteriori* estimate (MAP) and the *conditional mean* estimate (CM). Let the unknowns and measurements be the finite-dimensional random vectors $x \in \mathbb{R}^N$, $y \in \mathbb{R}^M$.

The computation of the MAP estimate is an optimization problem, while the computation of the CM estimate is an integration problem:

$$x_{\text{MAP}} = \text{sol} \max_x \pi(x | y) \quad (98)$$

$$x_{\text{CM}} = \mathbb{E}(x | y) = \int x \pi(x | y) \, \ddot{x}, \quad (99)$$

where sol reads as “solution of” the maximization problem, $\mathbb{E}(\cdot)$ denotes expectation, and the integral in (99) is an N -tuple integral.

The most common estimate of spread is the *conditional covariance*

$$\Gamma_{x|y} = \int (x - \mathbb{E}(x | y))(x - \mathbb{E}(x | y))^T \pi(x | y) \, \ddot{x}. \quad (100)$$

Here, $\Gamma_{x|y}$ is an $N \times N$ matrix and the integral (100) refers to a matrix of associated integrals.

Often, the marginal distributions of single variables are also of interest. These are formally obtained by integrating over all other variables

$$\pi(x_\ell | y) = \int_{x_{-\ell}} \pi(x | y) \, \ddot{x}_{-\ell}, \quad (101)$$

where the notation $(\cdot)_{-\ell}$ refers to all components *excluding* the ℓ th component. Note that $\pi(x_\ell | y)$ is a function of a single variable and can be visualized by plotting. The *credibility intervals* are the Bayesian counterpart to the frequentist confidence intervals, but the interpretation is different. The $p\%$ -credibility interval is a subset which contains $p\%$ of the probability mass of the *posterior distribution*.

Likelihood and Prior Models

The likelihood model $\pi(y | x)$ consists of modeling the forward problems and the related observational errors. In the likelihood model, all unknowns are treated as fixed. The most common likelihood model is based on the additive error model

$$y = \mathcal{F}(x) + e,$$

where e is the additive error term with distribution $\pi_e(e)$ which is usually modeled as mutually independent with x . In this case, we can get rid of the unknown additive error term by pre-marginalizing over it. We have formally $\pi(y | x, e) = \delta(y - \mathcal{F}(x) + e)$ and using the Bayes theorem

$$\pi(y | x) = \pi_e(y - \mathcal{F}(x)).$$

For more general derivation and other likelihood models, see, for example, [57].

In the special case of Gaussian additive errors $\pi_e(e) = \mathcal{N}(e_*, \Gamma_e)$, we get

$$\pi(y | x) \propto \exp\left(-\frac{1}{2}\|L_e(y - \mathcal{F}(x) - e_*)\|^2\right),$$

where $\Gamma_e^{-1} = L_e^T L_e$. In the very special case of $\pi_e(e) = \mathcal{N}(0, \gamma^2 I)$, we of course get the ordinary least squares functional for the posterior potential. This particular model, however, should always be subjected to assessment since it usually corresponds to an idealized measurement system.

For prior models $\pi(x)$ for the unknowns whose physical interpretation is a distributed parameter, Markov random fields are a common choice. The most common type is an improper prior model of the form

$$\pi(x) \propto \exp\left(-\frac{1}{2}\|L_x(x - x_*)\|^2\right), \quad (102)$$

where L_x is derived from a spatial differential operator. For example, $\|L_x(x - x_*)\|^2$ might be a discrete approximation for $\int_{\Omega} |\Delta x(\vec{r})|^2 d\vec{r}$. Such improper prior models may work well technically since the null space of L_x is usually such that it is annihilated in the posterior model. It must be noted, however, that there are constructions that yield proper prior models [57, 59, 67]. These are needed, for example, for the construction of approximation error models discussed in section “Approximation Error Approach.” Moreover, structural information related to inhomogeneities and anisotropicity of smoothness can be decoded in these models [59].

Nonstationary Problems

Inverse problems in which the unknowns are time varying are referred to as *nonstationary inverse problems* [57]. These problems are also naturally cast in the Bayesian framework. Nonstationary inverse problems are usually written as evolution–observation models in which the evolution of the unknown is typically modeled as a stochastic process. The related algorithms are sequential and in the most general form are of the Markov chain Monte Carlo type [32]. However, the most commonly used algorithms are based on the Kalman recursions [3, 57, 61].

A suitable statistical framework for dealing with unknowns that are modeled with stochastic processes and which are observed either directly or indirectly is the *state*

estimation framework. In this formalism, the unknown is referred to as *the state variable*, or simply *the state*. For treatises on state estimation and Kalman filtering theory in general, see, for example, [3, 34]. For the general nonlinear non-Gaussian treatment, see [32], and for state estimation with inverse problems, see [57].

The general discrete time *state space representation* of a dynamical system is of the form

$$x_{k+1} = F_k(x_k, w_k) \quad (103)$$

$$y_k = A_k(x_k, v_k), \quad (104)$$

where w_k is the *state noise process*, v_k is the *observation noise process*, and (103) and (104) are the *evolution model* and *observation model*, respectively. Here, the evolution model replaces the prior model in stationary inverse problems, while the observation model is usually the same as the (stationary) likelihood model. We do not state the exact assumptions here, since the assumptions may vary somewhat resulting in different variations of Kalman recursions; see, for example, [3]. It suffices here to state that the sequences of mappings F_t and A_t are assumed to be known and that the state and observation noise processes are temporally uncorrelated and that their (second-order, possibly time-varying) statistics are known. With these assumptions, the state process is a first-order Markov process. The first-order Markov property facilitates recursive algorithms for the state estimation problem. The Kalman recursions were first derived in [61].

Formally, the state estimation problem is to compute the distribution of a state variable $x_k \in \mathbb{R}^N$ given a set of observations $y_j \in \mathbb{R}^M$, $j \in \mathcal{I}$ where \mathcal{I} is a set of time indices. In particular, the aim is to compute the related conditional means and covariances. Usually, \mathcal{I} is a contiguous set of indices and we denote $Y_\ell = (y_1, \dots, y_\ell)$.

We can then state the following common state estimation problems:

- *Prediction.* Compute the conditional distribution of x_k given Y_ℓ , $k > \ell$.
- *Filtering.* Compute the conditional distribution of x_k given Y_ℓ , $k = \ell$.
- *Smoothing.* Compute the conditional distribution of x_k given Y_ℓ , $k < \ell$.

The solution of the state estimation problems in linear Gaussian cases is usually carried out by employing the Kalman filtering or smoothing algorithms that are based on Kalman filtering. These are recursive algorithms and may be either real-time, online, or batch-type algorithms.

In nonlinear and/or non-Gaussian cases, extended Kalman filtering (EKF) variants are usually employed. The EKF algorithms form a family of estimators that do not possess any optimality properties. For many problems, however, the EKF algorithms provide feasible state estimates. For EKF algorithms, see, for example, [3, 57]. Since the observation models with optical tomography are nonlinear, the EKF algorithms are a natural choice for nonstationary DOT problems; see [30, 66, 81].

The idea in extended Kalman filters is straightforward: the nonlinear mappings are approximated with the affine mappings given by the first two terms of the Taylor expansion. The version of extended Kalman filter that is most commonly used is the *local linearization version*, in which version the mappings are linearized at the best currently available state estimates, either the predicted or the filtered state. This necessitates the recomputation of the Jacobians $\partial A_t / \partial x_t$ at each time instant.

The EKF recursions take the form

$$x_{k|k-1} = F_{k-1}(x_{k-1|k-1}) + s_{k-1} + B_{k-1}(u_{k-1}) \quad (105)$$

$$\Gamma_{k|k-1} = J_{F_{k-1}} \Gamma_{k-1|k-1} J_{F_{k-1}}^T + \Gamma_{w_{k-1}} \quad (106)$$

$$K_k = \Gamma_{k|k-1} J_{A_k}^T (J_{A_k} \Gamma_{k|k-1} J_{A_k}^T + \Gamma_{v_k})^{-1} \quad (107)$$

$$\Gamma_{k|k} = (I - K_k J_{A_k}) \Gamma_{k|k-1} \quad (108)$$

$$x_{k|k} = x_{k|k-1} + K_k (y_k - A_k(x_{k|k-1})), \quad (109)$$

where $x_{k|k-1}$ and $x_{k|k}$ are the prediction and filtering estimates, respectively, and $\Gamma_{k|k-1}$ and $\Gamma_{k|k}$ are the approximate prediction and filtering covariances, respectively. Note that the Jacobian mappings (linearizations) are needed only in the computation of the covariances and the Kalman gain K_t .

The applications of EKF algorithms to nonstationary DOT problems have been considered in [30, 66, 81]. In [66], a random walk evolution model was constructed and used for tracking of targets in a cylindrical tank geometry. In [81], a cortical mapping problem was considered, in which the evolution model was augmented to include auxiliary periodic processes to allow for separation of cyclical phenomena from evoked responses. In [30], an elaborate physiological model was added to that of [81] to form the evolution model.

Approximation Error Approach

The approximation error approach was introduced in [57, 58] originally to handle pure model reduction errors. For example, in electrical impedance (resistance) tomography (EIT, ERT) and deconvolution problems, it was shown that significant model reduction is possible without essentially sacrificing the quality of estimates. With model reduction, we mean that very low-dimensional finite element approximations can be used for the forward problem. The approximation error approach relies heavily on the Bayesian framework of inverse problems, since the approximation and modeling errors are modeled as additive errors *over the prior model*.

In this following, we discuss the approximation error approach in a setting in which one distributed parameter is of interest, while another one is not, and there are additional uncertainties that are related, for example, to unknown boundary data. In addition, we formulate the problem to take into account model reduction errors. In the case of optical tomography, this would mean using very approximate forward solvers, for example.

Let now the unknowns be (μ_a, μ_s, ξ, e) , where e represents additive errors and ξ represents auxiliary uncertainties, such as unknown boundary data, and μ_a is of interest only. Let

$$y = \bar{A}(\mu_a, \mu_s, \xi) + e \in \mathbb{R}^m$$

denote an accurate model for the relation between the measurements and the unknowns.

In the approximation error approach, we proceed as follows. Instead of using the accurate forward model $(\mu_a, \mu_s, \xi) \mapsto \bar{A}(\mu_a, \mu_s, \xi)$ with (μ_a, μ_s, ξ) as the unknowns, we fix the random variables $(\mu_s, \xi) \leftarrow (\mu_{s,0}, \xi_0)$ and use a computationally (possibly drastically reduced) approximate model

$$\mu_a \mapsto A(\mu_a, \mu_{s,0}, \xi_0).$$

Thus, we write the measurement model in the form

$$y = \bar{A}(\mu_a, \mu_s, \xi) + e \tag{110}$$

$$= A(\mu_a, \mu_{s,0}, \xi_0) + (\bar{A}(\mu_a, \mu_s, \xi) - A(\mu_a, \mu_{s,0}, \xi_0)) + e \tag{111}$$

$$= A(\mu_a, \mu_{s,0}, \xi_0) + \varepsilon + e, \tag{112}$$

where we define the *approximation error* $\varepsilon = \varphi(\mu_a, \mu_s, \xi) = \bar{A}(\mu_a, \mu_s, \xi) - A(\mu_a, \mu_{s,0}, \xi_0)$. Thus, the approximation error is the discrepancy of predictions of the measurements (given the unknowns) when using the accurate model $\bar{A}(\mu_a, \mu_s, \xi)$ and the approximate model $A(\mu_a, \mu_{s,0}, \xi_0)$.

Using the Bayes' formula repeatedly, it can be shown that

$$\pi(y | x) = \int \pi_e(y - A(x, \mu_{s,0}, \xi_0) - \varepsilon) \pi_{\varepsilon|x}(\varepsilon | x) d\varepsilon \tag{113}$$

since e and x are mutually independent. Note that (112) and (113) are exact.

In the approximation error approach, the following Gaussian approximations are used: $\pi_e \approx \mathcal{N}(e_*, \Gamma_e)$ and $\pi_{\varepsilon|x} \approx \mathcal{N}(\varepsilon_{*,\mu_a}, \Gamma_{\varepsilon|\mu_a})$. Let the normal approximation for the joint density $\pi(\varepsilon, \mu_a)$ be

$$\pi(\varepsilon, \mu_a) \propto \exp \left\{ -\frac{1}{2} \begin{pmatrix} \varepsilon - \varepsilon_* \\ \mu_a - \mu_{a,*} \end{pmatrix}^T \begin{pmatrix} \Gamma_{\varepsilon\varepsilon} & \Gamma_{\varepsilon\mu_a} \\ \Gamma_{\mu_a\varepsilon} & \Gamma_{\mu_a\mu_a} \end{pmatrix}^{-1} \begin{pmatrix} \varepsilon - \varepsilon_* \\ \mu_a - \mu_{a,*} \end{pmatrix} \right\} \tag{114}$$

whence

$$\varepsilon_{*,\mu_a} = \varepsilon_* + \Gamma_{\varepsilon\mu_a} \Gamma_{\mu_a\mu_a}^{-1} (\mu_a - \mu_{a,*}) \tag{115}$$

$$\Gamma_{\varepsilon|\mu_a} = \Gamma_{\varepsilon\varepsilon} - \Gamma_{\varepsilon\mu_a} \Gamma_{\mu_a\mu_a}^{-1} \Gamma_{\mu_a\varepsilon}. \tag{116}$$

Define the normal random variable $v = e + \varepsilon$ so that $v | \mu_a \sim \mathcal{N}(v_{*,\mu_a}, \Gamma_{v|\mu_a})$. Thus, we obtain for the approximate likelihood distribution

$$\pi(y | \mu_a) \approx \mathcal{N}(y - A(\mu_a, \mu_{s,0}, \xi_0) - v_{*|\mu_a}, \Gamma_{v|\mu_a}).$$

Since we are after computational efficiency, a normal approximation $\pi(\mu_a) \approx \mathcal{N}(\mu_{a,*}, \Gamma_{\mu_a})$ for the prior model is also usually employed. Thus, we obtain the approximation for the posterior distribution

$$\pi(\mu_a | y) \propto \pi(y | \mu_a) \pi(\mu_a) \quad (117)$$

$$\propto \exp\left(-\frac{1}{2}\|L_{v|\mu_a}(y - A(\mu_a, \mu_{s,*}, \xi_*) - v_{*|\mu_a})\|^2\right) \quad (118)$$

$$+ \|L_{\mu_a}(\mu_a - \mu_{a,*})\|^2\right), \quad (119)$$

where $\Gamma_{v|\mu_a}^{-1} = L_{v|\mu_a}^T L_{v|\mu_a}$ and $\Gamma_{\mu_a \mu_a}^{-1} = L_{\mu_a}^T L_{\mu_a}$. See [68] or more details on the particular problem of marginalizing over the scattering coefficient.

The approximation error approach has been applied to various kinds of approximation and modeling errors as well as other inverse problems. Model reduction, domain truncation, and unknown anisotropy structures in diffuse optical tomography were treated in [12, 45, 46, 67]. Missing boundary data in the case of image processing and geophysical EIT were considered in [23] and [70], respectively. Furthermore, in [76–78], the problem of recovery from simultaneous geometry errors and model reduction was found to be possible. In [95], the radiative transfer model was replaced with the diffusion approximation. It was found that also in this kind of a case, the statistical structure of the approximation errors enabled the use of a significantly less complex model, again simultaneously with significant model reduction for the diffusion approximation. But also here, both the absorption and scattering coefficients were estimated simultaneously.

The approximation error approach was extended to nonstationary inverse problems in [51] in which linear nonstationary (heat transfer) problems were considered and in [50] and [52] in which nonlinear problems and state space identification problems were considered, respectively. A modification in which the approximation error statistics can be updated with accumulating information was proposed in [53] and an application to hydrogeophysical monitoring in [71].

Experimental Results

In this section, we show an example where the error model is employed for compensating the modeling errors caused by reduced discretization accuracy h and experimental DOT data is used for the observations.

Experiment and Measurement Parameters

The experiment was carried out with the frequency-domain (FD) DOT instrument at Helsinki University of Technology [75]. The measurement domain Ω is a cylinder with radius $r = 35$ mm and height 110 mm; see Fig. 7. The target consists of homogeneous material with two small cylindrical perturbations, as illustrated in

Fig. 7 Top: Measurement domain Ω . The dots denote the location of the sources and detectors. The (red) lines above and below the sources and detectors denote the truncated model domain Ω . The green line denotes the central slice of the domain Ω . Bottom: Central slice of the target (μ_a left, μ'_s right)

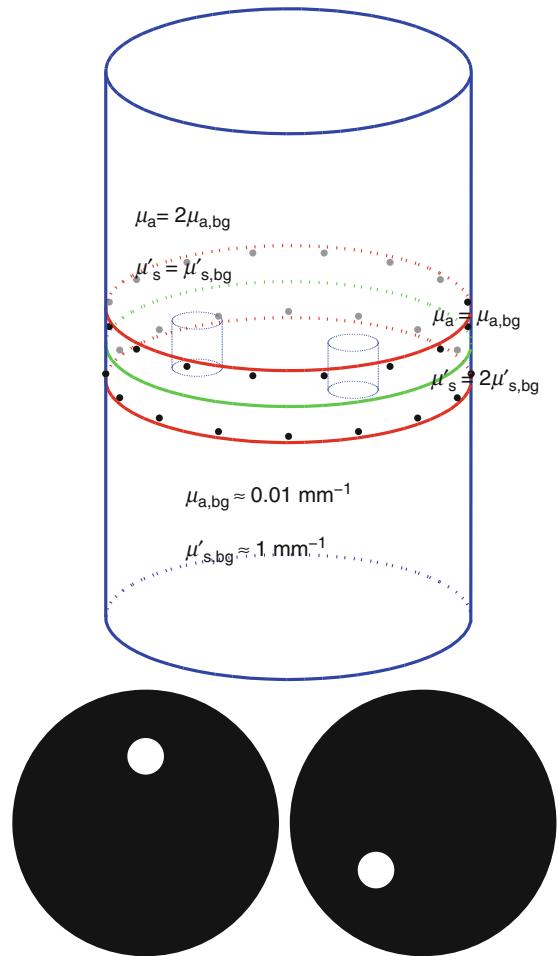

Fig. 7. The background optical properties of the phantom are approximately $\mu_{a,bg} = 0.01 \text{ mm}^{-1}$ and $\mu_{s,bg} = 1 \text{ mm}^{-1}$ at wavelength $\lambda \approx 800 \text{ nm}$. The cylindrical perturbations, which both have diameter and height of 9.5 mm, are located such that the central plane of the perturbations coincides with the central xy -plane of the cylinder domain Ω . For an illustration of the cross sections of μ_a and μ'_s , see bottom row in Fig. 7. The optical properties of perturbation 1 are approximately $\mu_{a,p1} = 0.02 \text{ mm}^{-1}$, $\mu_{s,p1} = 1 \text{ mm}^{-1}$ (i.e., purely absorption contrast) and the properties of perturbation 2 are $\mu_{a,p2} = 0.01 \text{ mm}^{-1}$, $\mu_{s,p2} = 2 \text{ mm}^{-1}$ (i.e., purely scatter contrast), respectively. The source and detector configuration in the experiment consisted of 16 sources and 16 detectors arranged in interleaved order on two rings located 6 mm above and below the central xy -plane of the cylinder domain. The locations of sources and detectors are shown with dots in Fig. 7. The measurements were carried out at $\lambda = 785 \text{ nm}$ with an optical power of 8 mW and

modulation frequency $2\pi f = 100$ MHz. The log amplitude and phase shift of the transmitted light was recorded at 12 farthermost detector locations for each source, leading to a real-valued measurement vector

$$y = \begin{pmatrix} \text{re}(\log(z)) \\ \text{im}(\log(z)) \end{pmatrix} \in \mathbb{R}^{384}$$

for the experiment. The statistics of measurement noise in the measurement y are not known. Thus, we employ the same implicit (ad hoc) noise model that was used for reconstructions from the same measurement realization in [88]. The noise model is

$$e \sim \mathcal{N}(0, \Gamma_e),$$

where Γ_e is a diagonal data scaling matrix which is tuned such that the initial (weighted) least squares (LS) residual

$$\|L_e(y - y_0)\|^2 = 2, \quad \Gamma_e^{-1} = L_e^T L_e$$

between the measured data y and forward solution y_0 at the initial guess $x = x_0$ becomes unity for both data types (log amplitude $\text{re}(\log(z))$ and phase $\text{im}(\log(z))$).

Prior Model

In this study, we use a proper Gaussian smoothness prior as the prior model for the unknowns. The absorption and scatter images μ_a and μ'_s are modeled as mutually independent Gaussian random fields with a joint prior model

$$\pi(x_\delta) \propto \exp \left\{ -\frac{1}{2} \|L_{x_\delta}(x_\delta - x_{\delta*})\|^2 \right\}, \quad L_{x_\delta}^T L_{x_\delta} = \Gamma_{x_\delta}^{-1}, \quad (120)$$

where

$$\Gamma_{x_\delta} = \begin{pmatrix} \Gamma_{\mu_a} & 0 \\ 0 & \Gamma_{\mu'_s} \end{pmatrix}.$$

The construction of the blocks Γ_{μ_a} and $\Gamma_{\mu'_s}$ has been explained for a two-dimensional case in [11], and the extension to three-dimensional case is straightforward. The parameters in the prior model were selected as follows. The correlation length for both μ_a and μ'_s in the prior was set as 11 mm. The correlation length can be viewed (roughly) as our prior estimate about the expected spatial size of perturbations in the target domain. The prior mean for absorption and scatter were set as $\mu_{a*} = 0.01 \text{ mm}^{-1}$ and $\mu_{s*} = 1 \text{ mm}^{-1}$, and the marginal standard deviations of absorption and scatter in each voxel were chosen such that $3\sigma_{\mu_a} = 0.01$ and $3\sigma_{\mu'_s} = 1$, respectively. This choice corresponds to assuming that the values of absorption and scatter are expected to lie within the intervals $\mu_a \in [0, 0.02]$ and

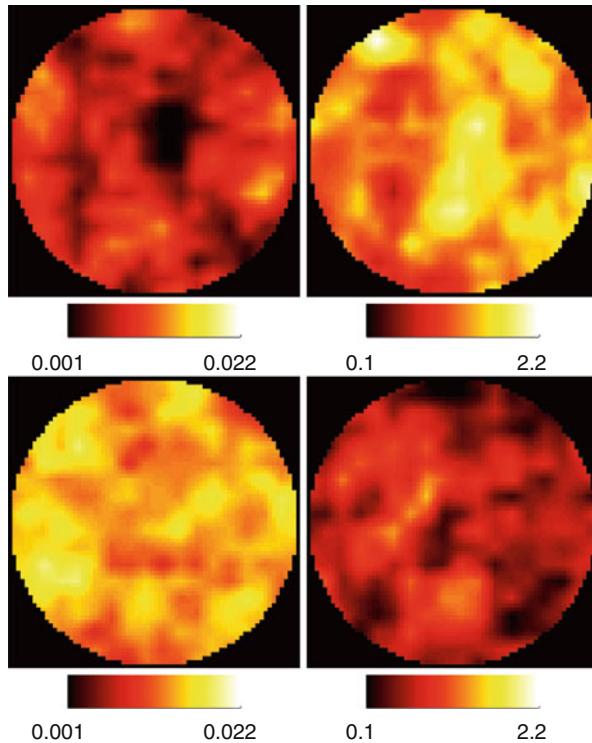

Fig. 8 Two random samples from the prior density (120). The images display the cross section of the 3D parameters at the central slice of the cylinder domain Ω . *Left:* Absorption μ_a . *Right:* Scatter μ'_s

$\mu'_s \in [0, 2]$ with *prior* probability of 99.7 %. Figure 8 shows two random samples from the prior model.

Selection of FEM Meshes and Discretization Accuracy

To select the discretization accuracy δ for the accurate forward model $A_{\Omega,\delta}(x_\delta)$, we adopted a similar procedure as in [11]. In this process, we computed relative error in the FEM solution with respect to the discretization level h and identified δ as that mesh density beyond which the relative error

$$\frac{\|A_{\Omega,h} - A_{\Omega,h'}\|}{\|A_{\Omega,h'}\|}$$

in both amplitude and phase parts of the forward solution was stabilized. The mesh for the reference model $A_{\Omega,h'}$ in the convergence analysis consisted of $N_n = 253,981$ node points and $N_e = 1,458,000$ (approximately) uniform tetrahedral elements. We found that the errors in the FEM solution were stabilized when using a (uniform) tetrahedral mesh with (approximately) 150,000 nodes or more, and thus,

Table 1 Mesh details for test case. N_n is the number of nodes, N_e is the number of tetrahedral elements in the mesh, and n_p is the number of voxels in the representation of μ_a and μ'_s . t is the wall clock time for one forward solution

| Model | N_n | N_e | n_p | t (s) |
|---------------------|---------|---------|-------|---------|
| $A_{\Omega,\delta}$ | 148,276 | 843,750 | 7,668 | 178 |
| $A_{\Omega,h}$ | 2,413 | 11,664 | 7,668 | 0.4 |

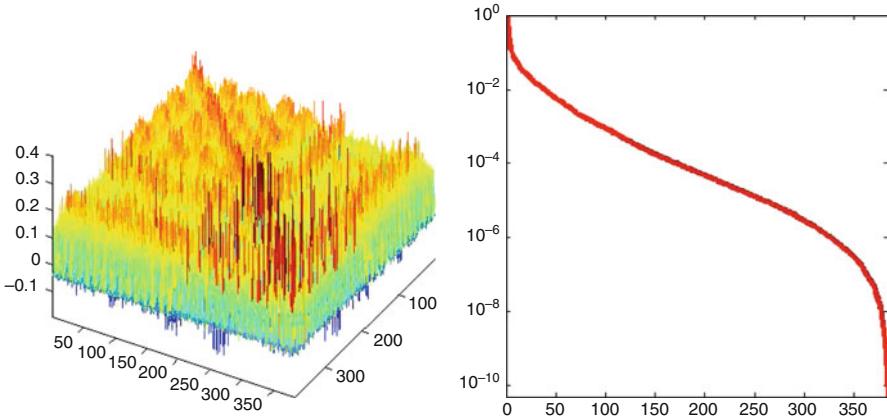

Fig. 9 Modeling error between the accurate model $A_{\Omega,\delta}$ and target model $A_{\Omega,h}$; see Table 1. *Left:* Covariance structure of the approximation error ε . The displayed quantity is the signed standard deviation $\text{sign}(\Gamma_\varepsilon) \cdot \sqrt{|\Gamma_\varepsilon|}$, where the product refers to the element-by-element (array) multiplication. *Right:* Normalized eigenvalues λ/λ_{\max} of Γ_ε .

we chose for the accurate model $A_{\Omega,\delta}$ a mesh with $N_n = 148,276$ node points. For the target model $A_{\Omega,h}$, we chose a mesh with $N_n = 2,413$ nodes; see Table 1. For the representation of the unknowns (μ_a, μ'_s) , the domain Ω was divided into $n_p = 7,668$ cubic voxels (i.e., number of unknowns $n = 15,336$) in both models $A_{\Omega,\delta}$ and $A_{\Omega,h}$. Thus, the projector $P : x_\delta \mapsto x_h$ between the models is the identity matrix.

Construction of Error Models

To construct the enhanced error model, we proceeded as in section ‘‘Approximation Error Approach.’’ The size of the random ensemble S from the prior model $\pi(x_\delta)$, Eq. 120, was $L = 384$. Figure 8 shows central xy -slices from two realizations of absorption and scatter images from the ensemble (the location of the slice is denoted by green line in Fig. 7). Using the ensemble, Gaussian approximations $\varepsilon \sim \mathcal{N}(\varepsilon_*, \Gamma_\varepsilon)$ for the error between the accurate model $A_{\Omega,\delta}$ and the target models were computed.

To assess the magnitude of the modeling error, we estimate signal-to-noise (SNR) ratio of the modeling error as

$$\text{SNR} = 10 \log_{10} \left(\frac{\|\overline{A}_{\Omega,\delta}\|^2}{\|\varepsilon_*\|^2 + \text{trace}(\Gamma_\varepsilon)} \right),$$

where $\overline{A}_{\Omega,\delta}$ is the mean of the accurate model $A_{\Omega,\delta}$ over the ensemble S . The SNR is estimated separately for the amplitude and phase part of the forward model.

Consider now the modeling error between the accurate model $A_{\Omega,\delta}$ ($N_n = 148,276$ nodes) and target model $A_{\Omega,h}$ ($N_n = 2,413$ nodes) in the first test case. In this case, the estimated SNRs for the modeling error in log amplitude and phase are approximately 20 and 13, corresponding to error levels of 10 and 22 %, respectively. These error levels exceed clearly typical levels of measurement noise in DOT measurements. Left image in Fig. 9 displays the covariance matrix Γ_ε , revealing the correlation structure of ε . Combining the high magnitude and complicated correlation structure of the modeling error ε with the fact that the inverse problem is sensitive to modeling errors, one can expect significant artifacts in the reconstructions with conventional noise model when employing the target model $A_{\Omega,h}$.

Right image in Fig. 9 shows normalized eigenvalues λ/λ_{\max} of Γ_ε for the modeling error between models $A_{\Omega,\delta}$ and $A_{\Omega,h}$ in the first test case. As can be seen, the eigenvalues are decaying rapidly and already the 40th eigenvalue is less than 1 % of the maximum. Roughly speaking, this rapid decay of the eigenvalues can be interpreted such that the variability in the modeling error can be well explained with a relatively small number of principal components. In other words, one can take this as a sign that the structure of the modeling error is not “heavily dependent” on the realization of x or the prior model $\pi(x)$, and thus, the error model can be expected to perform well.

Notice that the setting up of the error model is a computationally intensive task, while the use of the model is as with the conventional error model. The computation time for setting up the error model is roughly equivalent to the size of the ensemble times, the time for forward solution in the accurate and approximate models. However, the error model needs to be estimated only once for a fixed measurement setup, and this estimation can be offline.

Computation of the MAP Estimates

The MAP-CEM and MAP-EEM estimates are computed by a Polak Ribiere conjugate gradient algorithm which is equipped with an explicit line search. Similarly as in the initial estimation, the positivity prior of the absorption and scatter images is taken into account by using (scaled) logarithmic parameterization

$$\log \left(\frac{\mu_a}{\mu_{a0}} \right), \quad \log \left(\frac{\mu'_s}{\mu'_{s0}} \right)$$

in the unconstrained optimization process; for details, see [88].

Results are shown in Figs. 10 and 11 and computation times in Table 2.

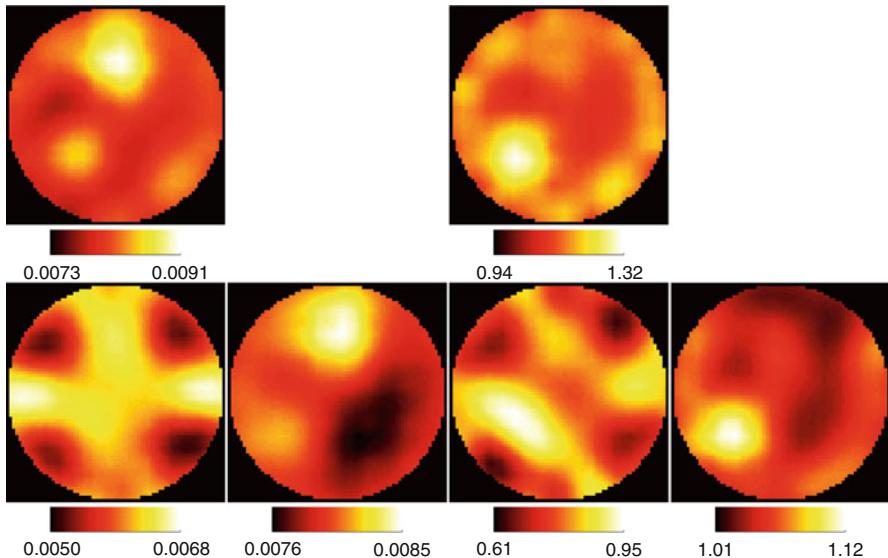

Fig. 10 Pure discretization errors. Central horizontal slice from the 3D reconstructions of absorption μ_a and scattering μ'_s . Top row: MAP estimate with the conventional error model (MAP-CEM) using the accurate forward model $A_{\Omega,\delta}$ (number of nodes in the FEM mesh $N_n = 148,276$). Left: $\mu_{a,CEM}$. Right: $\mu_{s,EEM}$. Bottom row: MAP estimates with the conventional (MAP-CEM) and enhanced error models (MAP-EEM) using the target model $A_{\Omega,h}$ (the number of nodes $N_n = 2,413$). Correct model domain $\Omega = \Omega$ is used in the target model $A_{\Omega,h}$. Columns from left to right: $\mu_{a,CEM}$, $\mu_{a,EEM}$, $\mu_{s,CEM}$, and $\mu_{s,EEM}$. The number of unknowns $x = (\mu_a, \mu'_s)^T$ in the estimation with both models, $A_{\Omega,\delta}$ and $A_{\Omega,h}$, was 15,336

The images in the top row display the MAP estimate with the conventional noise model using the accurate forward model $A_{\Omega,\delta}$ ($N_n = 148,276$). The estimated values of global parameters $\mu_{a0} = 0.0079 \text{ mm}^{-1}$ and $\mu_{s0} = 1.086 \text{ mm}^{-1}$ are relatively close to the background values $\mu_{a,bg} = 0.01 \text{ mm}^{-1}$ and $\mu_{s,bg} = 1 \text{ mm}^{-1}$ of the target phantom. As can be seen, the structure of the phantom is reconstructed well, but the contrast of the recovered inclusions is low compared to the (presumed) contrast. However, the low contrast is related to the measurement setup, not the reconstruction algorithm; the same measurement realization has previously been used for absolute reconstructions with different algorithm in [88], resulting to similar reconstruction quality and contrast in the optical properties. See also [89] for similar results with the same measurement system. The MAP-CEM estimate with the accurate model $A_{\Omega,\delta}$ can be considered here as a *reference estimate* using conventional noise model in absence of modeling errors caused by reduced discretization or domain truncation.

The MAP-CEM estimate using the coarse target model $A_{\Omega,h}$ ($N_n = 2,413$) is shown in the first and third images in the bottom row in Figs. 10 and 11. As can be seen, the use of reduced discretization has caused significant errors in the reconstruction and also the levels of μ_a and μ'_s are erroneous.

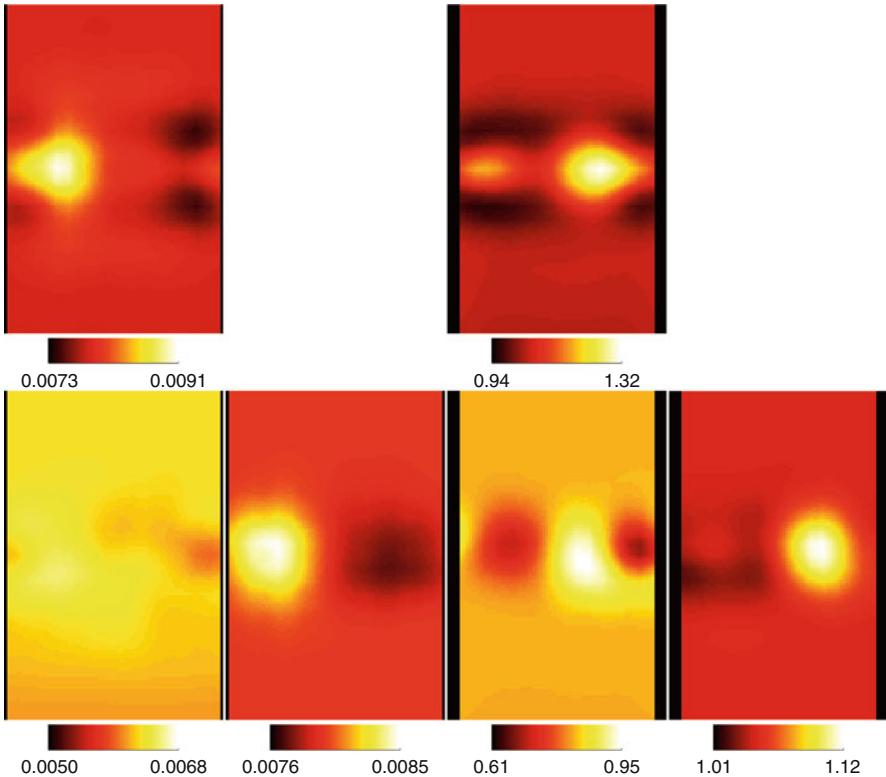

Fig. 11 Pure discretization errors. Vertical slices from the 3D reconstructions of absorption μ_a and scattering μ'_s . The slices have been chosen such that the inclusion in the parameter is visible. The arrangement of the images is equivalent to Fig. 10

Table 2 Reconstruction times for Figs. 10 and 11. t_{init} is the (wall clock) time for initial estimation, t_{MAP} for the MAP estimation, and t_{tot} the total reconstruction time (initial + MAP)

| Noise model | Forward model | t_{init} (s) | t_{MAP} (s) | t_{tot} (s) |
|-------------|---------------------|-----------------------|----------------------|----------------------|
| CEM | $A_{\Omega,\delta}$ | 126 min 20 s | 173 min 22 s | 299 min 44 s |
| CEM | $A_{\Omega,h}$ | 1 min 11 s | 7 min 18 s | 8 min 29 s |
| EEM | $A_{\Omega,h}$ | 28 s | 7 min 34 s | 8 min 2 s |

The MAP estimate with the enhanced error model using the coarse target model $A_{\Omega,h}$ is shown in the second and fourth images in the bottom row in Figs. 10 and 11. As can be seen, the estimate is very similar to the MAP-CEM estimate with the accurate model $A_{\Omega,\delta}$, showing that the use of enhanced error model has efficiently compensated for the errors caused by reduced discretization accuracy. These results indicate that the enhanced error model allows significant reduction in computation time without compromise in the reconstruction quality; whereas the reconstruction time for the MAP-CEM using accurate model $A_{\Omega,\delta}$ is very close to 5 h, the computation time for MAP-EEM is only 8 min.

5 Conclusion

In this chapter, we mainly discussed the use of the diffusion approximation for optical tomography. Because of the exponentially ill-posed nature of the corresponding inverse problem, diffuse optical tomography (DOT) gives low resolution images. Current research is focused on several areas: the use of auxiliary (multi-modality) information to improve DOT images, the development of smaller-scale (mesoscopic) imaging methods based on the radiative transfer equation, and the development of fluorescence and bioluminescence imaging techniques which give stronger contrast to features of interest. These methods are closely tied to the development of new experimental systems and to application areas which are driving the continued interest in this technique.

Abstract

Photoacoustic tomography (PAT), also known as thermoacoustic or optoacoustic tomography, is a rapidly emerging imaging technique that holds great promise for biomedical imaging. PAT is a hybrid imaging technique, and can be viewed either as an ultrasound mediated electromagnetic modality or an ultrasound modality that exploits electromagnetic-enhanced image contrast. In this chapter, we provide a review of the underlying imaging physics and contrast mechanisms in PAT. Additionally, the imaging models that relate the measured photoacoustic wavefields to the sought-after optical absorption distribution are described in their continuous and discrete forms. The basic principles of image reconstruction from discrete measurement data are presented, which includes a review of methods for modeling the measurement system response.

1 Introduction

Photoacoustic tomography (PAT), also known as thermoacoustic or optoacoustic tomography, is a rapidly emerging imaging technique that holds great promise for biomedical imaging [30, 31, 45, 61, 63]. PAT is a hybrid technique that exploits the thermoacoustic effect for signal generation. It seeks to combine the high electromagnetic contrast of tissue with the high spatial resolution of ultrasonic methods. Accordingly, PAT can be viewed either as an ultrasound mediated electromagnetic modality or an ultrasound modality that exploits electromagnetic-enhanced image contrast [65]. Since the 1990s, there have been numerous fundamental studies of photoacoustic imaging of biological tissue [19, 31, 41, 44, 46, 47, 57], and the development of PAT continues to progress at a tremendous rate [18, 24, 28, 30, 31, 33, 45, 64, 65].

When a short electromagnetic pulse (e.g., microwave or laser) is used to irradiate a biological tissue, the thermoacoustic effect results in the emission of acoustic signals that can be measured outside the object by use of wideband ultrasonic transducers. The objective of PAT is to produce an image that represents a map of the spatially variant electromagnetic absorption properties of the tissue, from knowledge of the measured acoustic signals. Because the optical absorption properties of tissue are highly related to its molecular constitution, PAT images can reveal the pathological condition of the tissue [11, 26] and therefore facilitate a wide range of diagnostic tasks. Moreover, when employed with targeted probes or optical contrast agents, PAT has the potential to facilitate high-resolution molecular imaging [32, 58] of deep structures, which cannot be achieved easily with pure optical methods.

From a physical perspective, the image reconstruction problem in PAT can be interpreted as an inverse source problem [6]. Accordingly, PAT is a computed imaging modality that utilizes an image reconstruction algorithm to form the image of the absorbed optical energy distribution. A variety of analytic image reconstruction algorithms have been developed for three-dimensional (3D) PAT,

assuming point-like ultrasound transducers with canonical measurement apertures [22, 23, 30, 31, 35, 64–66]. All known analytic reconstruction algorithms that are mathematically exact and numerically stable require complete knowledge of the photoacoustic wavefield on a measurement aperture that either encloses the entire object or extends to infinity. In many potential applications of PAT imaging, it is not feasible to acquire such measurement data. Because of this, iterative, or more generally, optimization-based, reconstruction algorithms for PAT are being developed actively [4, 5, 18, 48, 50] that provide the opportunity for accurate image reconstruction from incomplete measurement data. Iterative reconstruction algorithms also allow for accurate modeling of physical nonidealities in the data, such as those introduced by acoustic inhomogeneity and attenuation, or the response of the imaging system.

In this chapter, the physical principles of PAT are reviewed. We start with a review of the underlying imaging physics and contrast mechanisms in PAT. Subsequently, the imaging models that relate the measured photoacoustic wavefields to the sought-after optical absorption distribution are described in their continuous and discrete forms. The basic principles of image reconstruction from discrete measurement data are presented, which includes a review of methods for modeling the measurement system response. We defer a detailed description of analytic reconstruction algorithms and the mathematical properties of PAT in ► [Mathematics of Photoacoustic and Thermoacoustic Tomography](#).

2 Imaging Physics and Contrast Mechanisms

In PAT, a laser or microwave source is used to irradiate an object, and the thermoacoustic effect results in the generation of a pressure wavefield $p(\mathbf{r}, t)$ [45, 54, 65], where $\mathbf{r} \in \mathbb{R}^3$ and t is the temporal coordinate. The resulting pressure wavefield can be measured by use of wideband ultrasonic transducers located on a measurement aperture $\Omega_0 \subset \mathbb{R}^3$, which is a 2D surface that partially or completely surrounds the object. In this section, we review the physics that underlies the image contrast mechanism in PAT employing laser and microwave sources.

The Thermoacoustic Effect and Signal Generation

The generation of photoacoustic wavefields in an inviscid and lossless medium is described by the general photoacoustic wave equation [55, 56]

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) p(\mathbf{r}, t) = -\frac{\beta}{\kappa c^2} \frac{\partial^2 T(\mathbf{r}, t)}{\partial t^2}, \quad (1)$$

where ∇^2 is the 3D Laplacian operator, $T(\mathbf{r}, t)$ denotes the temperature rise within the object at location \mathbf{r} and time t due to absorption of the probing electromagnetic radiation, and $p(\mathbf{r}, t)$ denotes the resulting induced acoustic pressure. The quantities

β , κ , and c denote the thermal coefficient of volume expansion, isothermal compressibility, and speed of sound, respectively. Because an inviscid medium is assumed, the propagation of shear waves is neglected in Eq. (1), which is typically reasonable for soft-tissue imaging applications. Note that the spatial–temporal samples of $p(\mathbf{r}, t)$, which are subsequently degraded by the response of the imaging system, represent the measurement data in a PAT experiment.

When the temporal width of the exciting electromagnetic pulse is sufficiently short, the pressure wavefield is produced before significant heat conduction can take place. In this situation, the excitation is said to be in thermal confinement. Specifically, this occurs when the temporal width τ of the exciting electromagnetic pulse satisfies [56]

$$\tau < \frac{d_c^2}{4\alpha_{th}}, \quad (2)$$

where d_c and α_{th} denote the characteristic dimension (m) of the heated region and the thermal diffusivity (m^2/s).

Under conditions of thermal confinement, the temperature function $T(\mathbf{r}, t)$ satisfies

$$\rho C_V \frac{\partial T(\mathbf{r}, t)}{\partial t} = H(\mathbf{r}, t), \quad (3)$$

where ρ and C_V denote the mass density (kg/m^3) and specific heat capacity of the medium at constant volume. The quantity $H(\mathbf{r}, t)$ [$\text{J}/(\text{m}^3\text{s})$] is called the heating function that describes the energy per unit volume and time that is deposited in the medium by the exciting electromagnetic pulse. On substitution from Eq. (3) into Eq. (1), one obtains the simplified photoacoustic wave equation

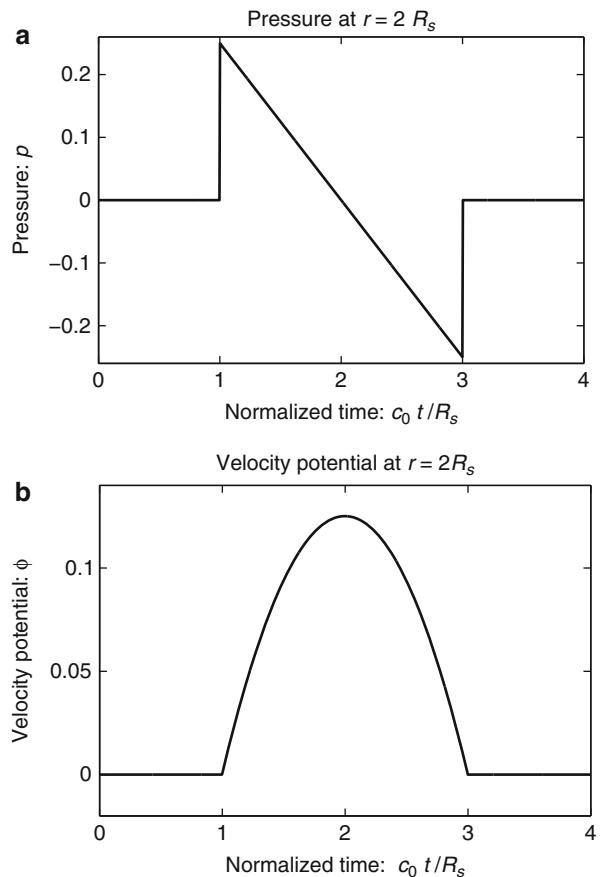

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) p(\mathbf{r}, t) = -\frac{\beta}{C_p} \frac{\partial H(\mathbf{r}, t)}{\partial t}, \quad (4)$$

where $C_p = \rho c^2 \kappa C_V$ [$\text{J}/(\text{kg K})$] denotes the specific heat capacity of the medium at constant pressure. It is sometimes convenient to work the velocity potential $\phi(\mathbf{r}, t)$ that is related to the pressure as $p(\mathbf{r}, t) = -\rho \frac{\partial \phi(\mathbf{r}, t)}{\partial t}$. It can be readily verified that Eq. (4) can be reexpressed in terms of $\phi(\mathbf{r}, t)$ as

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) \phi(\mathbf{r}, t) = \frac{\beta}{\rho C_p} H(\mathbf{r}, t). \quad (5)$$

The photoacoustic wave equations described by Eqs. (4) and (5) have been solved for a variety of canonical absorbers [15–17]. Figure 1 shows an example corresponding to a uniform spherical absorber. In this case, the optical absorber was assumed to possess a speed of sound c_0 that matched the background medium. Note that the pressure possesses an “N-shape” waveform. Solutions have also been derived for the case where the optical absorbers have acoustical properties that are different from those of the background medium [15].

Fig. 1 The pressure (a) and velocity potential (b) waveforms produced by the thermoacoustic effect for a uniform sphere of radius R_s

In practice, it is appropriate to consider the following separable form for the heating function

$$H(\mathbf{r}, t) = A(\mathbf{r})I(t), \quad (6)$$

where $A(\mathbf{r})$ (J/m^3) is the absorbed energy density and $I(t)$ denotes the temporal profile of the illuminating pulse.

When the exciting electromagnetic pulse duration τ is short enough to satisfy the acoustic stress-confinement condition

$$\tau < \frac{d_c}{c}, \quad (7)$$

in addition to the thermal-confinement condition in Eq. (2), one can approximate $I(t)$ by a Dirac delta function $I(t) \approx \delta(t)$. Physically, Eq. (7) requires that all of the thermal energy has been deposited by the electromagnetic pulse before the mass

density or volume of the medium has had time to change. In this case, the absorbed energy density $A(\mathbf{r})$ is related to the induced pressure wavefield $p(\mathbf{r}, t)$ at $t = 0$ as

$$p(\mathbf{r}, t = 0) = \Gamma A(\mathbf{r}), \quad (8)$$

where Γ is the dimensionless Gruneisen parameter. As discussed in detail later, the goal of PAT is to determine $A(\mathbf{r})$ or, equivalently, $p(\mathbf{r}, t = 0)$ from measurements of $p(\mathbf{r}, t)$ acquired on a measurement aperture. It is also useful to note that under the acoustic stress-confinement condition, Eq. (4) coupled with appropriate boundary conditions is mathematically equivalent to the initial value problem [34]

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) p(\mathbf{r}, t) = 0, \quad (9)$$

subject to

$$p(\mathbf{r}, t = 0) = \Gamma A(\mathbf{r}) \quad \text{and} \quad \left. \frac{\partial p(\mathbf{r}, t)}{\partial t} \right|_{t=0} = 0. \quad (10)$$

The effects of heterogeneous speed of sound or acoustic attenuation are not addressed above, but will be described later. In the following two subsections, a review of the physical object properties that give rise to image contrast, that is, variations in $A(\mathbf{r})$, are reviewed for the case of optical and microwave illumination.

Image Contrast in Laser-Based PAT

When an optical laser pulse is employed to induce the thermoacoustic effect, the heating function can be explicitly expressed as

$$H(\mathbf{r}, t) = \mu_a(\mathbf{r}) \Phi(\mathbf{r}, t), \quad (11)$$

where $\mu_a(\mathbf{r})$ ($1/\text{m}$) is the optical absorption coefficient of the medium and $\Phi(\mathbf{r}, t)$ [$\text{J}/(\text{m}^2\text{s})$] is the optical fluence rate [39]. Assuming $\Phi(\mathbf{r}, t) \equiv \Phi_s(\mathbf{r}) I(t)$, Eq. (11) can be expressed as

$$H(\mathbf{r}, t) = \underbrace{\mu_a(\mathbf{r}) \Phi_s(\mathbf{r})}_{A(\mathbf{r})} I(t), \quad (12)$$

where the absorbed energy density, which is the sought-after quantity in PAT, is now identified as

$$A(\mathbf{r}) \equiv \mu_a(\mathbf{r}) \Phi_s(\mathbf{r}). \quad (13)$$

Equation (13) reveals that image contrast in laser-based PAT is determined by the optical absorption properties of the object as well as variations in the fluence of

the illuminating optical radiation. Because only the optical absorption properties are intrinsic to the object, in implementation of PAT it is desirable to make the optical fluence $\Phi_s(\mathbf{r})$ as uniform as possible so one can unambiguously interpret $A(\mathbf{r}) \propto \mu_a(\mathbf{r})$. This presents experimental challenges, and computational methods for quantitative determination of $\mu_a(\mathbf{r})$ are being developed actively [9, 12, 68]. However, in most current implementations of PAT, an estimate of $A(\mathbf{r})$ represents the final image.

There are many desirable characteristics of laser-based PAT for biological imaging. The optical absorption coefficient $\mu_a(\mathbf{r})$ is a function of the molecular composition of tissue [11] and is therefore sensitive to tissue pathologies and functions. Specifically, PAT can deduce physiological parameters such as the oxygen saturation of hemoglobin and the total concentration of hemoglobin, as well as certain features of cancer such as elevated blood content of tissue due to angiogenesis [65].

Although pure optical imaging methods also are sensitive to such physiological parameters, they are limited by their relatively poor spatial resolution and inability to image deep tissue structures. PAT circumvents these limitations because diffusely scattered photons that are absorbed at deep locations are still useful for signal generation via the thermoacoustic effect. When the wavelength of the optical source lies in the range 700–900 nm, light can penetrate up to several centimeters in biological tissue. As described by Eq. (13), the optical fluence $\Phi_s(\mathbf{r})$, which contains ballistic and diffusely scattered photons, modulates $\mu_a(\mathbf{r})$. However, as described later, the spatial resolution of the reconstructed estimate of $A(\mathbf{r})$ is not directly affected by this and is determined largely by the properties of the measured pressure signal $p(\mathbf{r}, t)$.

Image Contrast in RF-Based PAT

When an RF pulse is employed to induce the thermoacoustic effect, the nature of the image contrast is different from that described above. A detailed analysis of this has been conducted by Li et al., in [40]. Consider the case of an RF pulse whose temporal width is much longer than the oscillation period of the electromagnetic wave at the center frequency ω_c . The RF source is assumed to produce a plane-wave with linear polarization and can be described as

$$e_{\text{in}}(t) = S(t)\cos(\omega_c t), \quad (14)$$

where $S(t)$ is a slowly varying envelope function. Furthermore, consider that the medium is isotropic and the electrical conductivity of the medium $\sigma(\mathbf{r}, \omega)$ can be approximated as

$$\sigma(\mathbf{r}, \omega) \approx \sigma(\mathbf{r}, \omega_c), \quad (15)$$

where ω represents the temporal frequency variable. Under the stated conditions, it is the short-time averaged heating function

$$\langle H(\mathbf{r}, t) \rangle \equiv \frac{1}{T_c} \int_t^{t+T_c} dt |H(\mathbf{r}, t)|, \quad (16)$$

where $T_c = \frac{2\pi}{\omega_c}$, which gives rise to signal generation in RF-based PAT [40]. It has been demonstrated [40] that this quantity can be expressed as

$$\langle H(\mathbf{r}, t) \rangle = A(\mathbf{r}) \frac{S^2(t)}{2}, \quad (17)$$

where $\frac{S^2(t)}{2}$ represents the electric field intensity of the RF source and

$$A(\mathbf{r}) \equiv \frac{\sigma(\mathbf{r}, \omega_c) |\tilde{E}(\mathbf{r}, \omega_c)|^2}{|\tilde{e}_{\text{in}}(\omega_c)|^2}, \quad (18)$$

where $\tilde{E}(\mathbf{r}, \omega_c)$ and $\tilde{e}_{\text{in}}(\omega_c)$ denote the temporal Fourier transforms of $E(\mathbf{r}, t)$ and $e_{\text{in}}(t)$ evaluated at $\omega = \omega_c$, with $E(\mathbf{r}, t)$ denoting the local electric field. Note that Eq. (18) represents the quantity that is estimated by conventional PAT reconstruction algorithms.

Equation (18) reveals that image contrast in RF-based PAT is determined by the electrical conductivity of the material, which is described by the complex permittivity, as well as variations in the illuminating electric field at temporal frequency component $\omega = \omega_c$. Because only the electrical conductivity is intrinsic to the object material, it is desirable to make $|\tilde{E}(\mathbf{r}, \omega_c)|^2$ as uniform as possible, so one can unambiguously interpret as the distribution of the conductivity. It has been demonstrated in computer-simulation and experimental studies [40] that estimates of $A(\mathbf{r})$ produced by conventional image reconstruction algorithms can be nonuniform and contain distortions due to diffraction of the electromagnetic wave within the object to be imaged. There remains a need to develop improved image reconstruction methods to mitigate these.

The complex permittivity of tissue has a strong dependence on the water content, temperature, and ion concentration. Because of this, any variations in blood flow in tissue will give rise to changes in the quantity of water and consequently to changes in its complex permittivity. RF-based PAT therefore has the high sensitivity to tissue properties of a microwave technique but requires solution of a tractable acoustic inverse source problem for image reconstruction.

Functional PAT

A highly desirable characteristic of PAT is its ability to provide detailed functional, in addition to anatomical, information regarding biological systems. In this section, we provide a brief review of functional imaging using PAT. For additional details, the reader is referred to parts IX and X in reference [55] and the references therein.

Due to optical contrast mechanism discussed in section “Image Contrast in Laser-Based PAT,” laser-based functional PAT operating in the near-infrared (NIR) frequency range can be employed to determine information regarding the oxygenated and deoxygenated hemoglobin within the blood of tissues. This can permit the study of vascularization and hemodynamics, which is relevant to brain imaging and cancer detection.

Functional PAT imaging of hemoglobin can be achieved by exploiting the known characteristic absorption spectra of oxygenated hemoglobin (HbO_2) and deoxygenated hemoglobin (Hb). Consider the situation where the optical fluence $\Phi_s(\mathbf{r})$ is known, and therefore the optical absorption coefficient $\mu_a(\mathbf{r})$ can be determined from the reconstructed absorbed energy density $A(\mathbf{r})$ via Eq. (13). Let $\mu_a^{\lambda_1}(\mathbf{r})$ and $\mu_a^{\lambda_2}(\mathbf{r})$ denote the reconstructed estimates of $\mu_a(\mathbf{r})$ corresponding to the cases where the wavelength of the optical source is set at λ_1 and λ_2 . From knowledge of these two estimates, the hemoglobin oxygen saturation distribution, denoted by $\text{SO}_2(\mathbf{r})$, is determined as

$$\text{SO}_2(\mathbf{r}) = \frac{\mu_a^{\lambda_2}(\mathbf{r})\epsilon_{\text{Hb}}^{\lambda_1} - \mu_a^{\lambda_1}(\mathbf{r})\epsilon_{\text{Hb}}^{\lambda_2}}{\mu_a^{\lambda_1}(\mathbf{r})\epsilon_{\Delta\text{Hb}}^{\lambda_2} - \mu_a^{\lambda_2}(\mathbf{r})\epsilon_{\Delta\text{Hb}}^{\lambda_1}}, \quad (19)$$

where $\epsilon_{\text{Hb}}^{\lambda}$ and $\epsilon_{\text{HbO}_2}^{\lambda}$ denote molar extinction coefficients of Hb and HbO_2 , and $\epsilon_{\Delta\text{Hb}}^{\lambda} \equiv \epsilon_{\text{HbO}_2}^{\lambda} - \epsilon_{\text{Hb}}^{\lambda}$. The distribution of the total hemoglobin concentration, denoted by $\text{HbT}(\mathbf{r})$, can be determined as

$$\text{HbT}(\mathbf{r}) = \frac{\mu_a^{\lambda_1}(\mathbf{r})\epsilon_{\Delta\text{Hb}}^{\lambda_2} - \mu_a^{\lambda_2}(\mathbf{r})\epsilon_{\Delta\text{Hb}}^{\lambda_1}}{\epsilon_{\text{Hb}}^{\lambda_1}\epsilon_{\text{HbO}_2}^{\lambda_2} - \epsilon_{\text{Hb}}^{\lambda_2}\epsilon_{\text{HbO}_2}^{\lambda_1}}. \quad (20)$$

An experimental investigation of functional PAT imaging of a rat brain was described in [59]. While in different physiological states, a rat was imaged using laser light at wavelengths 584 and 600 nm to excite the photoacoustic signals. A two-dimensional (2D) scanning geometry was employed, and the estimates of $A(\mathbf{r})$ were reconstructed by use of a backprojection reconstruction algorithm. Subsequently, estimates of $\text{SO}_2(\mathbf{r})$ and $\text{HbT}(\mathbf{r})$ were computed and are displayed in Fig. 2.

3 Principles of PAT Image Reconstruction

In the remainder of this chapter, we describe some basic principles that underlie image reconstruction in PAT. We begin by considering the image reconstruction problem in its continuous form. Subsequently, issues related to discrete imaging models that are employed in iterative image reconstruction methods are reviewed.

A schematic of a general PAT imaging geometry is shown in Fig. 3. A short laser or RF pulse is employed to irradiate an object and, as described earlier, the thermoacoustic effect results in the generation of a pressure wavefield $p(\mathbf{r}, t)$. The

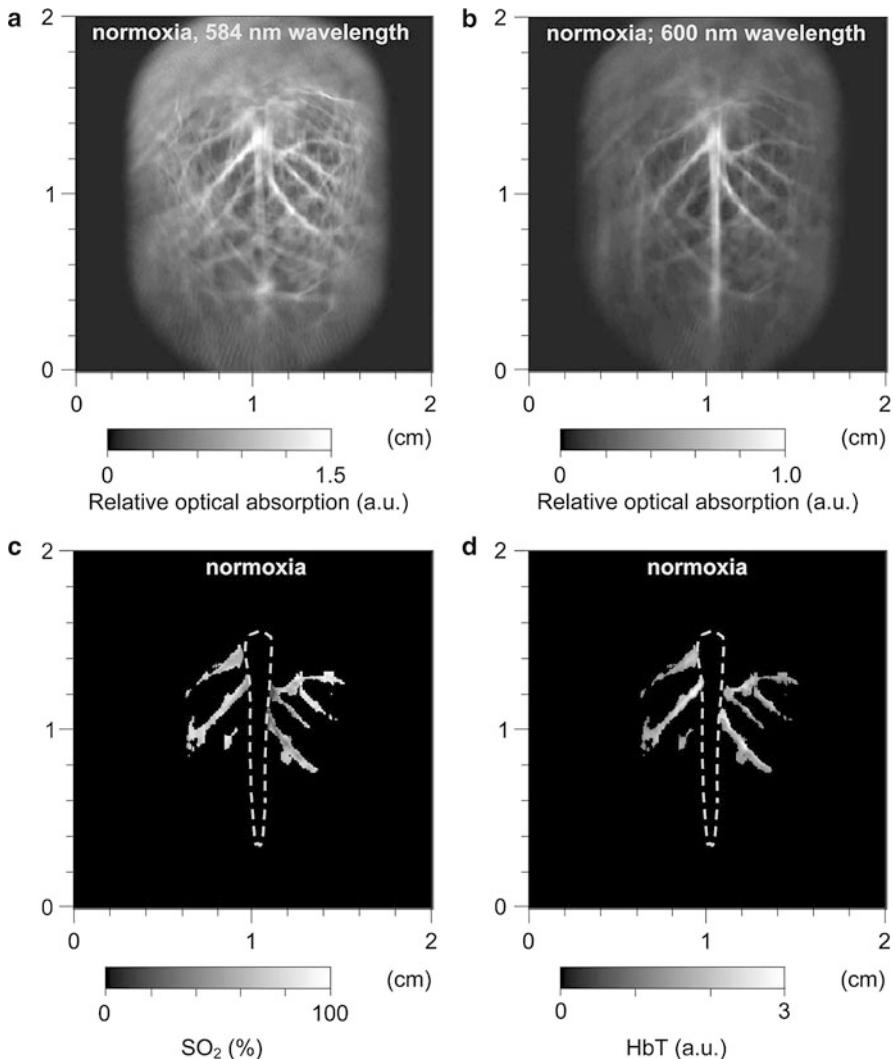

Fig. 2 Noninvasive spectroscopic photoacoustic imaging of HbT and SO_2 in the cerebral cortex of a rat brain. (a) and (b) Brain images generated by 584 and 600 nm laser light, respectively; (c) and (d) image of SO_2 and HbT in the areas of the cortical venous vessels (Reproduced from Wang et al. [59])

pressure wavefield propagates out of the object and is measured by use of wideband ultrasonic transducers located on a measurement aperture $\Omega_0 \subset \mathbb{R}^3$, which is a 2D surface that partially or completely surrounds the object. The coordinate $\mathbf{r}_0 \in \Omega_0$ will denote a particular transducer location. Although we will assume that the ultrasound transducers are point-like, it should be noted that alternative

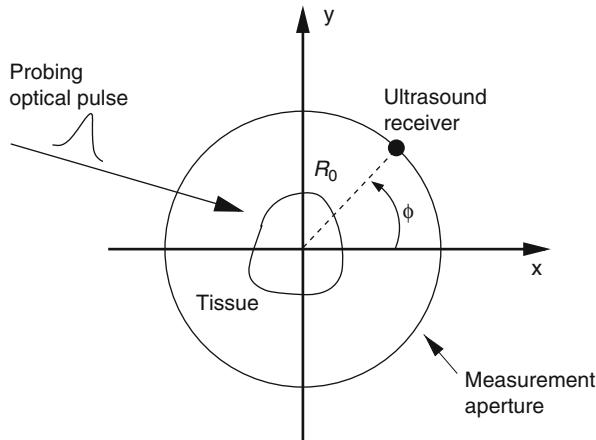

Fig. 3 A schematic of the PAT imaging geometry

implementations of PAT are being actively developed that employ integrating ultrasound detectors [24, 49].

PAT Imaging Models in Their Continuous Forms

When the object possesses homogeneous acoustic properties that match a uniform and lossless background medium, and the duration of the irradiating optical pulse is negligible (acoustic stress confinement is obtained), the pressure wavefield $p(\mathbf{r}_0, t)$ recorded at transducer location \mathbf{r}_0 can be expressed [65] as a solution to Eq.(9):

$$p(\mathbf{r}_0, t) = \frac{\beta}{4\pi C_p} \int_V d^3\mathbf{r} A(\mathbf{r}) \frac{d}{dt} \frac{\delta\left(t - \frac{|\mathbf{r}_0 - \mathbf{r}|}{c_0}\right)}{|\mathbf{r}_0 - \mathbf{r}|}, \quad (21)$$

where c_0 is the (constant) speed of sound in the object and background medium. The function $A(\mathbf{r})$ is compactly supported, bounded, and nonnegative, and the integration in Eq.(21) is performed over the object's support volume V . Equation (21) represents a canonical imaging model for PAT. The inverse problem in PAT is to determine an estimate of $A(\mathbf{r})$ from knowledge of the measured $p(\mathbf{r}_0, t)$. Note that, as described later, the measured $p(\mathbf{r}_0, t)$ will generally need to be corrected for degradation caused by the temporal and spatial response of the ultrasound transducer.

The imaging model in Eq.(21) can be expressed in an alternate but mathematically equivalent form as

$$g(\mathbf{r}_0, t) = \int_V d^3\mathbf{r} A(\mathbf{r}) \delta\left(t - \frac{|\mathbf{r}_0 - \mathbf{r}|}{c_0}\right), \quad (22)$$

where the integrated data function $g(\mathbf{r}_0, t)$ is defined as

$$g(\mathbf{r}_0, t) \equiv \frac{4\pi C_p c_0}{\beta} t \int_0^t dt' p(\mathbf{r}_0, t'). \quad (23)$$

Note that $g(\mathbf{r}_0, t)$ represents a scaled version of the acoustic velocity potential $\phi(\mathbf{r}_0, t)$. Equation (22) represents a spherical Radon transform [22, 43] and indicates that the integrated data function describes integrals over concentric spherical surfaces of radii $c_0 t$ that are centered at the receiving transducer location \mathbf{r}_0 . When these spherical surfaces can be approximated as planes, which would occur when imaging sufficiently small objects that are placed at the center of the scanning system, Eq. (22) can be approximated as a 3D Radon transform [30, 31].

Universal Backprojection Algorithm

A number of analytic image reconstruction algorithms [22, 34, 64, 65] for PAT have been developed in recent years for inversion of Eq. (21) or (22). A detailed description of analytic algorithms will be provided in ► [Mathematics of Photoacoustic and Thermoacoustic Tomography](#). However, the so-called universal backprojection algorithm [64] is reviewed below.

The three canonical measurement geometries in PAT employ measurement apertures Ω_0 that are planar [66], cylindrical [67], or spherical [61]. The universal backprojection algorithm proposed by Xu and Wang [64] has been explicitly derived for these geometries. In order to present the algorithm in a general form, let S denote a surface, where $S = \Omega_0$ for the spherical and cylindrical geometries. For the planar geometry, let $S = \Omega_0 + \Omega'_0$, where Ω'_0 is a planar surface that is parallel to Ω_0 and the object resides between Ω_0 and Ω'_0 .

It has been verified that the initial pressure distribution $p(\mathbf{r}, t = 0) = \Gamma A(\mathbf{r})$ can be mathematically determined from knowledge of the measured $p(\mathbf{r}_0, t)$, $\mathbf{r}_0 \in \Omega_0$, by use of the formula

$$p(\mathbf{r}, t = 0) = \frac{1}{\pi} \int_S dS \int_{-\infty}^{\infty} dk \tilde{p}(\mathbf{r}_0, k) \left[\mathbf{n}_0^S \cdot \nabla_0 \tilde{G}_k^{(in)}(\mathbf{r}, \mathbf{r}_0) \right], \quad (24)$$

where $\tilde{p}(\mathbf{r}_0, k)$ denotes the temporal Fourier transform of $p(\mathbf{r}_0, t)$ that is defined with respect to the reduced variable $\bar{t} = c_0 t$ as

$$\tilde{p}(\mathbf{r}_0, k) = \int_{-\infty}^{\infty} d\bar{t} p(\mathbf{r}_0, \bar{t}) \exp(i k \bar{t}). \quad (25)$$

Here, \mathbf{n}_0^S denotes the unit vector normal to the surface S pointing toward the source, ∇_0 denotes the gradient operator acting on the variable \mathbf{r}_0 , and $\tilde{G}_k^{(in)}(\mathbf{r}, \mathbf{r}_0) = \frac{\exp(-ik|\mathbf{r}-\mathbf{r}_0|)}{4\pi|\mathbf{r}-\mathbf{r}_0|}$ is a Green's function of the Helmholtz equation.

Equation (24) can be expressed in the form of a filtered backprojection algorithm as

$$p(\mathbf{r}, t = 0) = \int_{\Sigma_0} d\Sigma_0 \frac{b(\mathbf{r}_0, \bar{t} = |\mathbf{r} - \mathbf{r}_0|)}{\Sigma_0}, \quad (26)$$

where Σ_0 is the solid angle of the whole measurement surface Ω_0 with respect to the reconstruction point inside Ω_0 . Note that $\Sigma_0 = 4\pi$ for the spherical and cylindrical geometries, while $\Sigma_0 = 2\pi$ for the planar geometry. The solid angle differential $d\Sigma_0$ is given by

$$d\Sigma_0 = \frac{d\Omega_0}{|\mathbf{r} - \mathbf{r}_0|^2} \frac{\mathbf{n}_0^S \cdot (\mathbf{r} - \mathbf{r}_0)}{|\mathbf{r} - \mathbf{r}_0|}, \quad (27)$$

where $d\Omega_0$ is the differential surface area element on Ω_0 . The filtered data function $b(\mathbf{r}_0, \bar{t})$ is related to the measured pressure data as

$$b(\mathbf{r}_0, \bar{t}) = 2p(\mathbf{r}_0, \bar{t}) - 2\bar{t} \frac{\partial p(\mathbf{r}_0, \bar{t})}{\partial \bar{t}}. \quad (28)$$

Equation (26) has a simple interpretation. It states that $p(\mathbf{r}, t = 0)$, or equivalently $A(\mathbf{r})$, can be determined by backprojecting the filtered data function onto a collection of concentric spherical surfaces that are centered at each transducer location \mathbf{r}_0 .

The Fourier-Shell Identity

Certain insights regarding the spatial resolution of images reconstructed in PAT can be gained by formulating a Fourier domain mapping between the measured pressure data and the Fourier components of $A(\mathbf{r})$ [6]. Below we review a mathematical relationship between the pressure wavefield data function and its normal derivative measured on an arbitrary aperture that encloses the object and the 3D Fourier transform of the optical absorption distribution evaluated on concentric (Ewald) spheres [6]. We have referred to this relationship as a “Fourier-shell identity,” which is analogous to the well-known Fourier slice theorem of X-ray tomography.

Consider a measurement aperture Ω_0 that is smooth and closed, but is otherwise arbitrary, and let $\hat{s} \in \mathbf{S}^2$ denote a unit vector on the 3D unit sphere \mathbf{S}^2 . The 3D spatial Fourier transform of $A(\mathbf{r})$, denoted as $\tilde{A}(\nu)$, is defined as

$$\tilde{A}(\nu) = \int_V d\mathbf{r} A(\mathbf{r}) e^{-i\nu \cdot \mathbf{r}}, \quad (29)$$

where the 3D spatial frequency vector $\nu = (\nu_x, \nu_y, \nu_z)$ is the Fourier conjugate of \mathbf{r} . It has been demonstrated [6] that

$$\bar{A}(v = k\hat{s}) = \frac{iC_p}{k\beta\tilde{I}(k)} \int_{\Omega_0} dS' [\hat{n}' \cdot \nabla \tilde{p}(\mathbf{r}'_0, k) + ik\hat{n}' \cdot \hat{s} \tilde{p}(\mathbf{r}'_0, k)] e^{-ik\hat{s} \cdot \mathbf{r}'_0}, \quad (30)$$

where $\tilde{p}(\mathbf{r}_0, k)$ is defined in Eq. (25), dS' is the differential surface element on Ω_0 , and \hat{n}' is the unit outward normal vector to Ω_0 at the point $\mathbf{r}'_0 \in \Omega_0$. Equation (30) has been referred to as the *Fourier-shell identity* of PAT. Because \hat{s} can be chosen to specify any direction, $\bar{A}(v = k\hat{s})$ specifies the Fourier components of $A(\mathbf{r})$ that reside on a spherical surface of radius $|k|$, whose center is at the origin. Therefore, Eq. (30) specifies concentric “shells” of Fourier components of $A(\mathbf{r})$ from knowledge of $\tilde{p}(\mathbf{r}_0, k)$ and its derivative along the \hat{n}' direction at each point on the measurement aperture. As reviewed below, this will permit a direct and simple analysis of certain spatial resolution characteristics of PAT.

For a 3D time-harmonic inverse source problem, it is well known [10, 13, 14] that measurements of the radiated wavefield and its normal derivative on a surface that encloses the source specify the Fourier components of the source function that reside on an Ewald sphere of radius $k = \frac{\omega}{c}$, where ω is the temporal frequency. In PAT, the temporal dependence $I(t)$ of the heating function $H(\mathbf{r}, t)$ is not harmonic and, in general, $\tilde{I}(k) \neq 0$. In the ideal case where $I(t) = \delta(t)$, $\tilde{I}(k) = c$. Consequently, when Eq. (30) is applied to each temporal frequency component k of $\tilde{p}(\mathbf{r}_0, k)$, the entire 3D Fourier domain, with exception of the origin, is determined by the resulting collection of concentric spherical shells. This is possible because of the separable form of the heating function in Eq. (6).

Special Case: Planar Measurement Geometry

The Fourier-shell identity can be used to obtain reconstruction formulas for canonical measurement geometries. For example, consider the case of an infinite planar aperture Ω_0 . Specifically, we assume a 3D object is centered at the origin of a Cartesian coordinate system, and the measurement aperture Ω_0 coincides with the plane $y = d > R$, where R is the radius of the object. In this situation, $\mathbf{r}'_0 = (x', d, z')$, $dS' = dx'dz'$, and $\hat{n}' = \hat{y}$, where \hat{y} denotes the unit vector along the positive y -axis. The components of the unit vector \hat{s} will be denoted as (s_x, s_y, s_z) . Equation (30) can be expressed as the following two terms:

$$\bar{A}(v = k\hat{s}) = \bar{A}_1(v = k\hat{s}) + \bar{A}_2(v = k\hat{s}), \quad (31)$$

where

$$\bar{A}_1(v = k\hat{s}) \equiv \frac{iC_p}{kc\beta\tilde{I}(k)} e^{-ikds_y} \iint_{\infty} dx' dz' \left. \frac{\partial \tilde{p}(x', y, z', k)}{\partial y} \right|_{y=d} e^{-ik(x's_x + z's_z)}, \quad (32)$$

and

$$\bar{A}_2(v = k\hat{s}) \equiv \frac{-C_p s_y}{c\beta\tilde{I}(k)} e^{-ikds_y} \iint_{\infty} dx' dz' \tilde{p}(x', d, z', k) e^{-ik(x's_x + z's_z)}, \quad (33)$$

where, without confusion, we employ the notation $\tilde{p}(x, y, z, k) = \tilde{p}(\mathbf{r}_0, k)$.

It can be readily verified that Eqs. (32) and (33) can be reexpressed as

$$\bar{A}_1(v = k\hat{s}) \equiv \frac{iC_p}{kc\beta\tilde{I}(k)} e^{-ikds_y} \frac{\partial}{\partial y} \tilde{p}(ks_x, y, ks_z, k) \Big|_{y=d} \quad (34)$$

and

$$\bar{A}_2(v = k\hat{s}) \equiv \frac{-C_p s_y}{c\beta\tilde{I}(k)} e^{-ikds_y} \tilde{p}(ks_x, d, ks_z, k), \quad (35)$$

where $\tilde{p}(v_x, y, v_z, k)$ is the 2D spatial Fourier transform of $\tilde{p}(x, y, z, k)$ with respect to x and z (the detector plane coordinates):

$$\tilde{p}(v_x, y, v_z, k) \equiv \frac{1}{4\pi^2} \iint_{\infty} dx dz \tilde{p}(x, y, z, k) e^{-i(xv_x + zv_z)}. \quad (36)$$

The free-space propagator for time-harmonic homogeneous wavefields (see, e.g., Ref. [36], Chapter 4.2) can be utilized to compute the derivative in Eq. (34) as

$$\frac{\partial \tilde{p}(ks_x, y, ks_z, k)}{\partial y} = ik \sqrt{1 - s_x^2 - s_z^2} \tilde{p}(ks_x, y, ks_z, k) = iks_y \tilde{p}(ks_x, y, ks_z, k), \quad (37)$$

where $s_y \geq 0$. Equations (34)–(37) and (31) establish that

$$\bar{A}(v = k\hat{s}) = 2 \bar{A}_2(v = k\hat{s}) \quad \text{for } s_y \geq 0. \quad (38)$$

Equation (38) permits estimation of $\bar{A}(v = k\hat{s})$ on concentric half shells in the domain $v_y \geq 0$ and is mathematically equivalent to previously studied Fourier-based reconstruction formulas [29, 66]. Note that $A(\mathbf{r})$ is real valued, and therefore the Fourier components in the domain $v_y < 0$ can be determined by use of the Hermitian conjugate symmetry property of the Fourier transform.

Spatial Resolution from a Fourier Perspective

The Fourier-shell identity described in section “The Fourier-Shell Identity” is a convenient tool for understanding the spatial resolution characteristics of PAT. Below, we analyze the effects of finite transducer temporal bandwidth and aperture size on spatial resolution [6, 62]. The analysis is applicable to any measurement aperture Ω_0 that corresponds to a coordinate surface of a curvilinear coordinate system.

Effects of Finite Transducer Bandwidth

Consider a point-like ultrasonic transducer whose temporal filtering characteristics are described by the transfer function $\tilde{B}(k; \mathbf{r}_0)$. The \mathbf{r}_0 -dependence of $\tilde{B}(k; \mathbf{r}_0)$ permits transducers located at different measurement locations to be characterized by distinct transfer functions. The temporal Fourier transform of the measured pressure signal that has been degraded by the temporal response of the transducer will be denoted as $\tilde{p}_b(\mathbf{r}_0, k)$, in order to distinguish it from the ideal pressure signal $\tilde{p}(\mathbf{r}_0, k)$. Because the temporal transducer response can be described by a linear time-invariant system, the degraded and ideal pressure data are related as

$$\tilde{p}_b(\mathbf{r}_0, k) = \tilde{B}(k; \mathbf{r}_0) \tilde{p}(\mathbf{r}_0, k). \quad (39)$$

Consider the case where Ω_0 corresponds to a coordinate surface of a curvilinear coordinate system, that is, $\mathbf{r}_0 \in \Omega_0$ is a vector that varies in only two of its three components. For such surfaces, $B(k; \mathbf{r}'_0)$ can be interpreted as a 3D function that does not vary in the \hat{n}' direction and therefore $\hat{n}' \cdot \nabla \tilde{B}(k; \mathbf{r}'_0) = 0$. If the Fourier-shell identity in Eq. (30) is applied with the degraded data function $\tilde{p}_b(\mathbf{r}_0, k)$ replacing the ideal data, the 3D Fourier components of the resulting image, denoted by $A_b(\mathbf{r})$, are recovered as

$$\bar{A}_b(v = k\hat{s}) = \frac{iC_p}{k\beta\tilde{I}(k)} \int_{\Omega_0} dS' \tilde{B}(k; \mathbf{r}'_0) [\hat{n}' \cdot \nabla \tilde{p}(\mathbf{r}'_0, k) + ik\hat{n}' \cdot \hat{s}\tilde{p}(\mathbf{r}'_0, k)] e^{-ik\hat{s} \cdot \mathbf{r}'_0}. \quad (40)$$

On comparison of Eqs. (30) and (40), we observe that the spatially variant transducer transfer function $\tilde{B}(k; \mathbf{r}_0)$ modulates the integrand of the Fourier-shell identity. In this general case, the spatial resolution of $A(\mathbf{r})$ will be spatially variant.

If a collection of identical transducers spans Ω_0 , $\tilde{B}(k; \mathbf{r}_0) = \tilde{B}(k)$ will not depend on \mathbf{r}_0 and Eq. (40) reduces to the simple form

$$\bar{A}_b(v = k\hat{s}) = \tilde{B}(k)\bar{A}(v = k\hat{s}), \quad (41)$$

where $\bar{A}(v = k\hat{s})$ is the exact Fourier data as defined in Eq. (30). As shown in Fig. 4, the one-dimensional (1D) transfer function $\tilde{B}(k)$ of the transducer serves as a radially symmetric 3D filter that modifies $\bar{A}(v = k\hat{s})$. This establishes that the image degradation is described by a shift-invariant linear system:

$$A_b(\mathbf{r}) = A(\mathbf{r}) * B(\mathbf{r}), \quad (42)$$

where $*$ denotes a 3D convolution and

$$B(\mathbf{r}) = B(|\mathbf{r}|) = \int_0^\infty dk \tilde{B}(k) \frac{\sin(k|\mathbf{r}|)}{k|\mathbf{r}|} k^2 \quad (43)$$

is the point-spread function. Equation (43) is consistent with the results derived in Ref. [62].

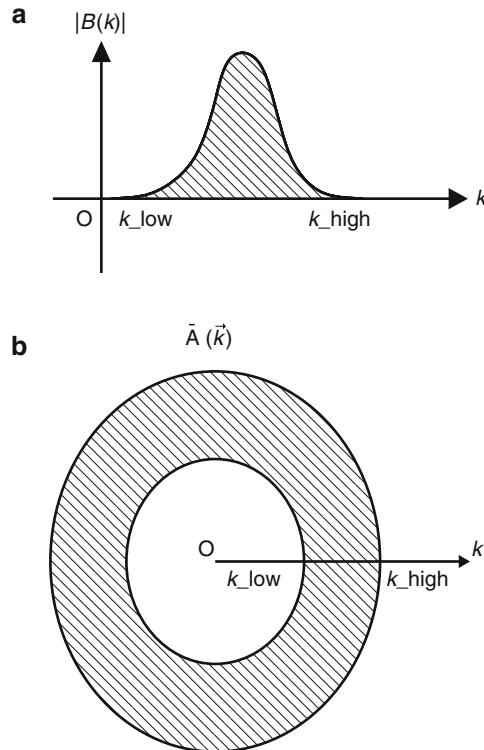

Fig. 4 (a) An example of a transducer transfer function $\tilde{B}(k)$. (b) The 1D function $\tilde{B}(k)$ acts as a radially symmetric filter in the 3D Fourier domain. The *shaded region* indicates the bandpass of 3D Fourier components that results from application of Eq. (41) (Reproduced from Anastasio et al. [6])

Effects of Nonpoint-Like Transducers

In addition to a nonideal temporal response, a transducer cannot be exactly point-like and will have a finite aperture size. To understand the effects of this on spatial resolution, we consider here a transducer that has an ideal temporal response (i.e., $\tilde{B}(k; \mathbf{r}_0) = 1$) but a finite aperture size [6]. We will assume that the surface of the transducer aperture is a subset of the measurement aperture Ω_0 .

It will be useful to employ a local 3D coordinate system whose origin coincides with the center of the detecting surface $\Omega_L \subseteq \Omega_0$, for a transducer at some arbitrary but fixed location $\mathbf{r}'_0 \in \Omega_0$. A vector in this system will be denoted as \mathbf{r}_L , and the collection of $\mathbf{r}_L \in \Omega_L$ spans all locations on the detecting surface of this transducer. For a transducer located at a different position $\mathbf{r}_0 \in \Omega_0$, the local coordinate vector will be denoted as

$$\mathbf{r}_L^0 = T_{\mathbf{r}_0}\{\mathbf{r}_L\}, \quad (44)$$

where $T_{\mathbf{r}_0}\{\cdot\}$ denotes the corresponding coordinate transformation. This indicates that the collection of vectors \mathbf{r}_L^0 corresponding to $\mathbf{r}_L \in \Omega_L$ reside in a local coordinate system whose origin is at \mathbf{r}_0 and span all locations on the detecting surface of the transducer centered at that location.

The measured pressure data $\tilde{p}_a(\mathbf{r}_0, k)$, where the subscript “ a ” denotes the data are obtained in the presence of a finite aperture, can be expressed as

$$\tilde{p}_a(\mathbf{r}_0, k) = \int_{\Omega_L} dS_L W(\mathbf{r}_L) \tilde{p}(\mathbf{r}_0 + \mathbf{r}_L^0, k), \quad (45)$$

where dS_L is the differential surface element on Ω_L and the aperture function $W(\mathbf{r}_L)$ describe the sensitivity of the transducers at location \mathbf{r}_L on their surfaces. We assume the aperture function is identical for all transducers, and therefore $W(\mathbf{r}_L)$ can be described simply in terms of the local coordinate \mathbf{r}_L . Note that \mathbf{r}_L^0 is a function of \mathbf{r}_L , as described by Eq. (44).

If the Fourier-shell identity in Eq. (30) is applied with the degraded data function $\tilde{p}_a(\mathbf{r}_0, k)$, the 3D Fourier components of the corresponding image $A_a(\mathbf{r})$ are recovered as

$$\begin{aligned} \bar{A}_a(v = k\hat{s}) &= \frac{iC_p}{k\beta\tilde{I}(k)} \int_{\Omega_L} dS_L W(\mathbf{r}_L) \\ &\times \int_{\Omega_0} d\Omega'_0 e^{-ik\hat{s}\cdot\mathbf{r}'_0} [\hat{n}' \cdot \nabla \tilde{p}(\mathbf{r}'_0 + \mathbf{r}_L^0, k) + ik\hat{n}' \cdot \hat{s} \tilde{p}(\mathbf{r}'_0 + \mathbf{r}_L^0, k)]. \end{aligned} \quad (46)$$

By use of the change-of-variable $\mathbf{r}_0 \equiv \mathbf{r}'_0 + \mathbf{r}_L^0$ in Eq. (46), one obtains

$$\begin{aligned} \bar{A}_a(v = k\hat{s}) &= \frac{iC_p}{k\beta\tilde{I}(k)} \int_{\Omega_L} dS_L W(\mathbf{r}_L) \\ &\times \int_{\Omega_0} d\Omega'_0 e^{-ik\hat{s}\cdot(\mathbf{r}_0 - \mathbf{r}_L^0)} [\hat{n}' \cdot \nabla \tilde{p}(\mathbf{r}_0, k) + ik\hat{n}' \cdot \hat{s} \tilde{p}(\mathbf{r}_0, k)], \end{aligned} \quad (47)$$

which cannot be simplified further.

The fact that Eq. (47) does not reduce to a simple form analogous to Eq. (41) reflects that the image degradation due to a finite transducer aperture is generally not described by a shift-invariant system [62]. A shift-invariant description is obtained for planar apertures where Eq. (44) reduces to $\mathbf{r}_L^0 = \mathbf{r}_L$, where \mathbf{r}_L^0 no longer has a dependence on \mathbf{r}_0 . In this case, Eq. (47) can be expressed as

$$\bar{A}_a(v = k\hat{s}) = \bar{W}(k\hat{s}) \bar{A}_a(v = k\hat{s}), \quad (48)$$

where

$$\bar{W}(k\hat{s}) \equiv \int_{\Omega_L} dS_L W(\mathbf{r}_L) e^{ik\hat{s}\cdot\mathbf{r}_L}. \quad (49)$$

Because, in this case, \mathbf{r}_L resides on a plane and $W(\mathbf{r}_L)$ is a real-valued function, Eq. (49) corresponds to the complex conjugate of the 2D Fourier transform of the aperture function. The point-spread function obtained by computing the 3D inverse Fourier transform of $\bar{W}(k\hat{s})$ reduces to a result given in [62].

4 Speed-of-Sound Heterogeneities and Acoustic Attenuation

In practice, the object to be imaged may not possess uniform acoustic properties, and the images reconstructed by use of algorithms that ignore this can contain artifacts and distortions. Below, we review some methods that can compensate for an object's frequency-dependent acoustic attenuation and heterogeneous speed-of-sound distribution.

Frequency-Dependent Acoustic Attenuation

Because the thermoacoustically induced pressure signals measured in PAT are broadband and ultrasonic attenuation is frequency dependent, in certain applications it may be important to compensate for this effect. Below, we describe a method described in [37] for achieving this.

Acoustic waves propagating in a lossy medium are attenuated with a linear attenuation coefficient $\alpha(\omega)$ of the general form [53]

$$\alpha(\omega) = \alpha_0 |\omega|^n, \quad (50)$$

where ω is the angular frequency of the wave [53]. For ultrasonic waves in tissue, $n \approx 1$ and $\alpha_0 \approx (10^{-7}/2\pi) \text{ cm}^{-1} \text{ rad}^{-1} \text{ s}$.

Assuming a uniform speed-of-sound distribution, a photoacoustic wave equation with consideration of acoustic attenuation can be expressed as [37]

$$\nabla^2 p(\mathbf{r}, t) - \frac{1}{c_0^2} \frac{\partial^2}{\partial t^2} p(\mathbf{r}, t) + L(t) * p(\mathbf{r}, t) = -\frac{\beta}{C_p} A(\mathbf{r}) \frac{\partial}{\partial t} I(t), \quad (51)$$

where $*$ denotes temporal convolution, c_0 is now a reference phase velocity, and the function $L(t)$ describes the effect of acoustic attenuation and is defined as

$$L(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega \left(K(\omega)^2 - \frac{\omega^2}{c_0^2} \right) \exp(-i\omega t), \quad (52)$$

where

$$K(\omega) \equiv \frac{\omega}{c(\omega)} + i\alpha(\omega). \quad (53)$$

Note that in this section, $p(\mathbf{r}, t)$ denotes the pressure that is affected by acoustic attenuation.

The phase velocity, denoted here by $c(\omega)$, also has a temporal frequency dependence according to the Kramers–Kronig relations. For $n = 1$, this relationship is given by

$$\frac{1}{c(\omega)} = \frac{1}{c_0} - \frac{2}{\pi} \alpha_0 \ln \left| \frac{\omega}{\omega_0} \right|, \quad (54)$$

where ω_0 is the reference frequency for which $c(\omega_0) = c_0$.

Let $\tilde{p}(\mathbf{r}, \omega)$ denote the temporal Fourier transform of the pressure data:

$$\tilde{p}(\mathbf{r}, \omega) = \int_{-\infty}^{\infty} dt p(\mathbf{r}, t) \exp(i\omega t). \quad (55)$$

It has been shown [37] that the Fourier transform of the attenuated data $\tilde{p}(\mathbf{r}, \omega)$ is related to the unattenuated data $p_{ideal}(\mathbf{r}, t)$ as

$$\begin{aligned} \tilde{p}(\mathbf{r}, \omega) &= I(\omega) \left(\frac{c_0}{c(\omega)} + i c_0 \alpha_0 \text{sgn}(\omega) \right)^{-1} \\ &\times \int_{-\infty}^{\infty} p_{ideal}(\mathbf{r}, t) \exp \left\{ i \left[\omega \frac{c_0}{c(\omega)} + i c_0 \alpha_0 |\omega| \right] t \right\} dt, \end{aligned} \quad (56)$$

where

$$p_{ideal}(\mathbf{r}, t) = \frac{\beta}{C_p} \int d\mathbf{r}' A(\mathbf{r}') \frac{d}{dt} \frac{\delta \left(t - \frac{|\mathbf{r}-\mathbf{r}'|}{c_0} \right)}{4\pi |\mathbf{r} - \mathbf{r}'|}, \quad (57)$$

is the solution to the photoacoustic wave equation in the absence of attenuation.

Equation (56) permits one to investigate the effect of acoustic attenuation in PAT. It can also be discretized to produce a linear system of equations that can be inverted numerically for removal of the effects of acoustic dispersion in the measured photoacoustic signals. Subsequently, a conventional PAT image reconstruction algorithm could be employed to estimate $A(\mathbf{r})$. A numerical example of this is provided in Ref. [37].

Weak Variations in the Speed-of-Sound Distribution

The conventional PAT imaging models described in section “PAT Imaging Models in Their Continuous Forms” assume that the object’s speed of sound is constant and equal to that of the background medium. In certain biomedical imaging applications,

this assumption does not reasonably hold true. For example, the speed of sound of breast tissue can vary from 1,400 to 1,540 m/s. Acoustic inhomogeneities can introduce significant wavefront aberrations in the photoacoustic signal that are not accounted for in the available reconstruction algorithms.

For a weakly acoustic scattering object, with consideration of phase aberrations due to the acoustic heterogeneities effects, the forward PAT imaging model can be expressed as a generalized Radon transform [4, 63]

$$\hat{g}(\mathbf{r}_0, \bar{t}) = \int_V d^3\mathbf{r} A(\mathbf{r}) \delta[\bar{t} - c_0 t_f(\mathbf{r}, \mathbf{r}_0)] \frac{c_0 t_f(\mathbf{r}, \mathbf{r}_0)}{|\mathbf{r}_0 - \mathbf{r}|}, \quad (58)$$

where $t_f(\mathbf{r}, \mathbf{r}_0)$ is the time of flight (TOF) for a pressure wave to travel from point \mathbf{r} within the object to transducer location \mathbf{r}_0 . For objects possessing weak acoustic heterogeneities, the TOF can be computed accurately as

$$t_f(\mathbf{r}, \mathbf{r}_0) = \int_{\mathbf{r}' \in L(\mathbf{r}, \mathbf{r}_0)} d^3\mathbf{r}' \frac{1}{c(\mathbf{r}')}, \quad (59)$$

where $c(\mathbf{r})$ is the spatially variant acoustic speed and the set $L(\mathbf{r}, \mathbf{r}_0)$ describes a line connecting \mathbf{r}_0 and \mathbf{r} .

The generalized Radon transform describes weighted integrals of $A(\mathbf{r})$ over iso-TOF surfaces that are not spherical in general. The iso-TOF surfaces are determined by the heterogeneous acoustic speed distribution $c(\mathbf{r})$ of the object. In the absence of acoustic heterogeneities, these are spherical surfaces with varying radii that are centered at \mathbf{r}_0 , and Eq. (58) reduces to the spherical Radon transform in Eq. (22). To establish this imaging model for PAT imaging, the iso-TOF surfaces that Eq. (58) integrates over need to be determined explicitly by use of a priori knowledge of the speed-of-sound distribution $c(\mathbf{r})$. Estimates of $c(\mathbf{r})$ can be obtained by performing an adjunct ultrasound computed tomography study of the object [25]. Subsequently, ray-tracing methods can be employed to identify the iso-TOF surfaces for each transducer position \mathbf{r}_0 . Once these path lengths are computed, the points in the object that have the same path lengths can be grouped together to form iso-TOF surfaces. No known analytic methods are available for inversion of Eq. (58). Accordingly, iterative methods have been employed for image reconstruction [3, 25].

A higher-order geometrical acoustics-based imaging model has also been recently proposed [42] that takes into account the first-order effect in the amplitude of the measured signal and higher-order perturbation to the travel times. By incorporating higher-order approximations to the travel time that incorporates the effect of ray bending, the accuracy of reconstructed images was significantly improved. More general reconstruction methods based on the concept of time-reversal are discussed in chapter ▶ [Mathematics of Photoacoustic and Thermoacoustic Tomography](#).

5 Data Redundancies and the Half-Time Reconstruction Problem

In this section, we review data redundancies that result from symmetries in the PAT imaging model [2, 5, 51, 70], which are related to the so-called half-time reconstruction problem of PAT [4]. Specifically, we describe how an image can be reconstructed accurately from knowledge of half of the temporal components recorded at all transducer locations on a closed measurement aperture.

Data Redundancies

Consider the spherical Radon transform imaging model in Eq. (22). Two half-time data functions $g^{(1)}(\mathbf{r}_0, \bar{t})$ and $g^{(2)}(\mathbf{r}_0, \bar{t})$ can be defined as

$$g^{(1)}(\mathbf{r}_0, \bar{t}) = \begin{cases} g(\mathbf{r}_0, \bar{t}) & : R_0 - R_A \leq \bar{t} \leq R_0 \\ 0 & : \text{otherwise,} \end{cases} \quad (60)$$

and

$$g^{(2)}(\mathbf{r}_0, \bar{t}) = \begin{cases} g(\mathbf{r}_0, \bar{t}) & : R_0 < \bar{t} \leq R_0 + R_A \\ 0 & : \text{otherwise.} \end{cases} \quad (61)$$

Here, R_0 denotes the radius of the measurement aperture Ω_0 , and R_A denotes the radius of support of $A(\mathbf{r})$. We assume that the object is acoustically homogeneous with speed of sound c_0 and $\bar{t} \equiv c_0 t$. Note that the data functions $g^{(1)}(\mathbf{r}_0, \bar{t})$ and $g^{(2)}(\mathbf{r}_0, \bar{t})$ each cover different halves of the complete data domain $\Omega_0 \times [R_0 - R_A, R_0 + R_A]$, and therefore $g(\mathbf{r}_0, \bar{t}) = g^{(1)}(\mathbf{r}_0, \bar{t}) + g^{(2)}(\mathbf{r}_0, \bar{t})$.

In the limit where $R_0 \rightarrow \infty$, the spherical Radon transform reduces to a conventional Radon transform that integrates over 2D planes. In that case, an obvious conjugate-view symmetry exists [10], and therefore, either of the half-time data functions $g^{(1)}(\mathbf{r}_0, \bar{t})$ and $g^{(2)}(\mathbf{r}_0, \bar{t})$ contains enough information, in a mathematical sense, for exact image reconstruction. Accordingly, a twofold data redundancy exists because the complete data function $g(\mathbf{r}_0, \bar{t})$ contains twice as much information as is theoretically necessary for exact image reconstruction.

In the case where R_0 is finite, a simple conjugate view symmetry does not exist. Nevertheless, it has been demonstrated that a twofold data redundancy exists in the complete data function $g(\mathbf{r}_0, \bar{t})$. This has been heuristically [50] and mathematically [5] by use of a layer-stripping procedure [2, 5, 50, 70]. This established that $A(\mathbf{r})$ can be recovered uniquely and stably from knowledge of either half-time data functions $g^{(1)}(\mathbf{r}_0, \bar{t})$ or $g^{(2)}(\mathbf{r}_0, \bar{t})$. A similar conclusion has been derived in Ref. [22] using a different mathematical approach.

Analytic inversion formulae for recovering $A(\mathbf{r})$ from knowledge of the half-time data functions $g^{(1)}(\mathbf{r}_0, \bar{t})$ or $g^{(2)}(\mathbf{r}_0, \bar{t})$ are not currently available. However, iterative reconstruction algorithms can be employed [4, 5] to determine $A(\mathbf{r})$.

Mitigation of Image Artifacts Due to Acoustic Heterogeneities

If the spatially variant speed of sound $c(\mathbf{r})$ is known, one can numerically invert a discretized version of Eq. (58) to determine an estimate of $A(\mathbf{r})$ [3]. However, in many applications of PAT, $c(\mathbf{r})$ is not known, and images are simply reconstructed by use of algorithms that assume a constant speed of sound. This can result in conspicuous image artifacts.

Let $\hat{g}(\mathbf{r}_0, \bar{t})$ denote a data function that is contaminated by the effects of speed-of-sound variations within the object that is related to $A(\mathbf{r})$ according to Eq. (58). Let $\hat{A}(\mathbf{r})$ denote an estimate of $A(\mathbf{r})$ that is reconstructed from $\hat{g}(\mathbf{r}_0, \bar{t})$ by use of a conventional reconstruction algorithm that assumes an acoustically homogeneous object. The quantities $\hat{g}^{(1)}(\mathbf{r}_0, \bar{t})$ and $\hat{g}^{(2)}(\mathbf{r}_0, \bar{t})$ denote half-time data functions that are defined in analogy with Eqs. (60) and (61) with $g(\mathbf{r}_0, \bar{t})$ replaced by $\hat{g}(\mathbf{r}_0, \bar{t})$.

An image reconstructed from $\hat{g}^{(1)}(\mathbf{r}_0, \bar{t})$ can sometimes contain reduced artifact levels as compared to one reconstructed from the complete data $\hat{g}(\mathbf{r}_0, \bar{t})$. To demonstrate this, in the discussion below, we consider the 2D problem and the spatially variant speed-of-sound distribution shown in Fig. 5. This speed-of-sound distribution is comprised of two uniform concentric disks that have c_0 and c_1 , with $c_0 \neq c_1$, and radii r_0 and r_1 , respectively. The background medium is assumed to have a speed of sound, c_0 .

The acoustic heterogeneity will cause the data function $\hat{g}(\mathbf{r}_0, \bar{t})$ to differ from the ideal one $g(\mathbf{r}_0, \bar{t})$. The magnitude of this difference will be smaller, in general, for small values of \bar{t} than for large values of \bar{t} . This can be understood by noting that, in general, $|t_f(\mathbf{r}, \mathbf{r}_0) - \frac{|\mathbf{r}_0 - \mathbf{r}|}{c_0}|$ will become larger as the path length through the speed-of-sound heterogeneity increases. This causes the surfaces of integration that contribute to $\hat{g}(\mathbf{r}_0, \bar{t})$ to become less spherical for larger values of \bar{t} . Accordingly, the

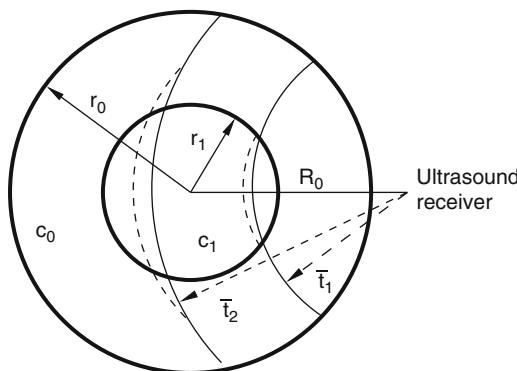

Fig. 5 A speed-of-sound distribution comprised of two uniform concentric regions. Superimposed on the figure are examples of how the surfaces of integration that contribution to the data function $g(\mathbf{r}_0, \bar{t})$ are perturbed

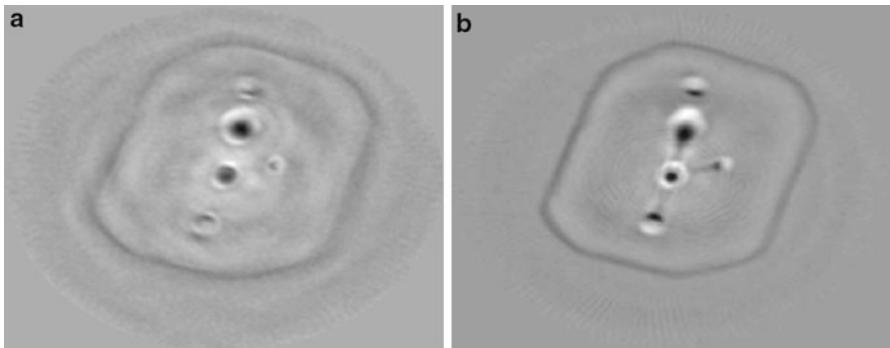

Fig. 6 Images of a phantom object reconstructed from experimentally measured **(a)** full-time, **(b)** first half-time data functions (Reproduced from Anastasio et al. [4])

data function $\hat{g}(\mathbf{r}_0, \bar{t})$ becomes less consistent with the spherical Radon transform model.

The discussion above suggests that a half-time reconstruction method that employs $\hat{g}^{(1)}(\mathbf{r}_0, \bar{t})$ can produce images with reduced artifact and distortion levels than contained in images reconstructed from the complete, or full-time, data $\hat{g}(\mathbf{r}_0, \bar{t})$. An example of this is shown in Fig. 6. The data corresponded to a physical phantom study using a microwave source, as described in Ref. [61]. Measurements were taken at 160 equally spaced positions on the 2D circular scanning aperture of radius 70 mm, and for each measurement, the received pressure signal was sampled at 2,000 points, at a sampling frequency of 50 MHz. Images were reconstructed from full- and half-time data, via the EM algorithm as described in Ref. [4]. The contrast and resolution of the images reconstructed from half-time data appears to be superior to that of the images reconstructed from the full-time data.

6 Discrete Imaging Models

The imaging models discussed so far were expressed in their continuous forms. In practice, PAT imaging systems record temporal and spatial samples of $p(\mathbf{r}_0, t)$, while the absorbed energy density is described by the function $A(\mathbf{r})$. Accordingly, a realistic imaging model should be described mathematically as a continuous-to-discrete (C–D) mapping [8]. Moreover, when iterative reconstruction algorithms are employed, a discrete representation of $A(\mathbf{r})$ is required to establish a suitable discrete-to-discrete approximate imaging model. In this section, we review these concepts within the context of PAT.

The remainder of this section is organized as follows. In section “Continuous-to-Discrete Imaging Models,” we review the C–D versions of the continuous-to-continuous (C–C) models in Eqs. (21) and (22). Finite-dimensional object representations are surveyed in section “Finite-Dimensional Object Representations” that

are used to establish the discrete-to-discrete (D–D) models in section ‘‘Discrete-to-Discrete Imaging Models.’’ In section ‘‘Iterative Image Reconstruction,’’ we briefly review some approaches to iterative image reconstruction that have been applied in PAT. The section concludes with a numerical example that demonstrates the effects of object representation error on image reconstruction accuracy.

Continuous-to-Discrete Imaging Models

In practice, $p(\mathbf{r}_0, t)$ and $g(\mathbf{r}_0, t)$ are discretized temporally and determined at a finite number of receiver locations. The vectors $\mathbf{p}, \mathbf{g} \in \mathbb{R}^N$ will represent lexicographically ordered representations of the sampled data functions, where the dimension N is defined by the product of the number of temporal samples acquired at each transducer location (S) and the number of transducer locations (M). Let Eqs. (21) and (22) be expressed in operator notation as

$$p(\mathbf{r}_0, t) = \mathcal{H}_p A(\mathbf{r}), \quad (62)$$

and

$$g(\mathbf{r}_0, t) = \mathcal{H}_g A(\mathbf{r}). \quad (63)$$

In general, a C–D operator can be interpreted as a discretization operator $\mathcal{D}_{\sigma\tau}$ acting on C–C operator \mathcal{H}_{CC} [8]. Let \mathbf{y} denote \mathbf{p} or \mathbf{g} and let \mathcal{H}_{CC} denote \mathcal{H}_p or \mathcal{H}_g . The notation $y_{[n]}$ will be used to denote the n th element of the vector \mathbf{y} . The C–D versions of Eqs. (21) and (22) can be expressed as

$$\mathbf{y} = \mathcal{D}_{\sigma\tau} \mathcal{H}_{CC} A(\mathbf{r}) = \mathcal{H}_{CD} A(\mathbf{r}), \quad (64)$$

where $\mathcal{D}_{\sigma\tau}$ is discretization operator that characterizes the temporal and spatial sampling characteristics of the ultrasonic transducer.

For the case where $\mathbf{y} = \mathbf{p}$ and $p(\mathbf{r}_0, t) = \mathcal{H}_p A(\mathbf{r})$, $\mathcal{D}_{\sigma\tau}$ will be denoted as $\mathcal{D}_{\sigma\tau}^{(p)}$ and is defined as

$$p_{[mS+s]} = [\mathcal{D}_{\sigma\tau}^{(p)} p(\mathbf{r}_0, t)]_{[mS+s]} \equiv \int_{-\infty}^{\infty} dt \tau_s(t) \int_{\Omega_0} d\Omega_0 p(\mathbf{r}_0, t) \sigma_m(\mathbf{r}_0), \quad (65)$$

where $m = 1, 2, \dots, M$ is the index that specifies the m th transducer location $\mathbf{r}_{0,m}$ on the measurement aperture Ω_0 , $s = 1, 2, \dots, S$ is the index of the time sample, and $\sigma_m(\mathbf{r}_0)$ and $\tau_s(t)$ are functions that describe the spatial and temporal *sampling apertures*, respectively. They are determined by the sampling properties of ultrasonic transducers. In the ideal case, where both apertures are described by Dirac delta functions, the s th temporal sample for the m th transducer location represents the pressure at time $s\Delta T$ and location $\mathbf{r}_{0,m}$, where ΔT is the temporal sampling interval, that is,

$$p_{[mS+s]} = p(\mathbf{r}_{0,m}, s\Delta T). \quad (66)$$

We can express explicitly the C–D imaging model involving the pressure data as

$$p_{[mS+s]} = \int_V d^3\mathbf{r} A(\mathbf{r}) h_{mS+s}(\mathbf{r}), \quad (67)$$

where V denotes the support volume of $A(\mathbf{r})$ and

$$h_{mS+s}(\mathbf{r}) \equiv \int_{-\infty}^{\infty} dt_0 \tau_s(t_0) \int_{\Omega_0} d\Omega_0 h(\mathbf{r}, \mathbf{r}_0; t_0) \sigma_m(\mathbf{r}_0) \quad (68)$$

defines a point response function. The kernel $h(\mathbf{r}, \mathbf{r}_0; t_0)$ is defined as

$$h(\mathbf{r}, \mathbf{r}_0; t_0) = \int_{-\infty}^{\infty} dt I(t) G(\mathbf{r}, \mathbf{r}_0; t, t_0), \quad (69)$$

where $I(t)$ is the temporal illumination function and $G(\mathbf{r}, \mathbf{r}_0; t, t_0)$ is the Green's function

$$G(\mathbf{r}, \mathbf{r}_0; t, t_0) = \frac{\beta}{4\pi C_p |\mathbf{r} - \mathbf{r}_0|} \frac{d\delta(t)}{dt} \Big|_{t=t_0 - \frac{|\mathbf{r}-\mathbf{r}_0|}{c_0}}. \quad (70)$$

By use of the singular value decomposition of the C–D operator in Eq. (67), a pseudoinverse solution can be computed numerically to estimate $A(\mathbf{r})$ [8].

In order to establish a C–D imaging model involving the integrated pressure data, to first order, we can approximate the integral operator in Eq. (23) as

$$g_{[mS+s]} = \frac{4\pi C_p c_0 s \Delta T}{\beta} \sum_{q=1}^s p_{[mS+q]}. \quad (71)$$

For the case where $\mathbf{y} = \mathbf{g}$ and $g(\mathbf{r}_0, t) = \mathcal{H}_g A(\mathbf{r})$, $\mathcal{D}_{\sigma\tau}$ will be denoted as $\mathcal{D}_{\sigma\tau}^{(g)}$ and is defined as

$$\begin{aligned} g_{[mS+s]} &= [\mathcal{D}_{\sigma\tau}^{(g)} g(\mathbf{r}_0, t)]_{[mS+s]} \\ &\equiv s \Delta T \sum_{q=1}^s \int_{-\infty}^{\infty} dt \tau_q(t) \int_{\Omega_0} d\Omega_0 \sigma_m(\mathbf{r}_0) \frac{d}{dt} \left(\frac{g(\mathbf{r}_0, t)}{t} \right). \end{aligned} \quad (72)$$

Note that, in practice, \mathbf{g} is not measured and is computed from the measured \mathbf{p} by use of Eq. (71). Therefore, it is not physically meaningful to interpret \mathbf{g} as being directly sampled from the raw measurement data.

Finite-Dimensional Object Representations

When iterative image reconstruction algorithms are employed, a finite-dimensional representation of $A(\mathbf{r})$ [8] is required. In this section, we review some finite-dimensional representations that have been employed in PAT. In the subsequent section, computer-simulation studies are conducted to demonstrate the effects of error in the object representation.

An N -dimensional representation of $A(\mathbf{r})$ can be described as

$$A_a(\mathbf{r}) = \sum_{n=1}^N \theta_{[n]} \phi_n(\mathbf{r}), \quad (73)$$

where the subscript a indicates that $A_a(\mathbf{r})$ is an approximation of $A(\mathbf{r})$. The functions $\phi_n(\mathbf{r})$ are called expansion functions and the expansion coefficients $\theta_{[n]}$ are elements of the N -dimensional vector $\boldsymbol{\theta}$. The goal of iterative image reconstruction methods is to estimate $\boldsymbol{\theta}$, for a fixed choice of the expansion functions $\phi_n(\mathbf{r})$.

The most commonly employed expansion functions are simple image voxels

$$\phi_n(x, y, z) = \begin{cases} 1, & \text{if } |x - x_n|, |y - y_n|, |z - z_n| \leq \epsilon/2 \\ 0, & \text{otherwise} \end{cases} \quad (74)$$

where $\mathbf{r}_n = (x_n, y_n, z_n)$ specify the coordinates of the n th grid point of a uniform Cartesian lattice and ϵ defines the spacing between lattice points.

In PAT, spherical expansion functions of the form

$$\phi_n(x, y, z) = \begin{cases} 1, & \text{if } \sqrt{(x - x_n)^2 + (y - y_n)^2 + (z - z_n)^2} \leq \epsilon/2 \\ 0, & \text{otherwise} \end{cases} \quad (75)$$

have also proven to be useful [18, 27]. The merit of this kind of expansion function is that the acoustic wave generated by each voxel can be calculated analytically. This facilitates determination of the system matrix utilized by iterative image reconstruction methods, as discussed below. Numerous other effective choices for the expansion functions [38] exist, including wavelets or other sets of functions that can yield sparse object representations [52].

In addition to an infinite number of choices for the expansion functions, there are an infinite number of ways to define the expansion coefficients $\boldsymbol{\theta}$. Some common choices include

$$\theta_{[n]} = \frac{V_{\text{cube}}}{V_{\text{voxel}}} \int_V d^3 \mathbf{r} \phi_n(\mathbf{r}) A(\mathbf{r}), \quad (76)$$

or

$$\theta_{[n]} = \int_V d^3 \mathbf{r} \delta(\mathbf{r} - \mathbf{r}_n) A(\mathbf{r}). \quad (77)$$

For a given N , different choices of ϕ_n and θ will yield object representations that possess different representation errors

$$\delta A(\mathbf{r}) = A(\mathbf{r}) - A_a(\mathbf{r}). \quad (78)$$

An example of the effects of such representation errors on iterative reconstruction methods is provided in section “Iterative Image Reconstruction.”

Discrete-to-Discrete Imaging Models

Discrete-to-discrete (D–D) imaging models are required for iterative image reconstruction. These can be obtained systematically by substitution of a finite-dimensional object representation into the C–D imaging model in Eq. (64):

$$\mathbf{y}_a = \mathcal{H}_{CD}\mathbf{A}_a(\mathbf{r}) = \sum_{n=1}^N \theta_{[n]} \mathcal{H}_{CD}\{\phi_n(\mathbf{r})\} \equiv \mathbf{H}\theta, \quad (79)$$

where the D–D operator \mathbf{H} is commonly referred to as the system matrix. The system matrix \mathbf{H} is of dimension $(MS) \times N$, and an element of \mathbf{H} will be denoted by $H_{[n,m]}$. Note that the data vector $\mathbf{y}_a \neq \mathbf{y}$, due to the fact that a finite-dimensional approximate object representation was employed. In other words, \mathbf{y}_a represents an approximation of the measured pressure data, denoted by \mathbf{p}_a , or the corresponding approximate integrated pressure data \mathbf{g}_a .

For the case where $\mathbf{y}_a = \mathbf{p}_a$, the system matrix \mathbf{H} will be denoted as $\mathbf{H}^{(p)}$ and its elements are defined as

$$H_{[mS+s,n]}^{(p)} = \int_V d^3\mathbf{r} \phi_n(\mathbf{r}) h_{mS+s}(\mathbf{r}) = \mathcal{D}_{\sigma\tau}^{(p)}\{p_n(\mathbf{r}_0, t_0)\}, \quad (80)$$

where $h_{mS+s}(\mathbf{r})$ is defined in Eq. (68) and

$$p_n(\mathbf{r}_0, t_0) = \int_V d^3\mathbf{r} \phi_n(\mathbf{r}) h(\mathbf{r}, \mathbf{r}_0; t_0). \quad (81)$$

Equation (80) provides a clear two-step procedure for computing the system matrix. First, $p_n(\mathbf{r}_0, t_0)$ is computed. Physically, this represents the pressure data, in its continuous form, received by an ideal point transducer when the absorbing object corresponds to $\phi_n(\mathbf{r})$. Secondly, a discretization operator is applied that samples the ideal data and degrades it by the transducer response. Alternatively, the elements of the system matrix can be measured experimentally by scanning an object whose form matches the expansion functions through the object volume and recording the resulting pressure signal at each transducer location $\mathbf{r}_{0,m}$, for each value of n (location of expansion function), at time intervals $s\Delta T$. For the case of spherical expansion elements, this approach was implemented in [18].

This two-step approach for determining \mathbf{H} be formulated as

$$\mathbf{H} = \mathbf{S} \circ \mathbf{H}_0, \quad (82)$$

where “ \circ ” denotes an element-wise product. Each element of \mathbf{H}_0 is defined as

$$H_{[mS+s,n]} = p_n(\mathbf{r}_{0,m}, s\Delta T). \quad (83)$$

The $MS \times N$ matrix \mathbf{S} can be interpreted as a sensitivity map, whose elements are defined as

$$S_{[mS+s,n]} = \frac{\mathcal{D}_{\sigma\tau}\{p_n(\mathbf{r}_0, t_0)\}}{p_n(\mathbf{r}_{0,m}, s\Delta T)}. \quad (84)$$

For the case where $\mathbf{y}_a = \mathbf{g}_a$, similar interpretations hold. The system matrix \mathbf{H} will be denoted as $\mathbf{H}^{(g)}$, and its elements are defined as

$$H_{[mS+s,n]}^{(g)} = \mathcal{D}_{\sigma\tau}^{(g)}\{g_n(\mathbf{r}_0, t_0)\}, \quad (85)$$

where

$$g_n(\mathbf{r}_0, t_0) = \frac{4\pi C_p c_0 t_0}{\beta} \int_0^{t_0} d\xi_0 \int_V d^3\mathbf{r} \phi_n(\mathbf{r}) h(\mathbf{r}, \mathbf{r}_0; \xi_0). \quad (86)$$

Numerical Example: Impact of Representation Error on Computed Pressure Data

Consider a uniform sphere of radius $R_s = 5$ mm as the optical absorber (acoustic source). Assuming Dirac delta (i.e., ideal) temporal and spatial sampling, the pressure data were computed at a measurement location \mathbf{r}_0 65 mm away from the center of the sphere by use of D-D and C-C imaging models. For the uniform sphere, the pressure waveform can be computed analytically as

$$\begin{aligned} p(\mathbf{r}_0, s\Delta T) &= \frac{d}{dt} \left[\frac{\beta}{4\pi C_p c_0 t} g(\mathbf{r}_0, t) \right] \Big|_{t=s\Delta T} \\ &= \begin{cases} \frac{\beta c_0^2}{2C_p |\mathbf{r}_0 - \mathbf{r}_c|} (|\mathbf{r}_0 - \mathbf{r}_c| - c_0 s\Delta T), & \text{if } |c_0 s\Delta T - |\mathbf{r}_0 - \mathbf{r}_c|| \leq R_s \\ 0, & \text{otherwise} \end{cases} \end{aligned} \quad (87)$$

where \mathbf{r}_c is the center of the spherical source and ΔT is the sampling interval. As discussed in section “The Thermoacoustic Effect and Signal Generation,” the pressure possesses an “N” shape waveform as shown as the dashed red curve in Fig. 7. Finite-dimensional object representations of the object were obtained according to Eq. (73) with $\phi_n(\mathbf{r})$ corresponding to the uniform spheres described

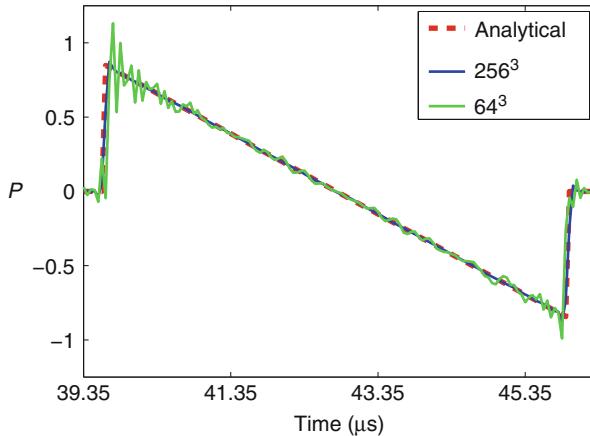

Fig. 7 Pressure data generated by continuous imaging model (red dash) and discrete imaging model using $256 \times 256 \times 256$ voxels (blue solid) and $64 \times 64 \times 64$ voxels (green solid)

in Eq.(75). The expansion coefficients were computed according to Eq.(76). Two approximate object representations were considered. The first representation employed $N = 256^3$ spherical expansion functions of radius 0.04 mm, while the second employed $N = 64^3$ expansion functions of radius 0.16 mm. The resulting pressure signals are shown as Fig. 7, where the speed of sound $c_0 = 1.521 \text{ mm}/\mu\text{s}$ and $\Delta T = 0.05 \mu\text{s}$. As expected, the error in the computed pressure data increases as the voxel size is increased. In practice, this error would represent a data inconsistency between the measured data and the assumed D-D imaging model, which can result in image artifacts as demonstrated by the example below.

Iterative Image Reconstruction

Once the system matrix \mathbf{H} is determined, as described in the previous section, an estimate of $A(\mathbf{r})$ can be computed in two distinct steps. First, from knowledge of the measured data and system matrix, Eq.(79) is inverted to estimate the expansion coefficients $\boldsymbol{\theta}$. Second, the estimated expansion coefficients are employed with Eq.(73) to determine the finite-dimensional approximation $A_a(\mathbf{r})$. Each of steps introduces error into the final estimate of $A(\mathbf{r})$. In the first step, due to noise in the measured data \mathbf{y}_a , modeling errors in \mathbf{H} , and/or if \mathbf{H} is not full rank, the true values coefficients $\boldsymbol{\theta}$ cannot generally be determined. The estimated $\boldsymbol{\theta}$ will therefore depend on the definition of the approximate solution and the particular numerical algorithm used to determine it. Even if $\boldsymbol{\theta}$ could somehow be determined exactly, the second step would introduce error due to the approximate finite-dimensional representation of $A(\mathbf{r})$ employed. This error is influenced by the choice of N and $\phi_n(\mathbf{r})$ and is object dependent.

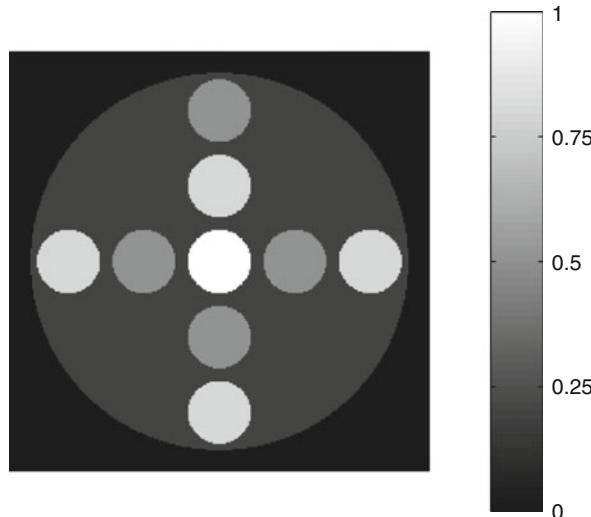

Fig. 8 The 2D numerical phantom θ representing the object function $A(\mathbf{r})$

Due to the large size of \mathbf{H} , iterative methods are often employed to estimate θ . Iterative approaches offer a fundamental and flexible way to incorporate a prior information regarding the object, to improve the accuracy of the estimated θ . A vast literature on iterative image reconstruction methods exists [7, 20, 21, 60], which we leave to the reader to explore. Examples of applications of iterative reconstruction methods in PAT are described in references [1, 4, 5, 18, 48, 69]. A numerical example demonstrating how object representation error can affect the accuracy of iterative image reconstruction is provided next.

Numerical Example: Influence of Representation Error on Image Accuracy

We assume focused transducers are employed that receive only acoustic pressure signals transmitted from the imaging plane and therefore the 3D spherical Radon transform imaging model to a 2D circular mean model. A 2D phantom comprised of uniform disks possessing different gray levels, radii, and locations was assumed to represent $A(\mathbf{r})$. The radius of the phantom was 1.0 (arbitrary units). A finite-dimensional representation $A_d(\mathbf{r})$ was formed according to Eq. (73), with $N = 256^2$ and $\phi_n(\mathbf{r})$ chosen to be conventional pixels described by a 2D version of Eq. (74). The expansion coefficients $\theta_{[n]}$ were computed by use of Eq. (77). Figure 8 displays the computed expansion coefficient vector θ that has been reshaped into a 256×256 for display purposes.

A circular measurement aperture Ω_0 of radius 1.2 that enclosed the object was employed. At each of 360 uniformly spaced transducer locations, $\mathbf{r}_{0,m}$, on the measurement circle, simulated pressure data \mathbf{p}_a were computed from the integrated data \mathbf{g} by use of the formula

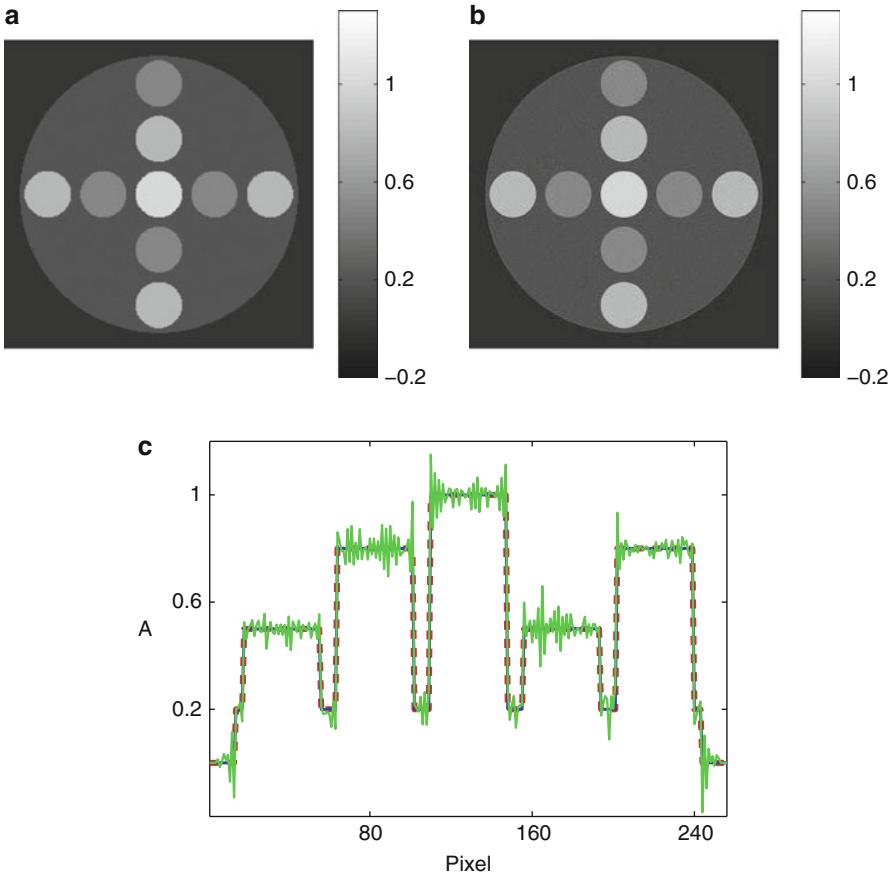

Fig. 9 Images reconstructed by the least-squares conjugate gradient algorithm from pressure data obtained by (a) numerical imaging model and (b) analytical imaging model. (c) Vertical profiles through the center of subfigure (a) (solid blue), subfigure (b) (solid green), and Fig. 8 (dashed red)

$$p_{a[mS+s]} = \frac{\beta}{4\pi C_p c_0} \left[\frac{g[mS+s+1]/(s+1) - g[mS+s-1]/(s-1)}{2\Delta T^2} \right]. \quad (88)$$

Two versions of the pressure data were computed, corresponding to the cases where \mathbf{g} was computed analytically or by use of the assumed D-D imaging model. These simulated pressure data are denoted by \mathbf{p}_a^{analy} and \mathbf{p}_a^{num} , respectively. At each transducer location, 300 temporal samples of $p(\mathbf{r}_0, t)$ were computed. Accordingly, the pressure vector \mathbf{p}_a was a column vector of length 360×300 .

The conjugate gradient algorithm was employed to find the least-squares estimate $\hat{\boldsymbol{\theta}}$,

$$\hat{\boldsymbol{\theta}} = \arg \min_{\boldsymbol{\theta}} \|\mathbf{p}_a - \mathbf{H}\boldsymbol{\theta}\|^2, \quad (89)$$

where $\mathbf{p}_a = \mathbf{p}_a^{analy}$ or \mathbf{p}_a^{num} . For the noiseless data, the images reconstructed from \mathbf{p}_a^{analy} and \mathbf{p}_a^{num} after 150 iterations are shown as Fig. 9a, b, respectively. The image reconstructed from the data \mathbf{p}_a^{num} is free of significant artifacts and is nearly identical to the original object. This is expected because the finite-dimensional object representation was used to produce the simulated measurement data and establish the system matrix, and therefore the system of equations in Eq. (79) is consistent. Generating simulation data in this way would constitute an “inverse crime.” Conversely, the image reconstructed from the data \mathbf{p}_a^{analy} contained high-frequency artifacts due to the fact that the system of equations in Eq. (79) is inconsistent. The error in the reconstructed images could be minimized by increasing the dimension of the approximate object representation. This simple example demonstrates the importance of carefully choosing a finite-dimensional object representation in iterative image reconstruction.

7 Conclusion

Photoacoustic tomography is a rapidly emerging biomedical imaging modality that possesses many challenges for image reconstruction. In this chapter, we have reviewed the physical principles of PAT. Contrast mechanisms in PAT were discussed, and the imaging models that relate the measured photoacoustic wavefields to the sought-after optical absorption distribution were described in their continuous and discrete forms.

Abstract

The chapter surveys the mathematical models, problems, and algorithms of the thermoacoustic tomography (TAT) and photoacoustic tomography (PAT). TAT and PAT represent probably the most developed of the several novel “hybrid” methods of medical imaging. These new modalities combine different physical types of waves (electromagnetic and acoustic in case of TAT and PAT) in such a way that the resolution and contrast of the resulting method are much higher than those achievable using only acoustic or electromagnetic measurements.

1 Introduction

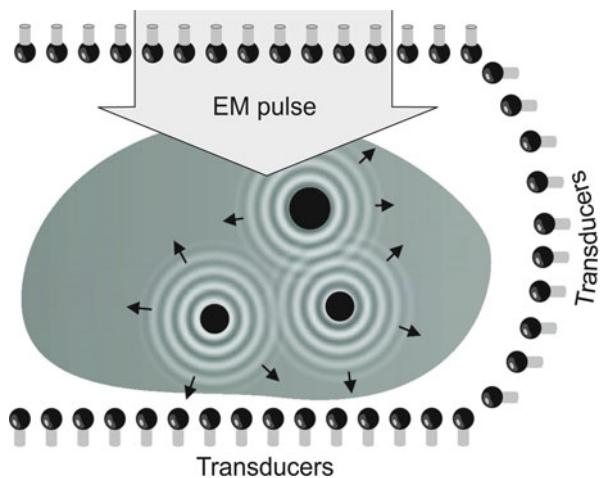

We provide here just a very brief description of the thermoacoustic tomography/photoacoustic tomography (TAT/PAT) procedure, since the relevant physics and biology details can be found in another chapter [94] in this volume, as well as in the surveys and books [93, 95]. In TAT (PAT), a short pulse of radio-frequency EM wave (correspondingly, laser beam) irradiates a biological object (e.g., in the most common application, human breast), thus causing small levels of heating. The resulting thermoelastic expansion generates a pressure wave that starts propagating through the object. The absorbed EM energy and the initial pressure it creates are much higher in the cancerous cells than in healthy tissues (see the discussion of this effect in [93–95]). Thus, if one could reconstruct the initial pressure $f(x)$, the resulting TAT tomogram would contain highly useful diagnostic information. The data for such a reconstruction are obtained by measuring time-dependent pressure $p(x, t)$ using acoustic transducers located on a surface S (we will call it the *observation* or *acquisition surface*) completely or partially surrounding the body (see Fig. 1). Thus, although the initial irradiation is electromagnetic, the actual reconstruction is based on acoustic measurements. As a result, the high contrast is produced due to a much higher absorption of EM energy by cancerous cells (ultrasound alone would not produce good contrast in this case), while the good (submillimeter) resolution is achieved by using ultrasound measurements (the radio-frequency EM waves are too long for high-resolution imaging). Thus, TAT, by using two types of waves, combines their advantages, while eliminating their individual deficiencies.

The physical principle upon which TAT/PAT is based was discovered by Alexander Graham Bell in 1880 [19], and its application for imaging of biological tissues was suggested a century later [21]. It began to be developed as a viable medical imaging technique in the middle of the 1990s [53, 69].

Some of the mathematical foundations of this imaging modality were originally developed starting in the 1990s for the purposes of the approximation theory, integral geometry, and sonar and radar (see [4, 7, 38, 54, 60] for references and extensive reviews of the resulting developments). Physical, biological, and mathematical aspects of TAT/PAT have been recently reviewed in [4, 38, 39, 54, 70, 89, 92, 93, 95].

TAT/PAT is just one, probably the most advanced at the moment, example of the several recently introduced hybrid imaging methods, which combine different

Fig. 1 Thermoacoustic tomography/photoacoustic tomography (TAT/PAT) procedure with a partially surrounding acquisition surface

types of radiation to yield high quality of imaging unobtainable by single-radiation modalities (see [10, 11, 40, 55, 95] for other examples).

2 Mathematical Models of TAT

In this section, we describe the commonly accepted mathematical model of the TAT procedure and the main mathematical problems that need to be addressed. Since for all our purposes PAT results in the same mathematical model (although the biological features that TAT and PAT detect are different; see details in Ref. [13]), we will refer to TAT only.

Point Detectors and the Wave Equation Model

We will mainly assume that point-like omnidirectional ultrasound transducers, located throughout an observation (acquisition) surface S , are used to detect the values of the pressure $p(y, t)$, where $y \in S$ is a detector location and $t \geq 0$ is the time of the observation. We also denote by $c(x)$ the speed of sound at a location x . Then, it has been argued that the following model describes correctly the propagating pressure wave $p(x, t)$ generated during the TAT procedure (e.g., [13, 31, 88, 94, 97]):

$$\begin{cases} p_{tt} = c^2(x)\Delta_x p, & t \geq 0, x \in \mathbb{R}^3 \\ p(x, 0) = f(x), p_t(x, 0) = 0. \end{cases} \quad (1)$$

Here $f(x)$ is the initial value of the acoustic pressure, which one needs to find in order to create the TAT image. In the case of a closed acquisition surface S , we will

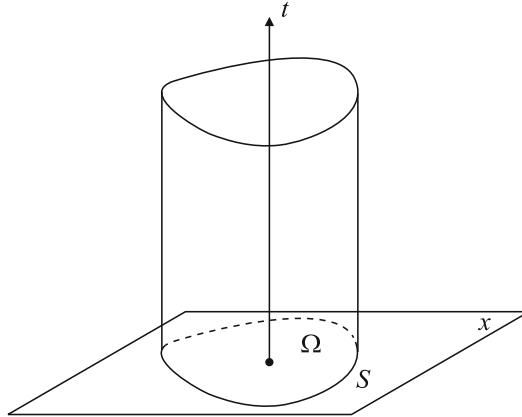

Fig. 2 The observation surface S and the domain Ω containing the object to be imaged

denote by Ω the interior domain it bounds. Notice that in TAT the function $f(x)$ is naturally supported inside Ω . We will see that this assumption about the support of f sometimes becomes crucial for the feasibility of reconstruction, although some issues can be resolved even if f has nonzero parts outside the acquisition surface.

The data obtained by the point detectors located on a surface S are represented by the function

$$g(y, t) := p(y, t) \quad \text{for } y \in S, t \geq 0. \quad (2)$$

Figure 2 illustrates the space-time geometry of (1).

We will incorporate the measured data g into the system (1), rewriting it as follows:

$$\begin{cases} p_{tt} = c^2(x) \Delta_x p, & t \geq 0, x \in \mathbb{R}^3 \\ p(x, 0) = f(x), p_t(x, 0) = 0 \\ p|_S = g(y, t), & (y, t) \in S \times \mathbb{R}^+ \end{cases} \quad (3)$$

Thus, the goal in TAT/PAT is to find, using the data $g(y, t)$ measured by transducers, the initial value $f(x)$ at $t = 0$ of the solution $p(x, t)$ of (3).

We will use the following notation:

Definition 1. We will denote by \mathcal{W} the forward operator

$$\mathcal{W} : f(x) \mapsto g(y, t), \quad (4)$$

where f and g are described in (3).

Remark 1.

- The reader should notice that if a different type of detector is used, the system (1) will still hold, while the measured data will be represented differently from (2) (see section “Variations on the Theme: Planar, Linear, and Circular Integrating Detectors”). This will correspondingly influence the reconstruction procedures.
- We can consider the same problem in the space \mathbb{R}^n of any dimension, not just in $3D$. This is not merely a mathematical abstraction. Indeed, in the case of the so-called integrating line detectors (section “Variations on the Theme: Planar, Linear, and Circular Integrating Detectors”), one deals with the $2D$ situation.

Acoustically Homogeneous Media and Spherical Means

If the medium being imaged is acoustically homogeneous (i.e., $c(x)$ equals to a constant, which we will assume to be equal to 1 in appropriate units), as it is approximately the case in breast imaging, one deals with the constant coefficient wave equation problem

$$\begin{cases} p_{tt} = \Delta_x p, & t \geq 0, x \in \mathbb{R}^3 \\ p(x, 0) = f(x), p_t(x, 0) = 0 \\ p|_S = g(y, t), & (y, t) \in S \times \mathbb{R}^+ \end{cases} \quad (5)$$

In this case, the well-known Poisson–Kirchhoff formulas [27, Chap. VI, Sect. 13.2, Formula (15)] for the solution of the wave equation give in $3D$

$$p(x, t) = a \frac{\partial}{\partial t} (t(Rf)(x, t)), \quad (6)$$

where

$$(Rf)(x, r) := \frac{1}{4\pi} \int_{|y|=1} f(x + ry) dA(y) \quad (7)$$

is the spherical mean operator applied to the function $f(x)$, dA is the standard area element on the unit sphere in \mathbb{R}^3 , and a is a constant. (Versions in all dimensions are known; see (16) and (15).) One can derive from here that knowledge of the function $g(x, t)$ for $x \in S$ and all $t \geq 0$ is equivalent to knowing the spherical mean $Rf(x, t)$ of the function f for any points $x \in S$ and any $t \geq 0$. One thus needs to study the spherical mean operator $R : f \rightarrow Rf$, or, more precisely, its restriction to the points $x \in S$ only, which we will denote by \mathcal{M} :

$$\mathcal{M}f(x, t) := \frac{1}{4\pi} \int_{|y|=1} f(x + ty) dA(y), \quad x \in S, t \geq 0. \quad (8)$$

Due to the connection between the spherical mean operator and the wave equation, one can choose to work with the former, and in fact many works on TAT do so. The spherical mean operator \mathcal{M} resembles the classical Radon transform, the common tool of computed tomography [63], which integrates functions over planes rather than spheres. This analogy with Radon transform, although often purely ideological, rather than technical, provides important intuition and frequently points in reasonable directions of study. However, when the medium cannot be assumed to be acoustically homogeneous, and thus $c(x)$ is not constant, the relation between TAT and integral geometric transforms, such as the Radon and spherical mean transforms to a large extent breaks down, and thus one has to work with the wave equation directly.

In what follows, we will address both models of TAT (the PDE model and the integral geometry model) and thus will deal with both forward operators \mathcal{W} and \mathcal{M} .

Main Mathematical Problems Arising in TAT

We now formulate a list of problems related to TAT, which will be addressed in detail in the rest of the article. (This list is more or less standard for a tomographic imaging method.)

Sufficiency of the data: The first natural question to ask is as follows: Is the data collected on the observation surface S sufficient for the unique reconstruction of the initial pressure $f(x)$ in (3)? In other words, is the kernel of the forward operator \mathcal{W} zero? Or, to put it differently, for which sets $S \in \mathbb{R}^3$ the data collected by transducers placed along S determines f uniquely? Yet another interpretation of this question is through observability of solutions of the wave equation on the set S : does observation on S of a solution of the problem (1) determine the solution uniquely?

When the speed of sound is constant, and thus the spherical mean model applies, the equivalent question is whether the operator \mathcal{M} has zero kernel on an appropriate class of functions (say, continuous functions with compact support). As it is explained in [7], the choice of precise conditions on the local function class, such as continuity, is of no importance for the answer to the uniqueness question, while behavior at infinity (e.g., compactness of support) is. So, without loss of generality, when discussing uniqueness, one can assume $f(x)$ in (3) to be infinitely differentiable.

Inversion formulas and algorithms: Since a practitioner needs to see the actual tomogram, rather than just know its existence, the next natural question arises: If uniqueness the data collected on S is established, what are the actual inversion formulas or algorithms? Here again one can work with smooth functions, in the end extending the formulas by continuity to a wider class.

Stability of reconstruction: If we can invert the transform and reconstruct f from the data g , how stable is the inversion? The measured data are unavoidably

corrupted by errors, and stability means that small errors in the data lead to only small errors in the reconstructed tomogram.

Incomplete data problems: What happens if the data is “incomplete,” for instance, if one can only partially surround the object by transducers? Does this lead to any specific deterioration in the tomogram and if yes, to what kind of deterioration?

Range descriptions: The next question is known to be important for the analysis of tomographic problems: What is the range of the forward operator $\mathcal{W} : f \mapsto g$ that maps the unknown function f to the measured data g ? In other words, what is the space of all possible “ideal” data $g(t, y)$ collected on the surface S ? In the constant speed of sound case, this is equivalent to the question of describing the range of the spherical mean operator \mathcal{M} in appropriate function spaces. Such ranges often have infinite co-dimensions, and the importance of knowing the range of Radon type transforms for analyzing problems of tomography is well known. For instance, such information is used to improve inversion algorithms, complete incomplete data, and discover and compensate for certain data errors (e.g., [41, 45, 63, 68, 70] and references therein). In TAT, range descriptions are also closely connected with the speed of sound determination problem listed next (see section “Reconstruction of the Speed of Sound” for a discussion of this connection).

Speed of sound reconstruction: As the reader can expect, reconstruction procedures require the knowledge of the speed of sound $c(x)$. Thus, the problem arises of the recovery of $c(x)$ either from an additional scan or (preferably) from the same TAT data.

Variations on the Theme: Planar, Linear, and Circular Integrating Detectors

In the most basic and well-studied version of TAT described above, one utilizes point-like broadband transducers to measure the acoustic wave on a surface surrounding the object of interest. The corresponding mathematical model is described by the system (3). In practice, the transducers cannot be made small enough, since smaller detectors yield weaker signals resulting in low signal-to-noise ratios. Smaller transducers are also more difficult to manufacture.

Since finite size of the transducers limits the resolution of the reconstructed images, researchers have been trying to design alternative acquisition schemes using receivers that are very thin but long or wide. Such are 2D planar detectors [24, 43] and 1D linear and circular [23, 42, 73, 103] detectors.

We will assume throughout this section that the speed of sound $c(x)$ is constant and equal to 1.

Planar detectors are made from a thin piezoelectric polymer film glued onto a flat substrate (see, e.g., [75]). Let us assume that the object is contained within the sphere of radius R . If the diameter of the planar detector is sufficiently large

(see [75] for details), it can be assumed to be infinite. The mathematical model of such an acquisition technique is no longer described by (3). Let us define the detector plane $\Pi(s, \omega)$ by equation $x \cdot \omega = s$, where ω is the unit normal to the plane and s is the (signed) distance from the origin to the plane. Then, while the propagation of acoustic waves is still modeled by (1), the measured data $g_{\text{planar}}(s, t, \omega)$ (up to a constant factor which we will, for simplicity, assume to be equal to 1) can be represented by the following integral:

$$g_{\text{planar}}(s, \omega, t) = \int_{\Pi(s, \omega)} p(x, t) dA(x)$$

where $dA(x)$ is the surface measure on the plane. Obviously,

$$g_{\text{planar}}(s, \omega, 0) = \int_{\Pi(s, \omega)} p(x, 0) dA(x) = \int_{\Pi(s, \omega)} f(x) dA(x) \equiv F(s, \omega),$$

i.e., the value of g at $t = 0$ coincides with the integral $F(s, \omega)$ of the initial pressure $f(x)$ over the plane $\Pi(s, \omega)$ orthogonal to ω .

One can show [24, 43] that for a fixed ω , function $g_{\text{planar}}(s, \omega, t)$ is the solution to 1D wave equation

$$\frac{\partial^2 g}{\partial s^2} = \frac{\partial^2 g}{\partial t^2},$$

and thus

$$\begin{aligned} g_{\text{planar}}(s, \omega, t) &= \frac{1}{2} [g_{\text{planar}}(s, \omega, s - t) + g_{\text{planar}}(s, \omega, s + t)] \\ &= \frac{1}{2} [F(s + t, \omega) + F(s - t, \omega)]. \end{aligned}$$

Since the detector can only be placed outside the object, i.e., $s \geq R$, the term $F(s + t, \omega)$ vanishes, and one obtains

$$g_{\text{planar}}(s, \omega, t) = F(s - t, \omega).$$

In other words, by measuring $g_{\text{planar}}(s, \omega, t)$, one can obtain values of the planar integrals of $f(x)$. If, as proposed in [24, 43], one conducts measurements for all planes tangent to the upper half sphere of radius R (i.e., $s = R, \omega \in S_+^2$), then the resulting data yield all values of the standard Radon transform of $f(x)$. Now the reconstruction can be carried out using one of the many known inversion algorithms for the latter transform [63].

Linear detectors are based on optical detection of acoustic signal. Some of the proposed optical detection schemes utilize as the sensitive element a thin straight optical fiber in combination with Fabry–Perot interferometer [23, 42]. Changes of

acoustic pressure on the fiber change (proportionally) its length; this elongation, in turn, is detected by the interferometer. A similar idea is used in [73]; in this work the role of a sensitive element is played by a laser beam passing through the water in which the object of interest is submerged, and thus the measurement does not perturb the acoustic wave. In both cases, the length of the sensitive element exceeds the size of the object, while the diameter of the fiber (or of the laser beam) can be made extremely small (see [75] for a detailed discussion), which removes restrictions on resolution one can achieve in the images.

Let us assume that the fiber (or laser beam) is aligned along the line $l(s_1, s_2, \omega_1, \omega_2) = \{x|x = s_1\omega_1 + s_2\omega_2 + s\omega\}$, where vectors ω_1, ω_2 , and ω form an orthonormal basis in \mathbb{R}^3 . Then the measured quantities $g_{\text{linear}}(s_1, s_2, \omega_1, \omega_2, t)$ are equal (up to a constant factor which, we will assume, equals to 1) to the following line integral:

$$g_{\text{linear}}(s_1, s_2, \omega_1, \omega_2, t) = \int_{\mathbb{R}^1} p(s_1\omega_1 + s_2\omega_2 + s\omega, t) ds.$$

Similar to the case of planar detection, one can show [23, 42, 73] that for fixed vectors ω_1, ω_2 the measurements $g_{\text{linear}}(s_1, s_2, \omega_1, \omega_2, t)$ satisfy the 2D wave equation

$$\frac{\partial^2 g}{\partial s_1^2} + \frac{\partial^2 g}{\partial s_2^2} = \frac{\partial^2 g}{\partial t^2}.$$

The initial values $g_{\text{linear}}(s_1, s_2, \omega_1, \omega_2, 0)$ coincide with the line integrals of $f(x)$ along lines $l(s_1, s_2, \omega_1, \omega_2)$. Suppose one makes measurements for all values of $s_1(\tau), s_2(\tau)$ corresponding to a curve $\gamma = \{x|x = s_1(\tau)\omega_1 + s_2(\tau)\omega_2, \tau_0 \leq \tau \leq \tau_1\}$ lying in the plane spanned by ω_1, ω_2 . Then one can try to reconstruct the initial value of g from the values of g on γ . This problem is a 2D version of (3), and thus the known algorithms (see Sect. 4) are applicable.

In order to complete the reconstruction from data obtained using line detectors, the measurements should be repeated with different directions of ω . For each value of ω , the 2D problem is solved; the solutions of these problems yield values of line integrals of $f(x)$. If this is done for all values of ω lying on a half circle, the set of the recovered line integrals of $f(x)$ is sufficient for reconstructing this function. Such a reconstruction represents the inversion of the well known in tomography X-ray transform. The corresponding theory and algorithms can be found, for instance, in [63].

Finally, the use of circular integrating detectors was considered in [103]. Such a detector can be made out of optical fiber combined with an interferometer. In [103], a closed-form solution of the corresponding inverse problem is found. However, this approach is very new, and neither numerical examples nor reconstructions from real data have been obtained yet.

3 Mathematical Analysis of the Problem

In this section, we will address most of the issues described in section “Main Mathematical Problems Arising in TAT,” except the reconstruction algorithms, which will be discussed in Sect. 4.

Uniqueness of Reconstruction

The problem discussed here is the most basic one for tomography: Given an acquisition surface S along which we distribute detectors, is the data $g(y, t)$ for $y \in S, t \geq 0$ (see (3)) sufficient for a unique reconstruction of the tomogram f ? A simple counting of variables shows that S should be a hypersurface in the ambient space (i.e., a surface in \mathbb{R}^3 or a curve in \mathbb{R}^2). As we will see below, although there are some simple counterexamples and remaining open problems, for all practical purposes, the uniqueness problem is positively resolved, and most surfaces S do provide uniqueness. We address this issue for acoustically homogeneous media first and then switch to the variable speed case.

Before doing so, however, we would like to dispel a concern that arises when one looks at the problem of recovering f from g in (3). Namely, an impression might arise that we consider an initial-boundary value (IBV) problem for the wave equation in the cylinder $\Omega \times \mathbb{R}^+$, and the goal is to recover the initial data f from the known boundary data g . This is clearly impossible, since according to standard PDE theorems (e.g., [27]), one can solve this IBV problem for **arbitrary** choice of the initial data f and boundary data g (as long as they satisfy simple compatibility conditions, which are fulfilled, for instance, if f vanishes near S and g vanishes for small t , which is the case in TAT). This means that apparently g contains essentially no information about f at all. This argument, however, is flawed, since the wave equation in (3) holds in the whole space, not just in Ω . In other words, S is not a boundary, but rather an observation surface. In particular, considering the wave equation in the exterior of S , one can derive that if f is supported inside Ω , the boundary values g of the solution p of (3) also determine the normal derivative of p at S for all positive times. Thus, we in fact have (at least theoretically) the full Cauchy data of the solution p on S , which should be sufficient for reconstruction. Another way of addressing this issue is to notice that if the speed of sound is constant, or at least non-trapping (see the definition below in section “Acoustically Inhomogeneous Media”), the energy of the solution in any bounded domain (in particular, in Ω) must decay in time. The decay when $t \rightarrow \infty$ together with the boundary data g guarantees the uniqueness of solution and thus uniqueness of recovery f .

These arguments, as the reader will see, play a role in understanding reconstruction procedures.

Acoustically Homogeneous Media

We assume here the sound speed $c(x)$ to be constant (in appropriate units, one can choose it to be equal to 1, which we will do to simplify considerations).

In order to state the first important result on uniqueness, let us recall the system (5), allowing an arbitrary dimension n of the space:

$$\begin{cases} p_{tt} = \Delta_x p, & t \geq 0, x \in \mathbb{R}^n \\ p(x, 0) = f(x), p_t(x, 0) = 0 \\ p|_S = g(y, t), & (y, t) \in S \times \mathbb{R}^+. \end{cases} \quad (9)$$

We introduce the following useful definition:

Definition 2. A set S is said to be a uniqueness set if when used as the acquisition surface, it provides sufficient data for unique reconstruction of the compactly supported tomogram f (i.e., the observed data g in (9) determines uniquely function f). Otherwise, it is called a nonuniqueness set.

In other words, S is a uniqueness set if the forward operator \mathcal{W} (or, equivalently, \mathcal{M}) has zero kernel.

We have not indicated above the smoothness class of $f(x)$. However, it is not hard to show (e.g., [7]) that the uniqueness does not depend on the smoothness of f ; for simplicity, the reader can assume that f is infinitely differentiable. On the other hand, compactness of support is important in what follows.

We will start with a very general statement about the acquisition (observation) sets S that provide insufficient information for unique reconstruction of f (see [7] for the proof and references):

Theorem 1. *If S is a nonuniqueness set, then there exists a nonzero harmonic polynomial Q , which vanishes on S .*

This theorem implies, in particular, that all “bad” (nonuniqueness) observation sets are algebraic, i.e., they have a polynomial vanishing on them. Turning this statement around, we conclude that any set S that is a uniqueness set for harmonic polynomials is sufficient for unique TAT reconstruction (although, as we will see in section “Incomplete Data,” this does not mean practicality of the reconstruction).

The proof of Theorem 1, which the reader can find in [7, 54], is not hard and in fact is enlightening, but providing it would lead us too far from the topic of this survey.

We will consider first the case of closed acquisition surfaces, i.e., the ones that completely surround the object to be imaged. We will address the general situation afterward.

Closed Acquisition Surfaces S

Theorem 2 ([7]). *If the acquisition surface S is the boundary of bounded domain Ω (i.e., a closed surface), then it is a uniqueness set. Thus, the observed data g in (9) determines uniquely the sought function $f \in L^2_{comp}(\mathbb{R}^n)$. (The statement holds, even though f is not required to be supported inside S .)*

Proof. Indeed, since there are no nonzero harmonic functions vanishing on a closed surface S , Theorem 1 implies Theorem 2. ■

There is, however, another more intuitive explanation of why Theorem 2 holds true (although it requires somewhat stronger assumptions or a more delicate proof than the one indicated below). Namely, since the solution p of (9) has compactly supported initial data, its energy is decaying inside any bounded domain, in particular inside Ω (see section “Acoustically Inhomogeneous Media” and [32, 47] and references therein about local energy decay). On the other hand, if there is nonuniqueness, there exists a nonzero f such that $g(y, t) = 0$ for all $y \in S$ and t . This means that we can add homogeneous Dirichlet boundary conditions $p|_S = 0$ to (9). But then the standard PDE theorems [27] imply that the energy stays constant in Ω . Combination of the two conclusions means that p is zero in Ω for all times t . It is well known [27] that such a solution of the wave equation must be identically zero everywhere, and thus $f = 0$.

This energy decay consideration can be extended to some classes of non-compactly supported functions f of the L^p classes, leading to the following result of [1]:

Theorem 3 ([1]). *Let S be the boundary of a bounded domain in \mathbb{R}^n and $f \in L^p(\mathbb{R}^n)$. Then:*

1. *If $p \leq \frac{2n}{n-1}$ and the spherical mean of f over almost every sphere centered on S is equal to zero, then $f = 0$.*
2. *The previous statement fails when $p > \frac{2n}{n-1}$ and S is a sphere.*

In other words, a closed surface S is a uniqueness set for functions $f \in L^p(\mathbb{R}^n)$ when $p \leq \frac{2n}{n-1}$ and might fail to be such when $p > \frac{2n}{n-1}$.

This result shows that the assumption, if not necessarily of compactness of support of f , but at least of a sufficiently fast decay of f at infinity, is important for the uniqueness to hold.

General Acquisition Sets S

Theorems 1 and 2 imply the following useful statement:

Theorem 4. *If a set S is not algebraic, or if it contains an open part of a closed analytic surface Γ , then it is a uniqueness set.*

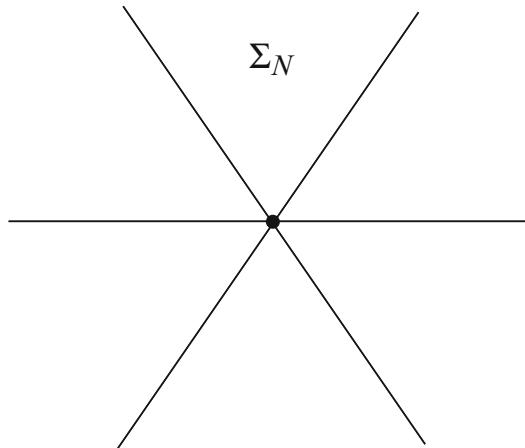

Fig. 3 Coxeter cross of N lines

Indeed, the first claim follows immediately from Theorem 1. The second one works out as follows: if an open subset of an analytic surface Γ is a nonuniqueness set, then by an analytic continuation type argument (see [7]), one can show that the whole Γ is such a set. However, this is impossible, due to Theorem 2.

There are simple examples of nonuniqueness surfaces. Indeed, if S is a plane in $3D$ (or a line in $2D$ or a hyperplane in dimension n) and $f(x)$ in (3) is odd with respect to S , then clearly the whole solution of (3) has the same parity and thus vanishes on S for all times t . This means that, if one places transducers on a planar S , they might register zero signals at all times, while the function f to be reconstructed is not zero. Thus, there is no uniqueness of reconstruction when S is a plane. On the other hand (see [27, 51]), if f is supported completely on one side of the plane S (the standard situation in TAT), it is uniquely recoverable from its spherical means centered on S and thus from the observed data g .

The question arises on what are other “bad” (nonuniqueness) acquisition surfaces than planes. This issue has been resolved in $2D$ only. Namely, consider a set of N lines on the plane intersecting at a point and forming at this point equal angles. We will call such a figure the Coxeter cross Σ_N (see Fig. 3). It is easy to construct a compactly supported function that is odd simultaneously with respect of all lines in Σ_N . Thus, a Coxeter cross is also a nonuniqueness set. The following result, conjectured in [60] and proven in the full generality in [7], shows that up to adding finitely many points, this is all that can happen to nonuniqueness sets:

Theorem 5 ([7]). *A set S in the plane \mathbb{R}^2 is a nonuniqueness set for compactly supported functions f , if and only if it belongs to the union $\Sigma_N \cup \Phi$ of a Coxeter cross Σ_N and a finite set of points Φ .*

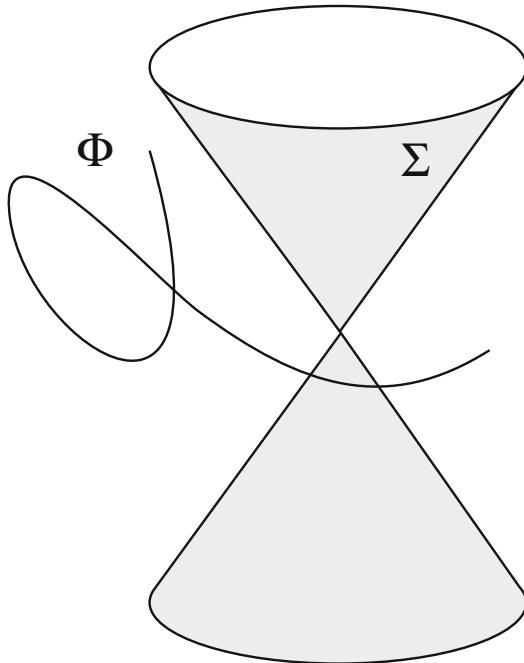

Fig. 4 The conjectured structure of a most general nonuniqueness set in 3D

Again, compactness of support is crucial for the proof provided in [7]. There are no other proofs known at the moment of this result (see the corresponding open problem in Sect. 5). In particular, there is no proven analogue of Theorem 3 for non-closed sets S (unless S is an open part of a closed analytic surface).

The n -dimensional (in particular, 3D) analogue of Theorem 5 has been conjectured [7], but never proven, although some partial advances in this direction have been made in [8, 36].

Conjecture 1. A set S in \mathbb{R}^n is a nonuniqueness set for compactly supported functions f , if and only if it belongs to the union $\Sigma \cup \Phi$, where Σ is the cone of zeros of a homogeneous (with respect to some point in \mathbb{R}^n) harmonic polynomial, and Φ is an algebraic subset of \mathbb{R}^n of dimension at most $n - 2$ (see Fig. 4).

Uniqueness Results for a Finite Observation Time

So far, we have addressed only the question of uniqueness of reconstruction in the nonpractical case of the infinite observation time. There are, however, results that guarantee the uniqueness of reconstruction for a finite time of observation. The general idea is that it is sufficient to observe for the time that it takes the geometric rays (see section “Acoustically Inhomogeneous Media”) from the interior Ω of S to reach S . In the case of a constant speed, which we will assume to be equal to 1,

the rays are straight and are traversed with the unit speed. This means that if D is the diameter of Ω (i.e., the maximal distance between two points in the closure of Ω), then after time $t = D$, all rays coming from Ω have left the domain. Thus, one hopes that waiting till time $t = D$ might be sufficient. In fact, due to the specific initial conditions in (3), namely, that the time derivative of the pressure is equal to zero at the initial moment, each singularity of f emanates two rays, and at least one of them will reach S in time not exceeding $D/2$. And indeed, the following result of [36] holds:

Theorem 6 ([36]). *If S is smooth and closed surface bounding domain Ω and D is the diameter of Ω , then the TAT data on S collected for the time $0 \leq t \leq 0.5D$ uniquely determines f .*

Notice that a shorter collection time does not guarantee uniqueness. Indeed, if S is a sphere and the observation time is less than $0.5D$, due to the finite speed of propagation, no information from a neighborhood of the center can reach S during observation. Thus, values of f in this neighborhood cannot be reconstructed.

Acoustically Inhomogeneous Media

We assume that the speed of sound is strictly positive, $c(x) > c > 0$, and such that $c(x) - 1$ has compact support, i.e., $c(x) = 1$ for large x .

Trapping and Non-trapping

We will frequently impose the so-called non-trapping condition on the speed of sound $c(x)$ in \mathbb{R}^n . To introduce it, let us consider the Hamiltonian system in $\mathbb{R}_{x,\xi}^{2n}$ with the Hamiltonian $H = \frac{c^2(x)}{2}|\xi|^2$:

$$\begin{cases} x'_t = \frac{\partial H}{\partial \xi} = c^2(x)\xi \\ \xi'_t = -\frac{\partial H}{\partial x} = -\frac{1}{2}\nabla(c^2(x))|\xi|^2 \\ x|_{t=0} = x_0, \quad \xi|_{t=0} = \xi_0. \end{cases} \quad (10)$$

The solutions of this system are called bicharacteristics, and their projections into \mathbb{R}_x^n are rays (or geometric rays).

Definition 3. We say that the speed of sound $c(x)$ satisfies the non-trapping condition, if all rays with $\xi_0 \neq 0$ tend to infinity when $t \rightarrow \infty$.

The rays that do not tend to infinity are called trapped.

A simple example, where quite a few rays are trapped, is the radial parabolic sound speed $c(x) = c|x|^2$.

It is well known (e.g., [46]) that singularities of solutions of the wave equation are carried by geometric rays. In order to make this statement more precise, we need

to recall the notion of a wave front set $WF(u)$ of a distribution $u(x)$ in \mathbb{R}^n . This set carries detailed information on singularities of $u(x)$.

Definition 4. Distribution $u(x)$ is said to be **microlocally smooth near a point** (x_0, ξ_0) , where $x_0, \xi_0 \in \mathbb{R}^n$, and $\xi_0 \neq 0$, if there is a smooth “cutoff” function $\phi(x)$ such that $\phi(x_0) \neq 0$ and that the Fourier transform $\widehat{\phi u}(\xi)$ of the function $\phi(x)u(x)$ decays faster than any power $|\xi|^{-N}$ when $|\xi| \rightarrow \infty$, in directions that are close to the direction of ξ_0 . (We remind the reader that if this Fourier transform decays that way in all directions, then $u(x)$ is smooth (infinitely differentiable) near the point x_0 .)

The **wave front set** $WF(u) \subset \mathbb{R}_x^n \times (\mathbb{R}_\xi^n \setminus 0)$ of u consists of all pairs (x_0, ξ_0) such that u is not microlocally smooth near (x_0, ξ_0) .

In other words, if $(x_0, \xi_0) \in WF(u)$, then u is not smooth near x_0 , and the direction of ξ_0 indicates why it is not: the Fourier transform does not decay well in this direction. For instance, if $u(x)$ consists of two smooth pieces joined non-smoothly across a smooth interface Σ , then $WF(u)$ can only contain pairs (x, ξ) such that $x \in \Sigma$ and ξ is normal to Σ at x .

It is known that the wave front sets of solutions of the wave equation propagate with time along the bicharacteristics introduced above. This is a particular instance of a more general fact that applies to general PDEs and can be found in [46, 84]. As a result, if after time T all the rays leave the domain Ω of interest, the solution becomes smooth (infinitely differentiable) inside Ω .

The notion of so-called local energy decay, which we survey next, is important for the understanding of the non-trapping conditions in TAT.

Local Energy Decay Estimates

Assuming that the initial data $f(x)$ (1) is compactly supported and the speed $c(x)$ is non-trapping, one can provide the **local energy decay estimates** [32, 90, 91]. Namely, in any bounded domain Ω , the solution $p(x, t)$ of (1) satisfies, for a sufficiently large T_0 and for any (k, m) , the estimate

$$\left| \frac{\partial^{k+|m|}}{\partial_t^k \partial_x^m} \right| \leq C_{k,m} v_k(t) \|f\|_{L^2}, \quad \text{for } x \in \Omega, t > T_0. \quad (11)$$

Here $v_k(t) = t^{-n+1-k}$ for even n and $v_k(t) = e^{-\delta t}$ for odd n and some $\delta > 0$. Any value T_0 larger than the diameter of Ω works in this estimate.

Uniqueness Result for Non-trapping Speeds

If the speed is non-trapping, the local energy decay allows one to start solving the problem (3) from $t = \infty$, imposing zero conditions at $t = \infty$ and using the measured data g as the boundary conditions. This leads to recovery of the whole solution and in particular its initial value $f(x)$. As the result, one obtains the following simple uniqueness result of [3]:

Theorem 7 ([3]). *If the speed $c(x)$ is smooth and non-trapping and the acquisition surface S is closed, then the TAT data $g(y, t)$ determines the tomogram $f(x)$ uniquely.*

Notice that the statement of the theorem holds even if the support of f is not completely inside of the acquisition surface S .

Uniqueness Results for Finite Observation Times

As in the case of constant coefficients, if the speed of sound is non-trapping, appropriately long finite observation time suffices for the uniqueness. Let us denote by $T(\Omega)$ the *supremum* of the time it takes the ray to reach S , over all rays originating in Ω . In particular, if $c(x)$ is trapping, $T(\Omega)$ might be infinite.

Theorem 8 ([86]). *The data g measured till any time T larger than $T(\Omega)$ is sufficient for the unique recovery of f .*

Stability

By stability of reconstruction of the TAT tomogram f from the measured data g , we mean that small variations of g in an appropriate norm lead to small variations of the reconstructed tomogram f , also measured by an appropriate norm. In other words, small errors in the data lead to small errors in the reconstruction.

We will try to give the reader a feeling of the general state of affairs with stability, referring to the literature (e.g., [5, 48, 54, 71, 86]) for further exact details.

We will consider as functional spaces the standard Sobolev spaces H^s of smoothness s . We will also denote, as before, by \mathcal{W} the operator transforming the unknown f into the data g .

Let us recall the notions of **Lipschitz and Hölder stability**. An even weaker **logarithmic stability** will not be addressed here. The reader can find discussion of the general stability notions and issues, as applied to inverse problems, in [49].

Definition 5. The operation of reconstructing f from g is said to be **Lipschitz stable** between the spaces H^{s_2} and H^{s_1} , if the following estimate holds for some constant C :

$$\|f\|_{H^{s_1}} \leq C \|g\|_{H^{s_2}}.$$

The reconstruction is said to be **Hölder stable** (a weaker concept), if there are constants $s_1, s_2, s_3, C, \mu > 0$, and $\delta > 0$ such that

$$\|f\|_{H^{s_1}} \leq C \|g\|_{H^{s_2}}^\mu$$

for all f such that $\|f\|_{H^{s_3}} \leq \delta$.

Stability can be also interpreted in the terms of the singular values σ_j of the forward operator $f \mapsto g$ in L^2 , which have at most power decay when $j \rightarrow \infty$. The faster is the decay, the more unstable the reconstruction becomes. The problems with singular values decaying faster than any power of j are considered to be extremely unstable. Even worse are the problems with exponential decay of singular values (analytic continuation or solving Cauchy problem for an elliptic operator belong to this class). Again, the book [49] is a good source for finding detailed discussion of such issues.

Consider as an example inversion of the standard in X-ray CT and MRI Radon transform that integrates a function f over hyperplanes in \mathbb{R}^n . It smoothes function by “adding $(n - 1)/2$ derivatives.” Namely, it maps continuously H^s -functions in Ω into the Radon projections of class $H^{s+(n-1)/2}$. Moreover, the reconstruction procedure is Lipschitz stable between these spaces (see [63] for detailed discussion).

One should notice that since the forward mapping is smoothing (it “adds derivatives” to a function), the inversion should produce functions that are less smooth than the data, which is an unstable operation. The rule of thumb is that the stronger is the smoothing, the less stable is the inversion (this can be rigorously recast in the language of the decay of singular values). Thus, problems that require reconstructing non-smooth functions from infinitely differentiable (or even worse, analytic) data are extremely unstable (with super-algebraic or exponential decay of singular values correspondingly). This is just a consequence of the standard Sobolev embedding theorems (see, e.g., how this applies in TAT case in [65]).

In the case of a constant sound speed and the acquisition surface completely surrounding the object, as we have mentioned before, the TAT problem can be recast as inversion of the spherical mean transform \mathcal{M} (see Sect. 2). Due to analogy between the spheres centered on S and hyperplanes, one can conjecture that the Lipschitz stability of **the inversion of the spherical mean operator \mathcal{M} is similar to that of the inversion of the Radon transform**. This indeed is the case, **as long as f is supported inside S** , as has been shown in [71]. In the cases when closed-form inversion formulas are available (see section “Constant Speed of Sound”), this stability can also be extracted from them. If the support of f does reach outside, **reconstruction of the part of f that is outside is unstable** (i.e., is not even Hölder stable, due to the reasons explained in section “Incomplete Data”).

In the case of **variable non-trapping speed of sound** $c(x)$, integral geometry does not apply anymore, and one needs to address the issue using, for instance, time reversal. In this case, stability follows by solving the wave equation in reverse time starting from $t = \infty$, as it is done in [3]. In fact, **Lipschitz stability in this case holds for any observation time exceeding $T(\Omega)$** (see [86], where microlocal analysis is used to prove this result).

The bottom line is that **TAT reconstruction is sufficiently stable, as long as the speed of sound is non-trapping**.

However, trapping speed does cause instability [48]. Indeed, since some of the rays are trapped inside Ω , the information about some singularities never reaches S (no matter for how long one collects the data), and thus, as it is shown in [65], the reconstruction is not even Hölder stable between any Sobolev spaces, and the

singular values have super-algebraic decay. See also section “Incomplete Data” below for a related discussion.

Incomplete Data

In the standard X-ray CT, incompleteness of data arises, for instance, if not all projection angles are accessible or irradiation of certain regions is avoided, or as in the ROI (region of interest) imaging, only the ROI is irradiated.

It is not that clear what incomplete data means in TAT. Usually one says that one deals with **incomplete TAT data if the acquisition surface does not surround the object of imaging completely**. For instance, in breast imaging it is common that only a half-sphere arrangement of transducers is possible. We will see, however, that **incomplete data effects in TAT can also arise due to trapping, even if the acquisition surface completely surrounds the object**.

The questions addressed here are the following:

1. Is the collected incomplete data sufficient for **unique reconstruction**?
2. If yes, does the incompleteness of the data have any effect on the **stability and quality of the reconstruction**?

Uniqueness of Reconstruction

Uniqueness of reconstruction issues can be considered essentially resolved for incomplete data in TAT, at least in most situations of practical interest. We will briefly survey here some of the available results. In what follows, the acquisition surface S is not closed (otherwise the problem is considered to have complete data).

Uniqueness for Acoustically Homogeneous Media

In this case, Theorem 4 contains some useful sufficient conditions on S that guarantee uniqueness. Microlocal results of [7, 61, 85], as well as the PDE approach of [36] further applied in [8], provide also some other conditions. We assemble some of these in the following theorem:

Theorem 9. *Let S be a non-closed acquisition surface in TAT. Each of the following conditions on S is sufficient for the uniqueness of reconstruction of any compactly supported function f from the TAT data collected on S :*

1. *Surface S is not algebraic (i.e., there is no nonzero polynomial vanishing on S).*
2. *Surface S is a uniqueness set for harmonic polynomials (i.e., there is no nonzero harmonic polynomial vanishing on S).*
3. *Surface S contains an open piece of a closed analytic surface Γ .*
4. *Surface S contains an open piece of an analytic surface Γ separating the space \mathbb{R}^n such that f is supported on one side of Γ .*
5. *For some point $y \in S$, the function f is supported on one side of the tangent plane T_y to S at y .*

For instance, if the acquisition surface S is just a tiny non-algebraic piece of a surface, data collected on S determines the tomogram f uniquely. However, one realizes that such data is unlikely to be useful for any practical reconstruction. Here the issue of stability of reconstruction kicks in, as it will be discussed in the stability subsection further down.

Uniqueness for Acoustically Inhomogeneous Media

In the case of a variable speed of sound, there still are uniqueness theorems for partial data [86, 87], e.g.:

Theorem 10 ([86]). *Let S be an open part of the boundary $\partial\Omega$ of a strictly convex domain Ω , and the smooth speed of sound equals 1 outside Ω . Then the TAT data collected on S for a time $T > T(\Omega)$ determines uniquely any function $f \in H_0^1(\Omega)$, whose support does not reach the boundary.*

A modification of this result that does not require strict convexity is also available in [87].

While useful uniqueness of reconstruction results exists for incomplete data problems, all such problems are expected to show instability. This issue is discussed in the subsections below. This will also lead to a better understanding of incomplete data phenomena in TAT.

“Visible” (“Audible”) Singularities

According to the discussion in section “Acoustically Inhomogeneous Media,” the singularities (the points of the wave front set $WF(f)$ of the function f in (3)) are transported with time along the bicharacteristics (10). Thus, in the x -space they are transported along the geometric rays. These rays may or may not reach the acquisition surface S , which triggers the introduction of the following notion:

Definition 6. A phase space point (x_0, ξ_0) is said to be “**visible**” (sometimes the word “**audible**” is used instead), if the corresponding ray (see (10)) reaches in finite time the observation surface S .

A region $U \subset \mathbb{R}^n$ is said to be in the **visibility zone**, if all points (x_0, ξ_0) with $x_0 \in U$ are visible.

An example of wave propagation through inhomogeneous medium is presented in Fig. 5. The open observation surface S in this example consists of the two horizontal and the left vertical sides of the square. Figure 5a shows some rays that bend, due to acoustic inhomogeneity, and leave through the opening of the observation surface S (the right side of the square). Figure 5b presents a flat phantom, whose wave front set creates these escaping rays, and thus is mostly invisible. Then Fig. 5c–f shows the propagation of the corresponding wave front.

Since the information about the horizontal boundaries of the phantom escapes, one does not expect to reconstruct it well. Figure 6 shows two phantoms and their reconstructions from the partial data: (a–b) correspond to the vertical flat

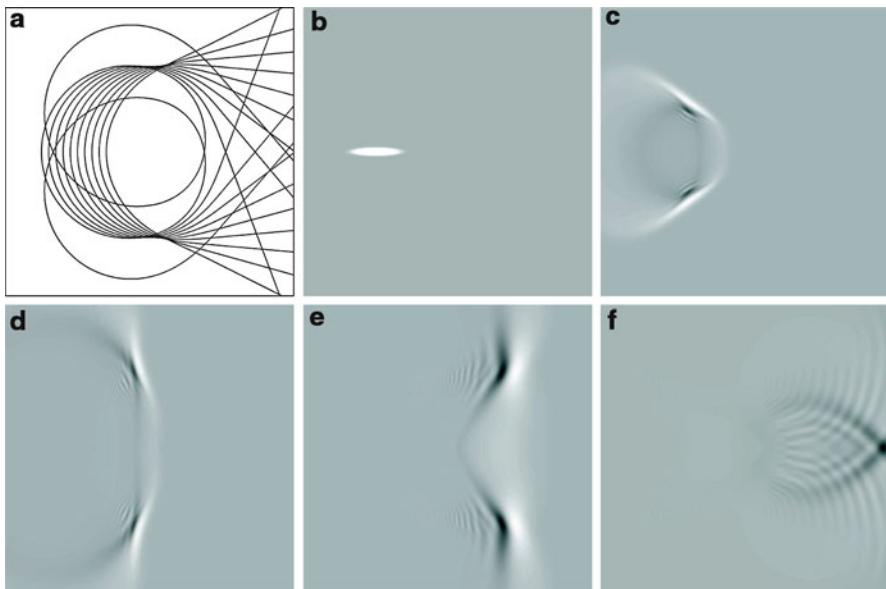

Fig. 5 (a) Some rays starting along the interval $x \in [-0.7, -0.2]$ in the vertical directions escape on the right; (b) a flat phantom with “invisible wave front”; (c–f) propagation of the flat front: most of the energy of the signal leaves the square domain through the hole on the right

phantom, whose only invisible singularities are at its ends. One sees essentially good reconstruction, with a little bit of blurring at the end points. On the other hand, reconstruction of the horizontal phantom with almost the whole wave front set invisible does not work. The next Fig. 7 shows a more complex square phantom, whose singularities corresponding to the horizontal boundaries are invisible, while the vertical boundaries are fine. One sees clearly that the invisible parts have been blurred away. On the other hand, Fig. 11a in Sect. 4 shows that one can reconstruct an image without blurring and with correct values, if the image is located in the visibility region. The reconstructed image in this figure is practically indistinguishable from the phantom shown in Fig. 10a.

Remark 2. If S is a closed surface and x_0 is a point outside of the convex hull of S , there is a vector $\xi_0 \neq 0$ such that (x_0, ξ_0) is “invisible.” Thus, the visibility zone does not reach outside the closed acquisition surface S .

Stability of Reconstruction for Incomplete Data Problems

In all examples above, uniqueness of reconstruction held, but the images were still blurred. The question arises whether the blurring of “invisible” parts is avoidable (after all, the uniqueness theorems seem to claim that “everything is visible”). The answer to this is, in particular, the following result of [65], which is an analogue of similar statements in X-ray tomography:

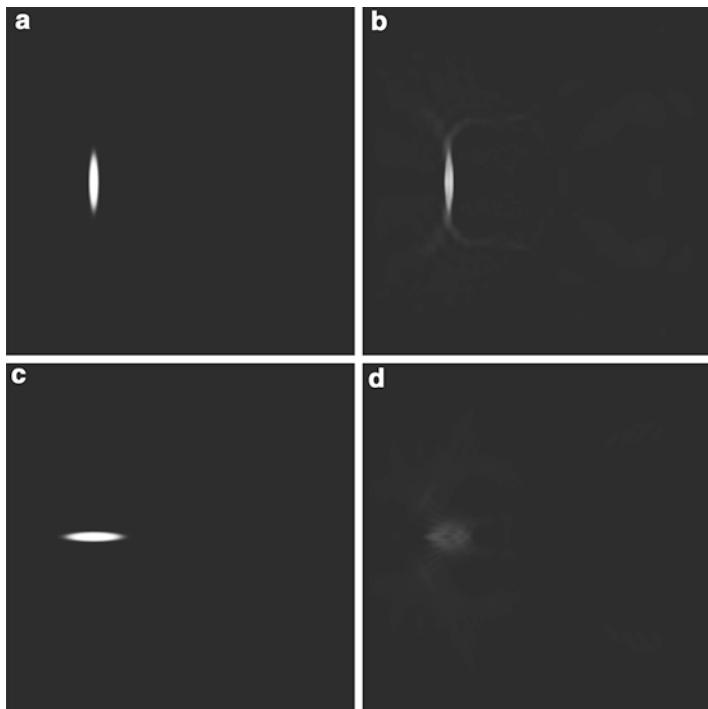

Fig. 6 Reconstruction with the same speed of sound as in Fig. 5: (a–b) a phantom with strong vertical fronts and its reconstruction; (c–d) a phantom with strong horizontal fronts and its reconstruction

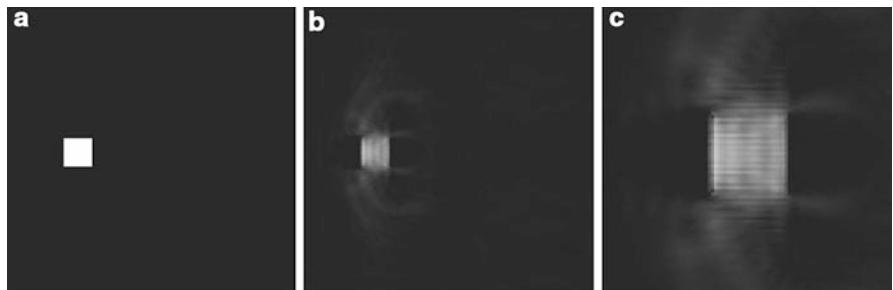

Fig. 7 Reconstruction with the same speed of sound as in Fig. 5: (a) a phantom; (b) its reconstruction; (c) a magnified fragment of (b)

Theorem 11 ([65]). *If there are invisible points (x_0, ξ_0) in $\Omega \times (\mathbb{R}_\xi^n \setminus 0)$, then inversion of the forward operator \mathcal{W} is not Hölder stable in any Sobolev spaces. The singular values σ_j of \mathcal{W} in L^2 decay super-algebraically.*

Thus, the presence of invisible singularities makes the reconstruction severely ill-posed. In particular, according to Remark 2, this theorem implies the following statement:

Corollary 1. *Reconstruction of the parts of $f(x)$ supported outside the closed observation surface S is unstable.*

On the other hand,

Theorem 12 ([86]). *All visible singularities of f can be reconstructed with Lipschitz stability (in appropriate spaces).*

Such a reconstruction of visible singularities can be obtained in many ways, for instance, just by replacing the missing data by zeros (with some smoothing along the junctions with the known data, in order to avoid artifact singularities). However, there is no hope for stable recovery of the correct values of $f(x)$, if there are invisible singularities.

Discussion of the Visibility Condition

Visibility for Acoustically Homogeneous Media

In the constant speed case, the rays are straight, and thus the visibility condition has a simple test:

Proposition 1 (e.g., [48, 99, 100]). *If the speed is constant, a point x_0 is in the visible region, if and only if any line passing through x_0 intersects at least once the acquisition surface S (and thus a detector location).*

Figure 8 illustrates this statement. It shows a square phantom and its reconstruction from complete data and from the data collected on the half circle S surrounding the left half of object. The parts of the interfaces where the normal to the interface that does not cross S are blurred.

Visibility for Acoustically Inhomogeneous Media

When the speed of sound is variable, an analogue of Proposition 1 holds, with lines replaced by rays.

Proposition 2 (e.g., [48, 65, 86]). *A point x_0 is in the visible region, if and only if for any $\xi_0 \neq 0$ at least one of the two geometric rays starting at (x_0, ξ_0) and at $(x_0, -\xi_0)$ (see (10)) intersects the acquisition surface S (and thus a detector location).*

The reader can now see an important difference between the acoustically homogeneous and inhomogeneous media. Indeed, even if S surrounds the support

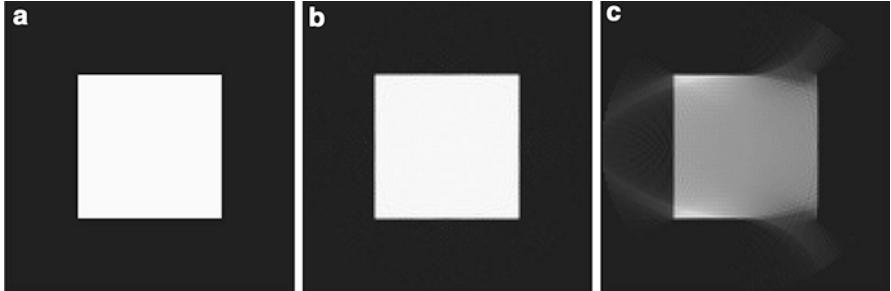

Fig. 8 Reconstruction from incomplete data using closed-form inversion formula in 2D; detectors are located on the left half circle of radius 1.05: (a) phantom; (b) reconstruction from complete data; and (c) reconstruction from the incomplete data

of f completely, trapped rays will never find their way to S , which will lead, as we know by now, to instabilities and blurring of some interfaces.

Thus, the presence of rays trapped inside the acquisition surface creates effects of incomplete data type. This is exemplified in Fig. 9 with a square phantom and its reconstruction shown in the presence of a trapping (parabolic) speed. Notice that the square centered at the center of symmetry of the speed is reconstructed very well (see Fig. 9d), since none of the rays carrying its singularities is trapped.

Range Conditions

In this section we address the problem of describing the ranges of the forward operators \mathcal{W} (see (4)) and \mathcal{M} (see (8)), the latter in the case of an acoustically homogeneous medium (i.e., for $c = \text{const}$). The ranges of these operators, similarly to the range of the Radon and X-ray transforms (see [63]), are of infinite co-dimensions. This means that ideal data g from a suitable function space satisfy infinitely many mandatory identities. Knowing the range is useful for many theoretical and practical purposes in various types of tomography (reconstruction algorithms, error corrections, incomplete data completion, etc.), and thus this topic has attracted a lot of attention (e.g., [41, 45, 63, 68, 70] and references therein).

As we will see in the next section, range descriptions in TAT are also intimately related to the recovery of the unknown speed of sound.

We recall [41, 45, 63] that for the standard Radon transform

$$f(x) \rightarrow g(s, \omega) = \int_{x \cdot \omega = s} f(x) dx, |\omega| = 1,$$

where f is assumed to be smooth and supported in the unit ball $B = \{x \mid |x| \leq 1\}$, the range conditions on $g(s, \omega)$ are:

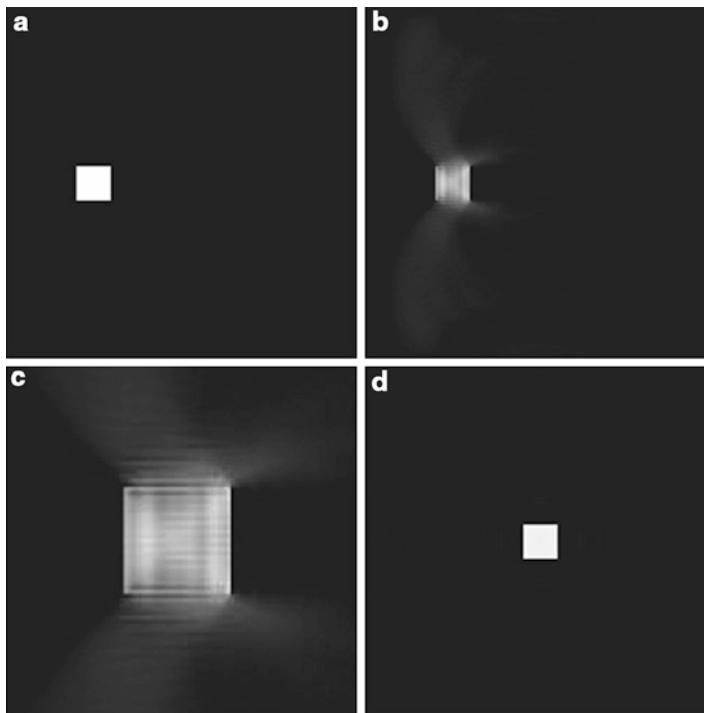

Fig. 9 Reconstruction of a square phantom from full data in the presence of a trapping parabolic speed of sound (the speed is radial with respect to the center of the picture): (a) an off-center phantom; (b) its reconstruction; (c) a magnified fragment of (b); (d) reconstruction of a centered square phantom

1. *Smoothness and support:* $g \in C_0^\infty([-1, 1] \times \mathcal{S})$, where \mathcal{S} is the unit sphere of vectors ω
2. *Evenness:* $g(-s, -\omega) = g(s, \omega)$
3. *Moment conditions:* for any integer $k \geq 0$, the k th moment

$$G_k(\omega) = \int_{-\infty}^{\infty} s^k g(\omega, s) ds$$

extends from the unit sphere \mathcal{S} to a homogeneous polynomial of degree k in ω .

The seemingly “trivial” evenness condition is sometimes the hardest to generalize to other transforms of Radon type, while it is often easier to find analogues of the moment conditions. This is exactly what happens in TAT.

For the operators \mathcal{W}, \mathcal{M} in TAT, some sets of range conditions of the moment type had been discovered over the years [7, 60, 78], but complete range descriptions started to emerge only since 2006 [2, 4–6, 9, 37, 54].

Range descriptions for the more general operator \mathcal{W} are harder to obtain than for \mathcal{M} , and complete range descriptions are not known for even dimensions or for the case of the variable speed of sound.

Let us address the case of the spherical mean operator \mathcal{M} first.

The Range of the Spherical Mean Operator \mathcal{M}

The support and smoothness conditions are not hard to come up with, at least when S is a sphere. By choosing an appropriate length scale, we can assume that the sphere is of radius 1 and centered at the origin and that the interior domain Ω is the unit ball $B = \{x \mid |x| = 1\}$. If f is smooth and supported inside B (i.e., $f \in C_0^\infty(B)$), then it is clear that the measured data satisfies the following:

Smoothness and support conditions:

$$g \in C_0^\infty(S \times [0, 2]). \quad (12)$$

An analogue of the moment conditions for $g(y, r) := \mathcal{M}f$ was implicitly present in [7, 60] and explicitly formulated as such in [78]:

Moment conditions: *for any integer $k \geq 0$, the moment*

$$M_k(y) = \int_0^\infty r^{2k+d-1} g(y, r) dr \quad (13)$$

extends from S to a (in general, nonhomogeneous) polynomial $Q_k(x)$ of degree at most $2k$.

These two types of conditions happen to be incomplete, i.e., infinitely many others exist. The Radon transform experience suggests to look for an analogue of evenness conditions. And indeed, a set of conditions called orthogonality conditions was found in [5, 9, 37].

Orthogonality conditions: Let $-\lambda_k^2$ be the eigenvalue of the Laplace operator Δ in B with zero Dirichlet conditions and ψ_k be the corresponding eigenfunctions. Then the following orthogonality condition is satisfied:

$$\int_{S \times [0, 2]} g(x, t) \partial_v \psi_\lambda(x) j_{n/2-1}(\lambda t) t^{n-1} dx dt = 0. \quad (14)$$

Here $j_p(z) = c_p z^{-p} J_p(z)$ is the so-called spherical Bessel function.

The range descriptions obtained in [5, 9, 37] demonstrated that these three types of conditions completely describe the range of the operator \mathcal{M} on functions $f \in C_0^\infty(B)$. At the same time, the results of [5, 37] showed that the moment conditions can be dropped in odd dimensions. It was then discovered in [2] that the moment

conditions can be dropped altogether in any dimension, since they follow from the other two types of conditions:

Theorem 13 ([2]). *Let S be the unit sphere. A function $g(y, t)$ on the cylinder $S \times \mathbb{R}^+$ can be represented as $\mathcal{M}f$ for some $f \in C_0^\infty(B)$ if and only if it satisfied the above smoothness and support and orthogonality conditions (12), (14).*

The statement also holds in the finite smoothness case, if one replaces the requirements by $f \in H_0^s(B)$ and $g \in H_0^{s+(n-1)/2}(S \times [0, 2])$.

The range of the forward operator \mathcal{M} has not been described when S is not a sphere, but, say, a convex smooth closed surface. The moment and orthogonality conditions hold for any S , and appropriate smoothness and support conditions can also be formulated, at least in the convex case. However, it has not been proven that they provide the complete range description.

It is quite possible that for nonspherical S the moment conditions might have to be included into the range description.

A different range description of the Fredholm alternative type was developed in [71] (see also [39] for description of this result).

The Range of the Forward Operator \mathcal{W}

We recall that the operator \mathcal{W} (see (4)) transforms the initial value f in (3) into the observed S values g of the solution. There exist Kirchhoff–Poisson formulas representing the solution p and thus $g = \mathcal{W}f$ in terms of the spherical means of f (i.e., in terms of $\mathcal{M}f$). However, translating the result of Theorem 13 into the language of \mathcal{W} is not straightforward, since in even dimensions these formulas are nonlocal ([27] p. 682):

$$\mathcal{W}f(y, t) = \frac{\sqrt{\pi}}{2\Gamma(n/2)} \left(\frac{1}{t} \frac{\partial}{\partial t} \right)^{(n-3)/2} t^{n-2} (\mathcal{M}f)(y, t), \text{ for odd } n. \quad (15)$$

and

$$\mathcal{W}f(y, t) = \frac{1}{\Gamma(n/2)} \left(\frac{1}{t} \frac{\partial}{\partial t} \right)^{(n-2)/2} \int_0^t \frac{r^{n-1} (\mathcal{M}f)(y, r)}{\sqrt{t^2 - r^2}} dr, \text{ for even } n. \quad (16)$$

The nonlocality of the transformation for even dimensions reflects the absence of Huygens' principle (i.e., absence of sharp rear fronts of waves) in these dimensions; it also causes difficulties in establishing the complete range descriptions. In particular, due to the integration in (16), $\mathcal{M}f(y, t)$ does not vanish for large times t anymore. One can try to use other known operators intertwining the two problems (see [5] and references therein), and some of which do preserve vanishing for large values of t , but this so far has led only to very clumsy range descriptions.

However, for odd dimensions, the range description of \mathcal{W} can be obtained. In order to do so, given the TAT data $g(y, t)$, let us introduce an auxiliary time-reversed problem in the cylinder $B \times [0, 2]$:

$$\begin{cases} q_{tt} - \Delta q = 0 \text{ for } (x, t) \in B \times [0, 2], \\ q(x, 2) = q_t(x, 2) = 0 \text{ for } x \in B, \\ q(y, t) = g(y, t) \text{ for } (y, t) \in S \times [0, 2]. \end{cases} \quad (17)$$

We can now formulate the range description from [37, 39]:

Theorem 14 ([37, 39]). *For odd dimensions n and S being the unit sphere, a function $g \in C_0^\infty(S \times [0, 2])$ can be represented as $\mathcal{W}f$ for some $f \in C_0^\infty(B)$ if and only if the following condition is satisfied:*

The solution q of (17) satisfies $q_t(x, 0) = 0$ for all $x \in B$.

Orthogonality type and Fredholm alternative type range conditions, equivalent to the one in the theorem above, are also provided in [37, 39].

Reconstruction of the Speed of Sound

Unsurprisingly, all inversion procedures outlined in Sect. 4 rely upon the knowledge of the speed of sound $c(x)$. Although often, e.g., in breast imaging, the medium is assumed to be acoustically homogeneous, this is not a good assumption in many other cases. It has been observed (e.g., [48, 50]) that replacing even slightly varying speed of sound with its average value might significantly distort the image; not only the numerical values, but also the shapes of interfaces between the tissues will be reconstructed incorrectly. Thus, the question of estimating $c(x)$ correctly becomes important. One possible approach [50] is to use an additional transmission ultrasound scan to reconstruct the speed beforehand. The question arises of whether one could determine the speed of sound $c(x)$ and the tomogram $f(x)$ (assuming that f is not zero) simultaneously from the TAT data. In fact, one needs only to determine $c(x)$ (without knowing f), since then inversion procedures of Sect. 4 would apply to recover f .

At the first glance, this seems to be an overly ambitious project. Indeed, if we denote the forward operator \mathcal{W} by \mathcal{W}_c , to indicate its dependence on the speed of sound $c(x)$, then the problem becomes, given the data g , to find both c and f from the equality

$$\mathcal{W}_c f = g. \quad (18)$$

A similar situation arises in the SPECT emission tomography (see [63] and references therein), where the role of the speed of sound is played by the unknown attenuation. It is known, however, that in SPECT the attenuation can be recovered for a “generic” f .

What is the reason for such a strange situation? It looks like for any c one could solve Eq. (18) for an f , and thus no information about c is contained in the data

g . This argument is incorrect for the following reason: the range of the forward operator, as we know already from the previous section, has infinite co-dimension. Thus, this range has a lot of space to “rotate” when c changes. Imagine for an instance that the rotation is so powerful that for different values of c the ranges have only zero (the origin) in common. Then, knowing g in the range, one would know which c it came from. Thus, the problem of recovering the speed of sound from the TAT data is closely related to the range descriptions.

Numerical inversions using algebraic iterative techniques (e.g., [102, 104]) show that recovering both c and f might be indeed possible.

Unfortunately, very little is known at the moment concerning this problem. Direct usage of range conditions attempted in [48] has led only to extremely weak and not practically useful results so far. A revealing relation to the transmission eigenvalue problem well known in inverse problems (see [26] for the survey) was recently discovered by D. Finch. Unfortunately, the transmission eigenvalue problem remains still unresolved. However, one can derive from this relation the following result regarding uniqueness of the reconstruction of the speed of sound, due to M. Agranovsky (a somewhat restricted version is due to D. Finch et al., both unpublished):

Theorem 15. *If two speeds satisfy the inequality $c_1(x) \geq c_2(x)$ for all $x \in \Omega$ and produce for some functions f_1, f_2 the same nonzero TAT data g (i.e., $\mathcal{W}c_1f_1 = g, \mathcal{W}c_2f_2 = g$), then $c_1(x) = c_2(x)$.*

It is known [49, Corollary 8.2.3] that if a function $f(x)$ is such that $\Delta f(x) \neq 0$ and for two acoustic speeds $c_1(x)$ and $c_2(x)$, it produces the same TAT data g , then $c_1 = c_2$.

It is clear that the problem of finding the speed of sound from the TAT data is still mostly unresolved.

4 Reconstruction Formulas, Numerical Methods, and Case Examples

Numerous formulas, algorithms, and procedures for reconstruction of images from TAT measurements have been developed by now. Most of these techniques require the data being collected on a closed surface (closed curve in 2D) surrounding the object to be imaged. Such methods are discussed in section “Full Data (Closed Acquisition Surfaces).” We review methods that work under the assumption of constant speed of sound in section “Constant Speed of Sound.” The techniques applicable in the case of the known variable speed of sound are considered in section “Constant Speed of Sound.” Closed surface measurements cannot always be implemented, since in some practical situations the object cannot be completely surrounded by the detectors. In this case, one has to resort to various approximate reconstruction techniques as discussed in section “Partial (Incomplete) Data.”

Full Data (Closed Acquisition Surfaces)

Constant Speed of Sound

When the speed of sound within the tissues is a known constant, the TAT problem can be reformulated (see Sect. 2) in terms of the values of the spherical means of the initial condition $f(x)$. These means can be easily recovered from the measurements of the acoustic pressure using formulas (15) and (16) (see the discussion in [7]). In this case, image reconstruction becomes equivalent to inverting the spherical mean transform \mathcal{M} . Thus, in what follows, we consider the problem of reconstructing a function $f(x)$ supported within the region bounded by a closed surface S from known values of its spherical integrals $g(y, r)$ with centers on S

$$g(y, r) = \int_{\mathbb{S}^{n-1}} f(y + r\omega) r^{n-1} d\omega, \quad y \in S, \quad (19)$$

where $d\omega$ is the standard measure on the unit sphere.

Series Solutions for Spherical Geometry

The first inversion procedures for the case of closed acquisition surfaces were described in [66, 67], where solutions were found for the cases of circular (in 2D) and spherical (in 3D) surfaces, respectively. These solutions were obtained by the harmonic decomposition of the measured data and of the sought function $f(x)$, followed by equating coefficients of the corresponding Fourier series. In particular, the 2D algorithm of [66] pertains to the case when the detectors are located on a circle of radius R . This method is based on the Fourier decomposition of f and g in angular variables

$$f(x) = \sum_{-\infty}^{\infty} f_k(\rho) e^{ik\varphi}, \quad x = (\rho \cos(\varphi), \rho \sin(\varphi)) \quad (20)$$

$$g(y(\theta), r) = \sum_{-\infty}^{\infty} g_k(r) e^{ik\theta}, \quad y = (R \cos(\theta), R \sin(\theta)),$$

where

$$(\mathcal{H}_m u)(s) = 2\pi \int_0^\infty u(t) J_m(st) t dt$$

is the Hankel transform and $J_m(t)$ is the Bessel function. As shown in [66], the Fourier coefficients $f_k(\rho)$ can be recovered from the known coefficients $g_k(r)$ by the following formula:

$$f_k(\rho) = \mathcal{H}_m \left(\frac{1}{J_k(\lambda|R|)} \mathcal{H}_0 \left[\frac{g_k(r)}{2\pi r} \right] \right).$$

This method requires division of the Hankel transform of the measured data by the Bessel functions J_k , which have infinitely many zeros. Theoretically, there is no problem: the range conditions (section “Range Conditions”) on the exact data g imply that the Hankel transform $\mathcal{H}_0[(2\pi r)^{-1}g_k(r)]$ has zeros that cancel those in the denominator. However, since the measured data always contain errors, the exact cancellation does not happen, and one needs a sophisticated regularization scheme to guarantee that the error remains bounded.

This difficulty can be avoided (see, e.g., [54]) by replacing the Bessel function J_0 in the inner Hankel transform by the Hankel function $H_0^{(1)}$. This yields the following formula for $f_k(\rho)$:

$$f_k(\rho) = \mathcal{H}_k \left(\frac{1}{H_k^{(1)}(\lambda|R|)} \int_0^\infty g_k(r) H_0^{(1)}(\lambda r) dr \right).$$

Unlike J_m , Hankel functions $H_m^{(1)}(t)$ do not have zeros for any real values of t , which removes the problems with division by zeros [66]. (A different way of avoiding divisions by zero was found in [44].)

This derivation can be repeated in 3D, with the exponentials $e^{ik\theta}$ replaced by the spherical harmonics and with cylindrical Bessel functions replaced by their spherical counterparts. By doing this, one arrives at the Fourier series method of [67] (see also [97]). The use of the Hankel function $H_0^{(1)}$ above is similar to the way the spherical Hankel function $h_0^{(1)}$ is utilized in [67] to avoid the divisions by zero.

Eigenfunction Expansions for a General Geometry

The series methods described in the previous section rely on the separation of variables that occurs only in spherical geometry. A different approach was proposed in [58]. It works for arbitrary closed surfaces, but is practical only for those with explicitly known eigenvalues and eigenfunctions of the Dirichlet Laplacian in the interior. These include, in particular, the surfaces of such bodies as spheres, half spheres, cylinders, cubes, and parallelepipeds, as well as the surfaces of crystallographic domains.

Let λ_m^2 and $u_m(x)$ be the eigenvalues and an orthonormal basis of eigenfunctions of the Dirichlet Laplacian $-\Delta$ in the interior Ω of a closed surface S :

$$\Delta u_m(x) + \lambda_m^2 u_m(x) = 0, \quad x \in \Omega, \quad \Omega \subseteq \mathbb{R}^n, \quad (21)$$

$$u_m(x) = 0, \quad x \in S,$$

$$\|u_m\|_2^2 \equiv \int_{\Omega} |u_m(x)|^2 dx = 1.$$

As before, one would like to reconstruct a compactly supported function $f(x)$ from the known values of its spherical integrals $g(y, r)$ (see (19)) with centers on S . Since $u_m(x)$ is the solution of the Dirichlet problem for the Helmholtz equation with zero

boundary conditions and the wave number λ_m , this function admits the Helmholtz representation

$$u_m(x) = \int_S \Phi_{\lambda_m}(|x - y|) \frac{\partial}{\partial n} u_m(y) ds(y) \quad x \in \Omega, \quad (22)$$

where $\Phi_{\lambda_m}(|x - y|)$ is a free-space Green's function of the Helmholtz equation (21) and n is the exterior normal to S .

The function $f(x)$ can be expanded into the series

$$\begin{aligned} f(x) &= \sum_{m=0}^{\infty} \alpha_m u_m(x), \text{ where} \\ \alpha_m &= \int_{\Omega} u_m(x) f(x) dx. \end{aligned} \quad (23)$$

A reconstruction formula for α_m (and thus for $f(x)$) will result, if one substitutes representation (22) into (23) and interchanges the orders of integration

$$\alpha_m = \int_{\Omega} u_m(x) f(x) dx = \int_S I(y, \lambda_m) \frac{\partial}{\partial n} u_m(y) dA(x), \quad (24)$$

where

$$I(y, \lambda) = \int_{\Omega} \Phi_{\lambda}(|x - y|) f(x) dx = \int_0^{\text{diam } \Omega} g(y, r) \Phi_{\lambda}(r) dr. \quad (25)$$

Now $f(x)$ can be obtained by summing the series (23). This method becomes computationally efficient when the eigenvalues and eigenfunctions are known explicitly, especially if a fast summation formula for the series (23) is available. This is the case when the acquisition surface S is the surface of a cube, and thus the eigenfunctions are products of sine functions. The resulting 3D reconstruction algorithm is extremely fast and precise (see [58]).

The above method has an interesting property. If the support of the source $f(x)$ extends outside Ω , the algorithm still yields theoretically an exact reconstruction of $f(x)$ inside Ω . Indeed, the value of the expression (22) for all x lying outside Ω is zero. Thus, when one computes (24) for $x \in \mathbb{R}^n \setminus \Omega$, values of $f(x)$ are multiplied by zero and do not affect further computation in any way. This feature is shared by the time-reversal method (see the corresponding paragraph in section ‘‘Constant Speed of Sound’’). The closed-form FBP-type reconstruction techniques considered in the next subsection do not have this property. In other words, in the presence of a source outside the measurement surface, reconstruction within Ω can be incorrect.

The reason for this difference is that all currently known closed-form FBP-type formulas rely (implicitly or explicitly) on the assumption that the wave propagates outside S in the whole free space and has no sources outside. On the other hand,

the eigenfunction expansion method and the time reversal rely only upon the time decay of the wave inside S , which is not influenced by f having a part outside S .

Closed-Form Inversion Formulas

Closed-form inversion formulas play a special role in tomography. They bring about better theoretical understanding of the problem and frequently serve as starting points for the development of efficient reconstruction algorithms. A well-known example of the use of explicit inversion formulas is the so-called filtered backprojection (FBP) algorithm in X-ray tomography, which is derived from one of the inversion formulas for the classical Radon transform (see, e.g., [63]).

The very existence of closed-form inversion formulas for TAT had been in doubt, till the first such formulas were obtained in odd dimensions by Finch et al. in [36], under the assumption that the acquisition surface S is a sphere. Suppose that the function $f(x)$ is supported within a ball of radius R and that the detectors are located on the surface $S = \partial B$ of this ball. Then some of the formulas obtained in [36] read as follows:

$$f(x) = -\frac{1}{8\pi^2 R} \Delta_x \int_{\partial B} \frac{g(y, |y-x|)}{|y-x|} dA(y), \quad (26)$$

$$f(x) = -\frac{1}{8\pi^2 R} \int_{\partial B} \left(\frac{1}{r} \frac{\partial^2}{\partial r^2} g(y, r) \right) \Bigg|_{r=|y-x|} dA(y), \quad (27)$$

$$f(x) = -\frac{1}{8\pi^2 R} \int_{\partial B} \left(\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial}{\partial r} \frac{g(y, r)}{r} \right) \right) \Bigg|_{r=|y-x|} dA(y), \quad (28)$$

where $dA(y)$ is the surface measure on ∂B and g represents the values of the spherical integrals (19).

These formulas have an FBP (filtered backprojection) nature. Indeed, differentiation with respect to r in (27) and (28) and the Laplace operator in (26) represent the filtration, while the (weighted) integrals correspond to the backprojection, i.e., integration over the set of spheres passing through the point of interest x and centered on S .

The so-called universal backprojection formula in 3D was found in [98] (it is also valid for the cylindrical and plane acquisition surfaces, see section ‘‘Partial (Incomplete) Data’’). In our notation, this formula takes the form

$$f(x) = \frac{1}{8\pi^2} \operatorname{div} \int_{\partial B} n(y) \left(\frac{1}{r} \frac{\partial}{\partial r} \frac{g(y, r)}{r} \right) \Bigg|_{r=|y-x|} dA(y), \quad (29)$$

or, equivalently,

$$f(x) = -\frac{1}{8\pi^2} \int_{\partial B} \frac{\partial}{\partial n} \left(\frac{1}{r} \frac{\partial}{\partial r} \frac{g(y, r)}{r} \right) \Bigg|_{r=|y-x|} dA(y), \quad (30)$$

where $n(y)$ is the exterior normal vector to ∂B . One can show [4, 64, 98] that formulas (26) through (29) are not equivalent on non-perfect data: the result will differ if these formulas are applied to a function that does not belong to the range of the spherical mean transform \mathcal{M} . A family of inversion formulas valid in \mathbb{R}^n for arbitrary $n \geq 2$ was found in [57]

$$f(x) = \frac{1}{4(2\pi)^{n-1}} \operatorname{div} \int_{\partial B} n(y) h(y, |x-y|) dA(y), \quad (31)$$

where

$$h(y, t) = \int_{\mathbb{R}^+} Y(\lambda t) \left[\int_0^{2R} J(\lambda r) g(y, r) dr - J(\lambda t) \int_0^{2R} Y(\lambda r) g(y, r) dr \right] \lambda^{2n-3} d\lambda \quad (32)$$

$$J(t) = \frac{J_{n/2-1}(t)}{t^{n/2-1}}, \quad Y(t) = \frac{Y_{n/2-1}(t)}{t^{n/2-1}}, \quad (33)$$

and $J_{n/2-1}(t)$ and $Y_{n/2-1}(t)$ are, respectively, the Bessel and Neumann functions of order $n/2 - 1$. In 3D, $J(t)$ and $Y(t)$ are simply $t^{-1} \sin t$ and $t^{-1} \cos t$, and formulas (31) and (32) reduce to (30).

In 2D, Eq. (32) also can be simplified [4], which results in the formula

$$f(x) = \frac{1}{2\pi^2} \operatorname{div} \int_{\partial B} n(y) \left[\int_0^{2R} g(y, r) \frac{1}{r^2 - |x-y|^2} dr \right] dl(y), \quad (34)$$

where ∂B now stands for the circle of radius R and $dl(y)$ is the standard arc length.

A different set of closed-form inversion formulas applicable in even dimensions was found in [35]. Formula (34) can be compared to the following inversion formulas from [35]

$$f(x) = \frac{1}{2\pi R} \Delta \int_{\partial B} \int_0^{2R} g(y, r) \log(r^2 - |x-y|^2) dr dl(y), \quad (35)$$

or

$$f(x) = \frac{1}{2\pi R} \int_{\partial B} \int_0^{2R} \frac{\partial}{\partial r} \left(r \frac{\partial}{\partial r} \frac{g(y, r)}{r} \right) \log(r^2 - |x-y|^2) dr dl(y). \quad (36)$$

Finally, a unified family of inversion formulas was derived in [64]. In our notation, it has the following form

$$f(x) = -\frac{4}{\pi R} \int_{\partial B} \left(\frac{\partial}{\partial t} K_n(y, t) \right) \Bigg|_{t=|x-y|} \frac{\langle y-x, y-\xi \rangle}{|x-y|} dA(y), \quad (37)$$

$$K_n(y, t) = -\frac{1}{16(2\pi)^{n-2}} \int_{\mathbb{R}^+} \lambda^{2n-3} Y(\lambda t) \left(\int_{\mathbb{R}^+} J(\lambda r) g(y, r) dr \right) d\lambda$$

where ∂B is the surface of a ball in \mathbb{R}^n of radius R , functions J and Y are in (33), and ξ is an arbitrary fixed vector. In particular, in 3D

$$J(t) = \sqrt{\frac{2}{\pi}} \frac{\sin t}{t}, \quad J(t) = \sqrt{\frac{2}{\pi}} \frac{\cos t}{t}$$

and, after simple calculation, the above inversion formula reduces to

$$f(x) = -\frac{1}{8\pi^2 R} \int_{\partial B} \left(\frac{\partial}{\partial r} \frac{1}{r} \frac{\partial}{\partial r} \frac{g(y, r)}{r} \right) \Bigg|_{r=|x-y|} \frac{\langle y-x, y-\xi \rangle}{|x-y|} dA(y). \quad (38)$$

Different choices of vector ξ in the above formula result in different inversion formulas. For example, if ξ is set to zero, the ratio $\frac{\langle y-x, y-\xi \rangle}{|x-y|}$ equals $R \cos \alpha$, where α is the angle between the exterior normal $n(y)$ and the vector $y-x$; when combined with the derivative in t , this factor produces the normal derivative, and the inversion formula (38) reduces to (30). On the other hand, the choice of $\xi = x$ in (38) leads to a formula

$$f(x) = -\frac{1}{8\pi^2 R} \int_{\partial B} \left(r \frac{\partial}{\partial r} \frac{1}{r} \frac{\partial}{\partial r} \frac{g(y, r)}{r} \right) \Bigg|_{r=|x-y|} dA(y),$$

which is reminiscent of formulas (26)–(28).

Green's Formula Approach and Some Symmetry Considerations

Let us suppose for a moment that the acoustic detectors could measure not only the pressure $p(y, t)$ at each point of the acquisition surface S , but also the normal derivative $\partial p / \partial n$ on S . Then the problem of reconstructing the initial pressure $f(x)$ becomes rather simple. Indeed, one can use the knowledge of the free-space Green's function for the wave equation and invoke the Green's theorem to represent the solution $p(x, t)$ of (3) in the form of integrals over S involving $p(x, t)$ and its

normal derivative and the Green's function and its normal derivative. (This can be done in the Fourier or time domains.) This would require infinite observation time, but in 3D the time $T(\Omega)$ will suffice, after which the wave escapes the region of interest (a cutoff also would work approximately in 2D similar to the time-reversal method). This Green's function approach happens to be, explicitly or implicitly, the starting point of all closed-form inversions described above. The trick is to rewrite the formula in such a way that the unknown in reality normal derivative $\partial p/\partial n$ disappears from the formula.

This was achieved in [57] by reducing the question to some integrals involving special functions and making the key observation that the integral

$$I_\lambda(x, y) = \int_{\partial B} J(\lambda|x - z|) \frac{\partial}{\partial n} Y(\lambda|y - z|) dA(z), \quad x, y \in B \subset \mathbb{R}^n$$

is a symmetric function of its arguments:

$$I_\lambda(x, y) = I_\lambda(y, x) \text{ for } x, y \in B \subset \mathbb{R}^n. \quad (39)$$

Similarly, the derivation of (37) in [64] employs the symmetry of the integral

$$K_\lambda(x, y) = \int_{\partial B} J(\lambda|x - z|) Y(\lambda|y - z|) dA(z), \quad x, y \in B \subset \mathbb{R}^n.$$

In fact, the symmetry holds for any integral

$$W_\lambda(x, y) = \int_{\partial B} U(\lambda|x - z|) V(\lambda|y - z|) dA(z), \quad x, y \in B \subset \mathbb{R}^n,$$

where $U(\lambda|x|)$ and $V(\lambda|x|)$ are any two radial solutions of the Helmholtz equation

$$\Delta u(x) + \lambda^2 u(x) = 0. \quad (40)$$

It is straightforward to verify this symmetry when S is a sphere and B is the corresponding ball, and the points x, y lie on the boundary S only, rather than anywhere in B . This follows immediately from the rotational symmetry of S . The same is true for the normal derivatives on S of $W_\lambda(x, y)$ in x and y .

This boundary symmetry happens to imply the needed full symmetry (39) for $x, y \in B$.

Indeed, $W_\lambda(x, y)$ is a solution of the Helmholtz equation separately as a function of x and of y . Let us introduce a family of solutions $\{w_n(x)\}_{n=0}^\infty$ of (40) in B , such that the members of this family form an orthonormal basis for all solutions of the latter equation in B . For example, the spherical waves, i.e., the products of spherical harmonics and Bessel functions, can serve as such a basis.

Then $W_\lambda(x, y)$ can be expanded in the following series:

$$W_\lambda(x, y) = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} b_{n,m} w_m(y) w_n(x). \quad (41)$$

Since $W_\lambda(x, y)$ is a solution to the Helmholtz equation in $\partial B \times \partial B$, coefficients $b_{n,m}$ are completely determined by the boundary values of W_λ . Since the boundary values are symmetric, the coefficients are symmetric, i.e., $b_{n,m} = b_{m,n}$ which by (41) immediately implies $W_\lambda(x, y) = W_\lambda(y, x)$ for all pairs $(x, y) \in B \times B$.

This consideration extends to infinite cylinders and planes. This explains why the “universal backprojection formula” (30) is valid also for infinite cylinders and planes [98]. Since the sort of symmetry used is shared only by these three smooth surfaces, we believe it is unlikely that a closed-form formula could exist for any other smooth acquisition surface. However, an exact formula has recently been obtained by L. Kunyansky for the case when observation surface S is a surface of a cube (unpublished).

Algebraic Iterative Algorithms

Iterative algebraic techniques are among the favorite tomographic methods of reconstruction and have been used in CT for quite a while [63]. They amount to discretizing the equation relating the measured data with the unknown source, followed by iterative solution of the resulting linear system. Iterative algebraic reconstruction algorithms frequently produce better images than those obtained by other methods. However, they are notoriously slow. In TAT, they have been used successfully for reconstructions with partial data [14, 15, 76], see section “Partial (Incomplete) Data.”

Parametrix Approaches

Some of the earlier non-iterative reconstruction techniques [53] were of approximate nature. For example, by approximating the integration spheres by their tangent planes at the point of reconstruction and by applying one of the known inversion formulas for the classical Radon transform, one can reconstruct an approximation to the image. Due to the evenness symmetry in the classical Radon projections (see section “Range Conditions”), the normals to the integration planes need only fill a half of a unit sphere, in order to make possible the reconstruction from an open measurement surface. A more sophisticated approach is represented by the so-called straightening methods [81, 82] based on the approximate reconstruction of the classical Radon projections from the values of the spherical mean transform $\mathcal{M}f$ of the function $f(x)$ in question. These methods yield not a true inversion, but rather what is called in microlocal analysis a **parametrix**. Application of a parametrix reproduces the function f with an additional, smoother term. In other words, the locations (and often the sizes) of jumps across sharp material interfaces, as well as the whole wave front set $WF(f)$, are reconstructed correctly, while the accuracy of the lower spatial frequencies cannot be guaranteed. (Sometimes, the

reconstructed function has a more general form Af , where A is an elliptic pseudo-differential operator [46, 84] of order zero. In this case, the sizes of the jumps across the interfaces might be altered.) Unlike the approximations resulting from the discretization of the exact inversion formulas (in the situations when such formulas are known), the parametrix approximations do not converge, when the discretization of the data is refined and the noise is eliminated. Parametrix reconstructions can be either accepted as approximate images or used as starting points for iterative algorithms.

These methods are closely related to the general scheme proposed in [20] for the inversion of the generalized Radon transform with integration over curved manifolds. It reduces the problem to a Fredholm integral equation of the second kind, which is well suited for numerical solution. Such an approach amounts to using a parametrix method as an efficient preconditioner for an iterative solver; the convergence of such iterations is much faster than that of algebraic iterative methods.

Numerical Implementation and Computational Examples

By discretizing exact formulas presented above, one can easily develop accurate and efficient reconstruction algorithms. The $3D$ case is especially simple: computation of derivatives in the formulas (26)–(30) and (38) can be easily done, for instance, by using finite differences; it is followed by the backprojection (described by the integral over ∂B), which requires prescribing quadrature weights for quadrature nodes that coincide with the positions of the detectors. The backprojection step is stable; the differentiation is a mildly unstable operation. The sensitivity to noise in measurements across the formulas presented above seems to be roughly the same. It is very similar to that of the widely used FBP algorithm of classical X-ray tomography [63]. In $2D$, the implementation is just a little bit harder: the filtration step in formulas (34)–(36) can be reduced to computing two Hilbert transforms (see [54]), which, in turn, can be easily done in the frequency domain.

The number of floating point operations (flops) required by such algorithms is determined by the slower backprojection step. In $3D$, if the number of detectors is m^2 and the size of the reconstruction grid is $m \times m \times m$, the backprojection step (and the whole algorithm) will require $O(m^5)$ flops. In practical terms, this amounts to several hours of computations on a single processor computer for a grid of size $129 \times 129 \times 129$.

In $2D$, the operation count is just $O(m^3)$. As it is discussed in section “Variations on the Theme: Planar, Linear, and Circular Integrating Detectors,” the $2D$ problem needs to be solved, when integrating line detectors are used. In this situation, the $2D$ problem needs to be solved m times in order to reconstruct the image, which raises the total operation count to $O(m^4)$ flops.

Figure 10 shows three examples of simulated reconstruction using formula (34). The phantom we use (Fig. 10a) is a linear combination of several characteristic functions of disks and ellipses. Figure 10b illustrates the image reconstruction within the unit circle from 257 equi-spaced projections each containing 129 spherical integrals. The detectors were placed on the concentric circle of radius 1.05.

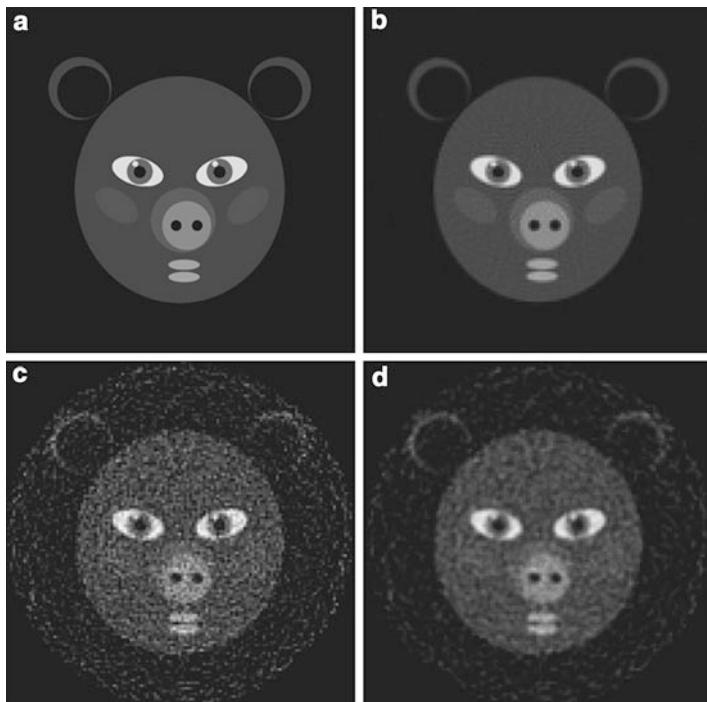

Fig. 10 Example of a reconstruction using formula (34): (a) phantom; (b) reconstruction from accurate data; (c) reconstruction from the data contaminated with 15 % noise; (d) reconstruction from the noisy data with additional smoothing

The image shown in Fig. 10c corresponds to the reconstruction from the simulated noisy data that were obtained by adding to projections values of a random variable scaled so that the L^2 intensity of the noise was 15 % of the intensity of the signal. Finally, Fig. 10d shows how the application of a smoothing filter (in the frequency domain) suppresses the noise; it also somewhat blurs the edges in the image.

Variable Speed of Sound

The reconstruction formulas and algorithms described in the previous section work under the assumption that the speed of sound within the region of interest is constant (or at least close to a constant). This assumption, however, is not always realistic, e.g., if the region of interest contains both soft tissues and bones, the speed of sound will vary significantly. Experiments with numerical and physical phantoms show [48, 50] that if acoustic inhomogeneities are not taken into account, the reconstructed image might be severely distorted. Not only the numerical values could be reconstructed incorrectly, but so would the material interface locations and discontinuity magnitudes.

Below we review some of the reconstruction methods that work in acoustically inhomogeneous media. We will assume that the speed of sound $c(x)$ is known,

smooth, positive, constant for large x , and non-trapping. In practice, a transmission ultrasound scan can be used to reconstruct $c(x)$ prior to thermoacoustic reconstruction, as it is done in [50].

Time Reversal

Let us assume temporarily that the speed of sound c is constant and the spatial dimension is odd. Then Huygens' principle guarantees that the sound wave will leave the region of interest Ω in time $T = c/(\text{diam } \Omega)$, so that $p(x, t) = 0$ for all $x \in \Omega$ and $t \geq T$. Now one can solve the wave equation back in time from $t = T$ to $t = 0$ in the domain $\Omega \times [T, 0]$, with zero initial conditions at T and boundary conditions on S provided by the data g collected by the detectors. Then the value of the solution at $t = 0$ will coincide with the initial condition $f(x)$ that one seeks to reconstruct. Such a solution of the wave equation is easily obtained numerically by finite difference techniques [42, 48]. The required number of floating point operations is actually lower than that of methods based on discretized inversion formulas ($\mathcal{O}(m^4)$ for time reversal on a grid $m \times m \times m$ in 3D versus $\mathcal{O}(m^5)$ for inversion formulas), which makes this method quite competitive even in the case of constant speed of sound.

Most importantly, however, the method is also applicable if the speed of sound $c(x)$ is variable and/or the spatial dimension is even. In these cases, the Huygens' principle does not hold, and thus the solution to the direct problem will not vanish within $\partial\Omega$ in finite time. However, the solution inside Ω will decay with time. Under the non-trapping condition, as it is shown in (11) (see [32, 90, 91]), the time decay is exponential in odd dimensions, but only algebraic in even dimensions. Although, in order to obtain theoretically exact reconstruction, one would have to start the time reversal at $T = \infty$, and numerical experiments (e.g., [48]) and theoretical estimates [47] show that in practice it is sufficient to start at the values of T when the signal becomes small enough and to approximate the unknown value of $p(x, T)$ by zero (a more sophisticated cutoff is used in [86]). This works [42, 48] even in 2D (where decay is the slowest) and in inhomogeneous media. However, when trapping occurs, the “invisible” parts blur away (see section “Incomplete Data” for the discussion).

Eigenfunction Expansions

An “inversion formula” that reconstructs the initial value $f(x)$ of the solution of the wave equation from values on the measuring surface S can be easily obtained using time reversal and Duhamel's principle [3]. Consider in Ω the operator $A = -c^2(x)\Delta$ with zero Dirichlet conditions on the boundary $S = \partial\Omega$. This operator is self-adjoint, if considered in the weighted space $L^2(\Omega; c^{-2}(x))$. Let us denote by E the operator of harmonic extension, which transforms a function ϕ on S to a harmonic function on Ω that coincides with ϕ on S . Then f can be reconstructed [3] from the data g in (3) by the following formula:

$$f(x) = (Eg|_{t=0}) - \int_0^\infty A^{-\frac{1}{2}} \sin(\tau A^{\frac{1}{2}}) E(g_{tt})(x, \tau) d\tau, \quad (42)$$

which is valid under the non-trapping condition on $c(x)$. However, due to the involvement of functions of the operator A , it is not clear how useful this formula can be.

One natural way to try to implement numerically the formula (42) is to use the eigenfunction expansion of the operator A in Ω (assuming that such expansion is known). This quickly leads to the following procedure [3]. The function $f(x)$ can be reconstructed inside Ω from the data g in (3), as the following $L^2(B)$ -convergent series:

$$f(x) = \sum_k f_k \psi_k(x), \quad (43)$$

where the Fourier coefficients f_k can be recovered from the data using one of the following formulas:

$$\begin{aligned} f_k &= \lambda_k^{-2} g_k(0) - \lambda_k^{-3} \int_0^\infty \sin(\lambda_k t) g_k''(t) dt, \\ f_k &= \lambda_k^{-2} g_k(0) + \lambda_k^{-2} \int_0^\infty \cos(\lambda_k t) g_k'(t) dt, \text{ or} \\ f_k &= -\lambda_k^{-1} \int_0^\infty \sin(\lambda_k t) g_k(t) dt = -\lambda_k^{-1} \int_0^\infty \int_S \sin(\lambda_k t) g(x, t) \overline{\frac{\partial \psi_k}{\partial n}(x)} dx dt, \end{aligned} \quad (44)$$

where

$$g_k(t) = \int_S g(x, t) \overline{\frac{\partial \psi_k}{\partial n}(x)} dx.$$

One notices that this is a generalization of the expansion method of [58] discussed in section “Eigenfunction Expansions for a General Geometry” to the case of a variable speed of sound. Unlike the algorithm of [58], this method does not require the knowledge of the whole space Green’s function for A (which is in this case unknown). However, computation of a large set of eigenfunctions and eigenvalues followed by the summation of the series (43) at the nodes of the computational grid may prove to be too time-consuming.

It is worthwhile to mention again that the non-trapping condition is crucial for the stability of any TAT reconstruction method in acoustically inhomogeneous media. As it was discussed in section “Discussion of the Visibility Condition,” trapping can significantly reduce the quality of reconstruction. It is, however, most probable that trapping does not occur much in biological objects.

Partial (Incomplete) Data

Reconstruction formulas and algorithms of the previous sections work under the assumption that the acoustic signal is measured by detectors covering a closed

surface S that surrounds completely the object of interest. However, in many practical applications of TAT, detectors can be placed only on a certain part of the surrounding surface. Such is the case, e.g., when TAT is used for breast screening – one of the most promising applications of this modality. Thus, one needs methods and algorithms capable of accurate reconstruction of images from partial (incomplete) data, i.e., from the measurements made on open surfaces (or open curves in $2D$).

Most exact inversion formulas and methods discussed above are based (explicitly or implicitly) on some sort of the Green's formula, Helmholtz representation, or eigenfunction decomposition for closed surfaces, and thus they cannot be extended to the case of partial data. The methods that do work in this situation rely on approximation techniques, as discussed below.

Constant Speed of Sound

Even the case of an acoustically homogeneous medium is quite challenging when reconstruction needs to be done from partial data (i.e., when the acquisition surface S is not closed). As it was discussed in section “Incomplete Data,” if the detectors located around the object in such a way that the “visibility” condition is not satisfied, accurate reconstruction is impossible: the “invisible” interfaces will be smoothed out in the reconstructed image. On the other hand, if the visibility condition is satisfied, the reconstruction is only mildly unstable (similarly to the inversion of the classic Radon transform) [71, 86]. If, in addition, the uniqueness of reconstruction from partial data is guaranteed (which is usually the case, see section “Uniqueness of Reconstruction”), one can hope to be able to develop an algorithm that would reconstruct quality images.

Special cases of open acquisition surfaces are a plane or an infinite cylinder, for which exact inversion formulas are known (see, e.g., [16, 34, 41, 96] for the plane and [101] for a cylinder). Of course, the plane or a cylinder would have to be truncated in any practical measurements. The resulting acquisition geometry will not satisfy the visibility condition, and material interfaces whose normals do not intersect the acquisition surface will be blurred.

Iterative algebraic techniques (see the corresponding paragraph in section “Constant Speed of Sound”) were among the first methods successfully used for reconstruction from surfaces only partially surrounding the object (e.g., [14, 15, 76]). As it is mentioned in section “Constant Speed of Sound,” such methods are very slow. For example, reconstructions in [14] required the use of a cluster of computers and took 100 iterations to converge.

Parametrix-type reconstructions in the partial data case were proposed in [17]. A couple of different parametrix-type algorithms were proposed in [72, 74]. They are based on applying one of the exact inversion formulas for full circular acquisition to the available partial data, with zero-filled missing data, and some correction factors. Namely, since the missing data is replaced by zeros, each line passing through a node of the reconstruction grid will be tangent either to one or to two circles of integration. Therefore, some directions during the backprojection step will be

represented twice and some only once. This, in turn, will cause some interfaces to appear twice stronger than they should be. The use of weight factors was proposed in [72, 74] in order to partially compensate for this distortion. In particular, in [72] smooth weight factors (depending on a reconstruction point) are assigned to each detector in such a way that the total weight for each direction is exactly one. This method is not exact; the error is described by a certain smoothing operator. However, the singularities (or jumps) in the image will be reconstructed correctly. As shown by numerical examples in [72], such a correction visually significantly improves the reconstruction. Moreover, iterative refinement is proposed in [72, 74] to further improve the image, and it is shown to work well in numerical experiments.

Returning to non-iterative techniques, one should mention an interesting attempt made in [78, 79] to generate the missing data using the moment range conditions for \mathcal{M} (see section ‘‘Range Conditions’’). The resulting algorithm, however, does not seem to recover the values well, although, as expected, it reconstructs all visible singularities.

An accurate $2D$ non-iterative algorithm for reconstruction from data measured on an open curve S was proposed in [59]. It is based on precomputing approximations of plane waves in the region of interest Ω by the single-layer potentials of the form

$$\int_S Z(\lambda|y - x|)\rho(y)dl(y),$$

where $\rho(y)$ is the density of the potential, which needs to be chosen appropriately, $dl(y)$ is the standard arc length, and $Z(t)$ is either the Bessel function $J_0(t)$ or the Neumann function $Y_0(t)$. Namely, for a fixed ξ one finds numerically the densities $\rho_{\xi,J}(y)$ and $\rho_{\xi,Y}(y)$ of the potentials

$$W_J(x, \rho_{\xi,J}) = \int_S J_0(\lambda|y - x|)\rho_{\xi,J}(y)dl(y), \quad (45)$$

$$W_Y(x, \rho_{\xi,Y}) = \int_S Y_0(\lambda|y - x|)\rho_{\xi,Y}(y)dl(y), \quad (46)$$

where $\lambda = |\xi|$, such that

$$W_J(x, \rho_{\xi,J}) + W_Y(x, \rho_{\xi,Y}) \approx \exp(-i\xi \cdot x) \text{ for all } x \in \Omega. \quad (47)$$

Obtaining such approximations is not trivial. One can show that exact equality in (47) cannot be achieved, due to different behavior at infinity of the plane wave and the approximating single-layer potentials. However, as shown by numerical examples in [59], if each point in Ω is ‘‘visible’’ from S , very accurate *approximations* can be obtained, while keeping the densities $\rho_{\xi,J}$ and $\rho_{\xi,Y}$ under certain control.

Once the densities $\rho_{\xi,J}$ and $\rho_{\xi,Y}$ have been found for all ξ , function $f(x)$ can be easily reconstructed. Indeed, for the Fourier transform $\hat{f}(\xi)$ of $f(x)$

$$\hat{f}(\xi) = \frac{1}{2\pi} \int_{\Omega} f(x) \exp(-i\xi \cdot x) dx,$$

one obtains, using (47)

$$\begin{aligned} \hat{f}(\xi) &\approx \frac{1}{2\pi} \int_{\Omega} f(x) [W_J(x, \rho_{\xi,J}) + W_Y(x, \rho_{\xi,Y})] dx \\ &= \frac{1}{2\pi} \int_S \left[\int_{\Omega} f(x) J_0(\lambda|y-x|) dx \right] \rho_{\xi,J}(y) dl(y) \\ &\quad + \frac{1}{2\pi} \int_S \left[\int_{\Omega} f(x) Y_0(\lambda|y-x|) dx \right] \rho_{\xi,Y}(y) dl(y), \end{aligned} \quad (48)$$

where the inner integrals are computed from the data g

$$\int_{\Omega} f(x) J_0(\lambda|y-x|) dx = \int_{R^+} g(y, r) J_0(\lambda r) dr, \quad (49)$$

$$\int_{\Omega} f(x) Y_0(\lambda|y-x|) dx = \int_{R^+} g(y, r) Y_0(\lambda r) dr. \quad (50)$$

Formula (48), in combination with (49) and (50), yields values of $\hat{f}(\xi)$ for arbitrary ξ . Now $f(x)$ can be recovered by numerically inverting the Fourier transform or by a reduction to an FBP inversion [63] of the regular Radon transform.

The most computationally expensive part of the algorithm, which is computing the densities $\rho_{\xi,J}$ and $\rho_{\xi,Y}$, needs to be done only once for a given acquisition surface. Thus, for a scanner with a fixed S , the resulting densities can be precomputed once and for all. The actual reconstruction part then becomes extremely fast.

Examples of reconstructions from incomplete data using this technique of [59] are shown in Fig. 11. The images were reconstructed within the unit square $[-1, 1] \times [-1, 1]$, while the detectors were placed on the part of the concentric circle of radius 1.3 lying to the left of line $x_1 = 1$. We used the same phantom as in Fig. 10a; the reconstruction from the data with added 15 % noise is shown in Fig. 11b; Fig. 11c demonstrates the results of applying additional smoothing filter to reduce the effects of noise in the data.

Variable Speed of Sound

The problem of numerical reconstruction in TAT from the data measured on open surfaces in the presence of a known variable speed of sound currently remains largely open. One of the difficulties was discussed in section ‘Incomplete Data’: even if the speed of sound $c(x)$ is non-trapping, it can happen that some of the characteristics escape from the region of interest to infinity without intersecting the open measuring surface. Then stable reconstruction of the corresponding interfaces will become impossible. It should be possible, however, to develop stable

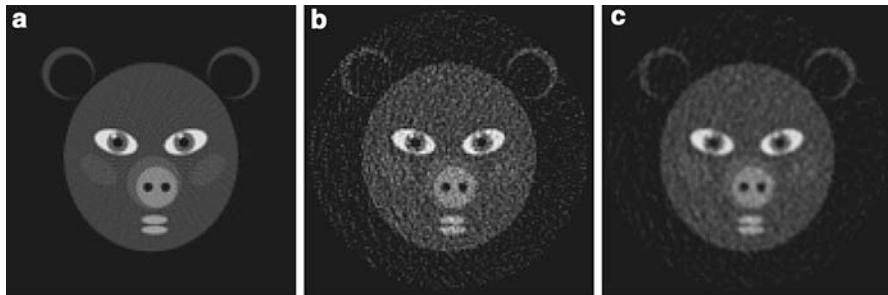

Fig. 11 Examples of reconstruction from incomplete data using the technique of [59]. Detectors are located on the part of circular arc of radius 1.3 lying left of the line $x_1 = 1$. (a) Reconstruction from accurate data, (b) reconstruction from the data with added 15 % noise, (c) reconstruction from noisy data with additional smoothing filter

reconstruction algorithms in the case when the whole object of interest is located in the visible zone.

The generalization of the method of [59] to the case of variable speed of sound is so far problematic, since this algorithm is based on the knowledge of the open space Green's function for the Helmholtz equation. In the case of a nonconstant $c(x)$, this Green's function is position dependent, and its numerical computation is likely to be prohibitively time-consuming.

A promising approach to this problem, currently under development, is to use time reversal with the missing data replaced by zeros or maybe by a more clever extension (e.g., using the range conditions, as in [78, 79]). This would produce an initial approximation to $f(x)$, which one can try to refine by fixed-point iterations; however, the pertinent questions concerning such an algorithm remain open.

An interesting technique of using a reverberant cavity enclosing the target to compensate for the missing data is described in [28].

5 Final Remarks and Open Problems

We list here some unresolved issues of mathematics of TAT/PAT, as well as some developments that were not addressed in the main text.

1. The issue of uniqueness acquisition sets S (i.e., such that transducers distributed along S provide sufficient information for TAT reconstruction) can be considered to be resolved, for most practical purposes. However, there remain significant unresolved theoretical questions. One of them consists of proving an analogue of Theorem 5 for non-compactly supported functions with a sufficiently fast (e.g., super-exponential) decay at infinity. The original (and the only known) proof of this theorem uses microlocal techniques [7, 85] that significantly rely upon the compactness of support. However, one hopes that the condition of a fast

decay should suffice for this result. In particular, there is no proven analogue of Theorem 3 for non-closed sets S (unless S is an open part of a closed analytic surface).

Techniques developed in [36] (see also [8] for their further use in TAT) might provide the right approach.

This also relates to still unresolved situation in dimensions 3 and higher. Namely, one would like to prove Conjecture 1.

2. Concerning the inversion methods, one notices that closed-form formulas are known only for spherical, cylindrical, and planar acquisition surfaces. The question arises whether closed-form inversion formulas could be found for any other smooth closed surface? It is the belief of the authors that the answer to this question is negative.

Another feature of the known closed-form formulas that was mentioned before is that they do not work correctly if the support of the sought function $f(x)$ lies partially outside the acquisition surface. Time reversal and eigenfunction expansion methods do not suffer from this deficiency. The question arises whether one could find closed-form formulas that reconstruct the function inside S correctly, in spite of it having part of its support outside. Again, the authors believe that the answer is negative.

3. The complete range description of the forward operator \mathcal{W} in even dimensions is still not known. It is also not clear whether one can obtain complete range descriptions for nonspherical observation sets S or for a variable sound speed. The moment and orthogonality conditions do hold in the case of a constant speed and arbitrary closed surface, but they do not provide a complete description of the range. For acoustically inhomogeneous media, an analogue of orthogonality conditions exists, but it also does not describe the range completely.
4. The problem of unique determination of the speed of sound from TAT data is largely open.
5. As it was explained in the text, knowing full Cauchy data of the pressure p (i.e., its value and the value of its the normal derivative) on the observation surface S leads to unique determination and simple reconstruction of f . However, the normal derivative is not measured by transducers and thus needs to be either found mathematically or measured in a different experiment. Thus, feasibility of techniques [12, 25] relying on full Cauchy data requires further mathematical and experimental study.
6. In the standard X-ray CT, as well as in SPECT, the **local tomography** technique [33, 56] is often very useful. It allows one to emphasize in a stable way singularities (e.g., tissue interfaces) of the reconstruction, even in the case of incomplete data (in the latter case, the invisible parts will be lost). An analogue of local tomography can be easily implemented in TAT, for instance, by introducing an additional high-pass filter in the FBP-type formulas.
7. The mathematical analysis of TAT presented in the text did not take into account the issue of modeling and compensating for the **acoustic attenuation**. This subject is addressed in [22, 52, 62, 80, 83], but probably cannot be considered completely resolved.

8. **Quantitative PAT:** This chapter, as well as most other papers devoted to TAT/PAT, is centered on finding the initial pressure $f(x)$. This pressure, which is proportional to the initial energy deposition, is related to the optical parameters (attenuation and scattering coefficients) of the tissue. The nontrivial issue of recovering these parameters, after the initial pressure $f(x)$ is found, is addressed in the recent works [18, 29, 30].
9. The TAT technique discussed in the chapter uses active interrogation of the medium. There is a discussion in the literature of a **passive version of TAT**, where no irradiation of the target is involved [77].

Acknowledgments The work of both authors was partially supported by the NSF DMS grant 0908208. The first author was also supported by the NSF DMS grant 0604778 and by the KAUST grant KUS-CI-016-04 through the IAMCS. The work of the second author was partially supported by the DOE grant DE-FG02-03ER25577. The authors express their gratitude to NSF, DOE, KAUST, and IAMCS for the support.

Abstract

In this chapter a general mathematical model of Optical Coherence Tomography (OCT) is presented on the basis of the electromagnetic theory. OCT produces high-resolution images of the inner structure of biological tissues. Images are obtained by measuring the time delay and the intensity of the backscattered light from the sample considering also the coherence properties of light. The

scattering problem is considered for a weakly scattering medium located far enough from the detector. The inverse problem is to reconstruct the susceptibility of the medium given the measurements for different positions of the mirror. Different approaches are addressed depending on the different assumptions made about the optical properties of the sample. This procedure is applied to a full field OCT system and an extension to standard (time and frequency domain) OCT is briefly presented.

1 Introduction

Optical Coherence Tomography (OCT) is a noninvasive imaging technique producing high-resolution images of biological tissues. OCT is based on Low (time) Coherence Interferometry and takes into account the coherence properties of light to image microstructures with resolution in the range of few micrometers. Standard OCT operates using broadband and continuous wave light in the visible and near-infrared spectrum. OCT images are obtained by measuring the time delay and the intensity of backscattered or back-reflected light from the sample under investigation. Since it was first established in 1991 by Huang et al. [24], the clinical applications of OCT have been greatly improved. Ophthalmology remains the dominant one, initially applied in 1993 [17, 41]. The main reason is that OCT has limited penetration depth in biological tissues, but high resolution. The theory of OCT has been analyzed in details in review papers [14, 16, 32, 36, 44] in book chapters [15, 19, 42] and in books [4, 5, 10].

To derive a mathematical model for the OCT system, the scattering properties of the sample need to be described. There exist several different approaches to model the propagation of light within the sample: the radiative transfer equation with scattering and absorption coefficients [9, 38, 45], Lambert–Beer’s law with the attenuation coefficient [39, 46], the equations of geometric optics with the refractive index [7], and Maxwell’s equations with the susceptibility (or the refractive index) as optical parameters of the medium [6, 12, 27, 37, 43]. Also statistical approaches using Monte Carlo simulations are used [2, 11, 26, 31, 40].

This chapter describes the propagation of the electromagnetic wave through the sample using Maxwell’s equations and adopts the analysis based on the theory of electromagnetic fields scattered by inhomogeneous media [8, 20]. The sample is hereby considered as a linear dielectric medium (potentially inhomogeneous and anisotropic). Moreover, the medium is considered weakly scattering so that the first-order Born approximation can be used and, as it is usually assumed in OCT, the backscattered light is detected far enough from the sample so that the far field approximation is valid. Starting from this model, different reconstruction formulas for special cases regarding the inner structure of the sample are presented.

This chapter is organized as follows. In Sect. 2, the principles of OCT and different variants of OCT systems are presented. Section 3 describes the solution of Maxwell’s equations and an appropriate formula for the measurements of OCT is derived. Given the initial field and the optical properties (the susceptibility) of the

sample, the solution of the direct problem is obtained in Sect. 4. An iterative scheme is derived in the last section for the reconstruction of the unknown susceptibility, which is the inverse problem of OCT.

2 Basic Principles of OCT

OCT is used to gain information about the light scattering properties of an object by illuminating it with some short laser pulse and measuring the backscattered light.

The name “Optical Coherence Tomography” is motivated by the way the scattering data are measured: To get more precise measurements, the backscattered light is not directly detected, but first superimposed with the original laser pulse and then the intensity of this interference pattern is measured (this means that one measures the “coherence” of these two light beams).

Experimentally, this is done by separating the incoming light at a beam splitter into two identical beams which travel two different paths. One beam is simply reflected by a mirror and sent back to the beam splitter, while the other beam is directed to the sample. At the beam splitter, the beam reflected by the mirror and the backscattered light from the sample are recombined and sent to the detector [16, 25, 44]. See Fig. 1 for an illustration of this procedure.

There exist different variants of the OCT regarding the way the measurements are done:

Time and frequency domain OCT: In time domain OCT, the position of the mirror is varied and for each position one measurement is performed. On the other hand, in frequency domain OCT, the reference mirror is fixed and the detector is replaced by a spectrometer. Both methods provide equivalent measurements which are connected by a Fourier transform.

Standard and full field OCT: In standard OCT, the incoming light is focused through objective lenses to one spot in a certain depth in the sample and the backscattered light is measured in a point detector. This means that to obtain information of the whole sample, a transversal-lateral scan has to be performed

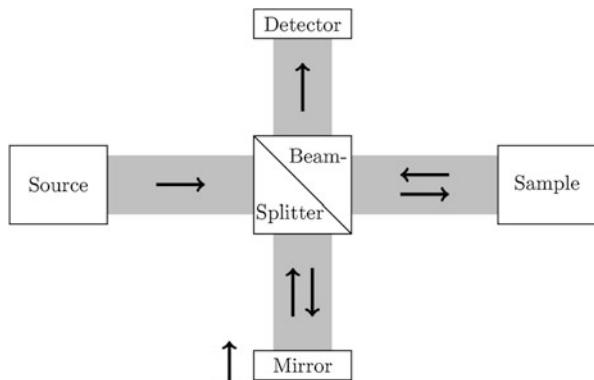

Fig. 1 Schematic diagram of the light traveling in an OCT system. The laser beam emitted by the source is divided at the beam splitter into two light beams; one is reflected at a mirror, the other one backscattered from the sample. The superposition of the two reflected beams is then measured at the detector

(by moving the light beam over the frontal surface of the sample). In full field OCT, the entire frontal surface of the sample is illuminated at once and the single point detector is replaced by a two-dimensional detector array, for instance by a charge-coupled device (CCD) camera.

Polarization-sensitive OCT: In classical OCT setups, the electromagnetic wave is simply treated as a scalar quantity. In polarization-sensitive OCT, however, the illuminating light beams are polarized and the detectors measure the intensity of the two polarization components of the interfered light.

There are also further modifications such as Doppler OCT and quantum OCT, which are not addressed here. In this chapter, the focus is mainly on time domain full field OCT, but also the others are discussed.

3 The Direct Scattering Problem

To derive a mathematical model for an OCT system, one has to describe on one hand the propagation and the scattering of the laser beam in the presence of the sample and on the other hand the way how this scattered wave is measured at the detectors. For the first part, the interaction of the incoming light with the sample can be modeled with Maxwell's macroscopic equations.

Maxwell's Equations

Maxwell's equations in matter consist of the partial differential equations

$$\operatorname{div}_x D(t, x) = 4\pi\rho(t, x), \quad t \in \mathbb{R}, x \in \mathbb{R}^3, \quad (1a)$$

$$\operatorname{div}_x B(t, x) = 0, \quad t \in \mathbb{R}, x \in \mathbb{R}^3, \quad (1b)$$

$$\operatorname{curl}_x E(t, x) = -\frac{1}{c} \frac{\partial B}{\partial t}(t, x), \quad t \in \mathbb{R}, x \in \mathbb{R}^3, \quad (1c)$$

$$\operatorname{curl}_x H(t, x) = \frac{4\pi}{c} J(t, x) + \frac{1}{c} \frac{\partial D}{\partial t}(t, x), \quad t \in \mathbb{R}, x \in \mathbb{R}^3, \quad (1d)$$

relating the following physical quantities (at some time $t \in \mathbb{R}$ and some location $x \in \mathbb{R}^3$):

| Speed of light | c | \mathbb{R} |
|-----------------------------------|--------------|----------------|
| External charge density | $\rho(t, x)$ | \mathbb{R} |
| External electric current density | $J(t, x)$ | \mathbb{R}^3 |
| Electric field | $E(t, x)$ | \mathbb{R}^3 |
| Electric displacement | $D(t, x)$ | \mathbb{R}^3 |
| Magnetic induction | $B(t, x)$ | \mathbb{R}^3 |
| Magnetic field | $H(t, x)$ | \mathbb{R}^3 |

Maxwell's equations do not yet completely describe the propagation of the light (even assuming that the charge density ρ and the current density J are known, there are only 8 equations for the 12 unknowns E , D , B , and H).

Additionally to Maxwell's equations, it is therefore necessary to specify the relations between the fields D and E as well as between B and H .

Let $\Omega \subset \mathbb{R}^3$ denote the domain where the sample is located. It is considered as a nonmagnetic, dielectric medium without external charges or currents, this means that for all $t \in \mathbb{R}$ and all $x \in \Omega$ the electric and magnetic fields fulfil the relations

$$D(t, x) = E(t, x) + \int_0^\infty \chi(\tau, x) E(t - \tau, x) d\tau, \quad (2a)$$

$$B(t, x) = H(t, x), \quad (2b)$$

$$\rho(t, x) = 0, \quad (2c)$$

$$J(t, x) = 0, \quad (2d)$$

where the function $\chi : \mathbb{R} \times \mathbb{R}^3 \rightarrow \mathbb{R}^{3 \times 3}$ (for convenience, χ is also defined for negative times by $\chi(t, x) = 0$ for $t < 0$, $x \in \mathbb{R}^3$) is called the (electric) susceptibility and is the quantity to be recovered. The time dependence of χ hereby describes the fact that a change in the electric field E cannot immediately cause a change in the electric displacement D . Since this delay is quite small, it is sometimes ignored and $\chi(t, x)$ is then replaced by $\delta(t)\chi(x)$. Moreover, the medium is often considered to be isotropic, which means that χ is a multiple of the identity matrix.

The sample is situated in vacuum and the assumptions (2) are modified by setting for all $t \in \mathbb{R}$ and all $x \in \mathbb{R}^3 \setminus \Omega$

$$D(t, x) = E(t, x), \quad (3a)$$

$$B(t, x) = H(t, x), \quad (3b)$$

$$\rho(t, x) = 0, \quad (3c)$$

$$J(t, x) = 0. \quad (3d)$$

This simply corresponds to extend the Eq. (2) to $\mathbb{R} \times \mathbb{R}^3$ and to assume $\chi(t, x) = 0$ for all $t \in \mathbb{R}$, $x \in \mathbb{R}^3 \setminus \Omega$.

In this case of a nonmagnetic medium, Maxwell's equations result into one equation for the electric field E . To get rid of the convolution in (2a), it is practical to consider the Fourier transform with respect to time. In the following, the convention

$$\hat{f}(\omega, x) = \int_{-\infty}^{\infty} f(t, x) e^{i\omega t} dt,$$

for the Fourier transform of a function f with respect to t is used.

Proposition 1. Let E , D , B , and H fulfil Maxwell's equations (1). Moreover, let assumptions (2) and (3) be satisfied. Then the Fourier transform \hat{E} of E fulfils the vector Helmholtz equation

$$\operatorname{curl}_x \operatorname{curl}_x \hat{E}(\omega, x) - \frac{\omega^2}{c^2} (\mathbb{1} + \hat{\chi}(\omega, x)) \hat{E}(\omega, x) = 0, \quad \omega \in \mathbb{R}, x \in \mathbb{R}^3. \quad (4)$$

Proof. Applying the curl to (1c) and using (1d) with the assumptions $B = H$ and $J = 0$, yields

$$\operatorname{curl}_x \operatorname{curl}_x E(t, x) = -\frac{1}{c} \frac{\partial \operatorname{curl}_x B}{\partial t}(t, x) = -\frac{1}{c^2} \frac{\partial^2 D}{\partial t^2}(t, x). \quad (5)$$

The Fourier transform of (2a) and (3a) and the Fourier convolution theorem (recall that χ is set to zero outside Ω) imply that

$$\hat{D}(\omega, x) = (\mathbb{1} + \hat{\chi}(\omega, x)) \hat{E}(\omega, x), \quad \text{for all } \omega \in \mathbb{R}, x \in \mathbb{R}^3.$$

Therefore, the Eq. (4) follows by taking the Fourier transform of (5). \square

Initial Conditions

The sample is illuminated with a laser beam described initially (before it interacts with the sample) by the electric field $E^{(0)} : \mathbb{R} \times \mathbb{R}^3 \rightarrow \mathbb{R}^3$ which is (together with some magnetic field) a solution of Maxwell's equations (1) with the assumptions (3) for all $x \in \mathbb{R}^3$. Then, it follows from the proof of the Proposition 1, for $\chi = 0$, that

$$\operatorname{curl}_x \operatorname{curl}_x \hat{E}^{(0)}(\omega, x) - \frac{\omega^2}{c^2} \hat{E}^{(0)}(\omega, x) = 0, \quad \omega \in \mathbb{R}, x \in \mathbb{R}^3. \quad (6)$$

Moreover, it is assumed that $E^{(0)}$ does not interact with the sample until the time $t = 0$, which means that $\operatorname{supp} E^{(0)}(t, \cdot) \cap \Omega = \emptyset$ for all $t \leq 0$.

The electric field $E : \mathbb{R} \times \mathbb{R}^3 \rightarrow \mathbb{R}^3$ generated by this incoming light beam in the presence of the sample is then a solution of Maxwell's equations (1) with the assumptions (2) and the initial condition

$$E(t, x) = E^{(0)}(t, x) \quad \text{for all } t \leq 0, x \in \mathbb{R}^3. \quad (7)$$

Since Maxwell's equations for E in Proposition 1 are reformulated as an equation for the Fourier transform \hat{E} , it is helpful to rewrite the initial condition in terms of \hat{E} .

Proposition 2. Let E (together with some magnetic field H) fulfil Maxwell's equations (1) with the assumptions (2) and (3) and with the initial condition (7).

Then the Fourier transform of $E - E^{(0)}$ fulfills that the function $\omega \mapsto \hat{E}(\omega, x) - \hat{E}^{(0)}(\omega, x)$, defined on \mathbb{R} , can be extended to a square integrable, holomorphic function on the upper half plane $\mathbb{H} = \{\omega \in \mathbb{C} \mid \operatorname{Im}(\omega) > 0\}$ for every $x \in \mathbb{R}^3$.

Proof. From the initial condition (7) it follows that $E(t, x) - E^{(0)}(t, x) = 0$ for all $t \leq 0$. Thus, the result is a direct consequence from the Paley–Wiener theorem, which is based on the fact that in this case

$$\hat{E}(\omega, x) - \hat{E}^{(0)}(\omega, x) = \int_0^\infty (E - E^{(0)})(t, x) e^{i\omega t} dt$$

is well defined for all $\omega \in \mathbb{H}$ and complex differentiable with respect to $\omega \in \mathbb{H}$. \square

Remark that the electric field E is uniquely defined by (4) and [Proposition 2](#).

The Measurements

The measurements are obtained by the combination of the backscattered field from the sample and the back-reflected field from the mirror. In practice, see Fig. 1, the sample and the mirror are in different positions. However, without loss of generality, a placement of them around the origin is assumed in the proposed formulation, in order to avoid rotating the coordinate system. To do so, the simultaneous illumination of the sample and the mirror is suppressed and two different illumination schemes are considered. The gain is to keep the same coordinate system but the reader should not be confused with illumination at different times.

Thus, the electric field E , which is obtained by illuminating the sample with the initial field $E^{(0)}$ (that is E solves (4) with the initial condition (7)), is combined with E_r , which is the electric field obtained by replacing the sample by a mirror and illuminating with the same initial field $E^{(0)}$.

The mirror is placed orthogonal to the unit vector $e_3 = (0, 0, 1)$ through the point re_3 . As in (7), it is assumed that $\operatorname{supp} E^{(0)}(t, \cdot)$ does not interact with the mirror for $t < 0$, so that

$$E_r(t, x) = E^{(0)}(t, x) \quad \text{for all } t < 0, x \in \mathbb{R}^3. \quad (8)$$

Then the resulting electric field $E_r : \mathbb{R} \times \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is given as the solution of the same equations as E (Maxwell's equations (1) together with the assumptions (2) and initial condition (8)) with the susceptibility χ replaced by the susceptibility χ_r of the mirror at position r . One sort of (ideal) mirror can be described via the susceptibility $\chi_r(t, x) = 0$ for $x_3 > r$ and $\chi_r(t, x) = C\delta(t)\mathbb{1}$ for $x_3 \leq r$ with an (infinitely) large constant $C > 0$.

The intensity I_r of each component of the superposition of the electric fields E and E_r averaged over all time is measured at some detector points. The detectors are positioned at all points on the plane

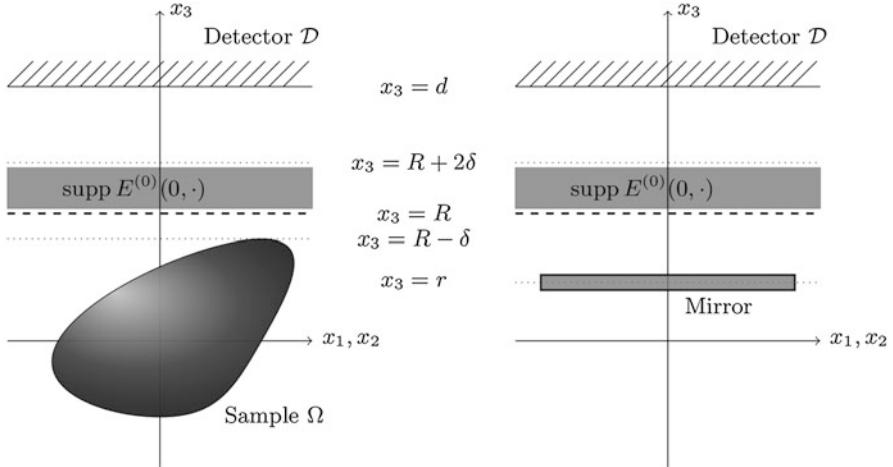

Fig. 2 The two scattering problems involved in OCT: On the left hand side the scattering of the initial wave on the sample Ω ; on the right hand side the reference problem where the initial wave $E^{(0)}$ is reflected by a perfect mirror at a tunable position $r \in (-\infty, R)$. The two resulting electric fields, E and E_r , are then combined and this superposition $E + E_r$ is measured at the detector surface D

$$\mathcal{D} = \{x \in \mathbb{R}^3 \mid x_3 = d\}$$

parallel to the mirror at a distance $d > 0$ from the origin. The mirror and the sample are both located in the lower half plane of the detector surface with some minimal distance to \mathcal{D} . Moreover, the highest possible position $R \in (\delta, d - 2\delta)$ of the mirror shall be by some distance $\delta > 0$ closer to the detector than the sample, this means (see Fig. 2)

$$\sup_{x \in \Omega} x_3 < R - \delta \quad \text{and} \quad r \in (-\infty, R). \quad (9)$$

To simplify the argument, let us additionally assume that the incoming electric field $E^{(0)}$ does not influence the detector after the time $t = 0$, meaning that

$$E^{(0)}(t, x) = 0 \quad \text{for all } t \geq 0, x \in \mathcal{D}. \quad (10)$$

At the detector array, the data are obtained by measuring

$$I_{r,j}(x) = \int_0^\infty |E_j(t, x) + E_{r,j}(t, x)|^2 dt, \quad x \in \mathcal{D}, j \in \{1, 2, 3\}. \quad (11)$$

In standard OCT, the polarization is usually ignored. In this case, only the total intensity $I_r = \sum_{j=1}^3 I_{r,j}$ needs to be measured, see Sect. 5 for the reconstruction formulas in the isotropic case.

In this measurement setup, it is easy to acquire besides the intensity I_r also the intensity of the two waves E and E_r separately by blocking one of the two waves E and E_r at a time. Practically, it is sometimes not even necessary to measure them since the intensity of the reflected laser beam E_r can be explicitly calculated from the knowledge of the initial beam $E^{(0)}$, and the intensity of E is usually negligible compared with the intensity I_r (because of the assumption (10), the field E contains only backscattered light at the detector after the measurement starts). Therefore, one can consider instead of I_r the function

$$M_{r,j}(x) = \frac{1}{2} \left(I_{r,j} - \int_0^\infty |E_j(t, x)|^2 dt - \int_0^\infty |E_{r,j}(t, x)|^2 dt \right) \quad (12)$$

for $r \in (-\infty, R)$, $j \in \{1, 2, 3\}$, and $x \in \mathcal{D}$ as the measurement data.

Proposition 3. *Let the initial conditions (7) and (8) and the additional assumption (10) be satisfied. Then, for all $x \in \mathcal{D}$, $r \in (-\infty, R)$, and $j \in \{1, 2, 3\}$ the measurements M_r , defined by (12), fulfil*

$$M_{r,j}(x) = \int_{-\infty}^\infty (E_j - E_j^{(0)})(t, x)(E_{r,j} - E_j^{(0)})(t, x) dt \quad (13a)$$

$$= \int_{-\infty}^\infty (\hat{E}_j - \hat{E}_j^{(0)})(\omega, x) \overline{(\hat{E}_{r,j} - \hat{E}_j^{(0)})(\omega, x)} d\omega, \quad (13b)$$

Proof. Expanding the function $I_{r,j}$, given by (11), gives

$$I_{r,j}(x) = \int_0^\infty (|E_j(t, x)|^2 + |E_{r,j}(t, x)|^2 + 2E_j(t, x)E_{r,j}(t, x)) dt.$$

Thus, by the Definition (12) of M_r , it follows that

$$M_{r,j}(x) = \int_0^\infty E_j(t, x)E_{r,j}(t, x) dt,$$

which, using the assumption (10), can be rewritten in the form

$$M_{r,j}(x) = \int_0^\infty (E_j - E_j^{(0)})(t, x)(E_{r,j} - E_j^{(0)})(t, x) dt.$$

Then, since E and E_r coincide with $E^{(0)}$ for $t < 0$, see (7) and (8), the integration can be extended to all times. This proves the formula (13a) for M_r . The second formula follows from Plancherel's theorem. \square

4 Solution of the Direct Problem

In this section the solution of the direct problem, to determine the measurements M_r , defined by (13a), from the susceptibility χ , is derived using Born and far field approximation for the electric field.

Proposition 4. *Let E be a solution of the Eqs. (4) and (7). Then, the Fourier transform \hat{E} solves the Lippmann–Schwinger integral equation*

$$\hat{E}(\omega, x) = \hat{E}^{(0)}(\omega, x) + \left(\frac{\omega^2}{c^2} \mathbb{1} + \operatorname{grad}_x \operatorname{div}_x \right) \int_{\mathbb{R}^3} G(\omega, x - y) \hat{\chi}(\omega, y) \hat{E}(\omega, y) dy, \quad (14)$$

where G is the fundamental solution of the Helmholtz equation given by

$$G(\omega, x) = \frac{e^{i\frac{\omega}{c}|x|}}{4\pi|x|}, \quad x \neq 0, \omega \in \mathbb{R}.$$

Proof. Equation (4) can be rewritten in the form

$$\operatorname{curl}_x \operatorname{curl}_x \hat{E}(\omega, x) - \frac{\omega^2}{c^2} \hat{E}(\omega, x) = \phi(\omega, x)$$

with the inhomogeneity

$$\phi(\omega, x) = \frac{\omega^2}{c^2} \hat{\chi}(\omega, x) \hat{E}(\omega, x). \quad (15)$$

Using that $\hat{E}^{(0)}$ solves (6), the difference $\hat{E} - \hat{E}^{(0)}$ satisfies the inhomogeneous vector Helmholtz equation

$$\operatorname{curl}_x \operatorname{curl}_x (\hat{E} - \hat{E}^{(0)})(\omega, x) - \frac{\omega^2}{c^2} (\hat{E} - \hat{E}^{(0)})(\omega, x) = \phi(\omega, x). \quad (16)$$

The divergence of this equation, using that $\operatorname{div}_x \operatorname{curl}_x (\hat{E} - \hat{E}^{(0)}) = 0$, implies

$$\operatorname{div}_x (\hat{E} - \hat{E}^{(0)})(\omega, x) = -\frac{c^2}{\omega^2} \operatorname{div}_x \phi(\omega, x). \quad (17)$$

Applying the vector identity

$$\operatorname{curl}_x \operatorname{curl}_x (\hat{E} - \hat{E}^{(0)}) = \operatorname{grad}_x \operatorname{div}_x (\hat{E} - \hat{E}^{(0)}) - \Delta_x (\hat{E} - \hat{E}^{(0)})$$

in (16) and using (17) yields

$$\Delta_x(\hat{E} - \hat{E}^{(0)})(\omega, x) + \frac{\omega^2}{c^2}(\hat{E} - \hat{E}^{(0)})(\omega, x) = -\frac{c^2}{\omega^2} \operatorname{grad}_x \operatorname{div}_x \phi(\omega, x) - \phi(\omega, x).$$

This is a Helmholtz equation for $\hat{E} - \hat{E}^{(0)}$ and the general solution which is (with respect to ω) holomorphic in the upper half plane (equivalent to (7) by [Proposition 2](#)) is given by, see [8]

$$\begin{aligned} (\hat{E} - \hat{E}^{(0)})(\omega, x) &= -\frac{c^2}{\omega^2} \int_{\mathbb{R}^3} G(\omega, x - y) \left(\frac{\omega^2}{c^2} \mathbb{1} + \operatorname{grad}_y \operatorname{div}_y \right) \phi(\omega, y) dy \\ &= -\frac{c^2}{\omega^2} \left(\frac{\omega^2}{c^2} \mathbb{1} + \operatorname{grad}_x \operatorname{div}_x \right) \int_{\mathbb{R}^3} G(\omega, x - y) \phi(\omega, y) dy. \end{aligned}$$

For the last equality, integration by parts and $\operatorname{grad}_x G(\omega, x - y) = -\operatorname{grad}_y G(\omega, x - y)$ were used. The Lippmann–Schwinger equation (14) follows from the last expression inserting the expression (15) for ϕ . \square

This integral equation uniquely defines the electric field E . The reader is referred to [1, 8] for the isotropic case and to [33] for an anisotropic medium.

Born and Far Field Approximation

To solve the Lippmann–Schwinger equation (14), the medium is assumed to be weakly scattering, which means that $\hat{\chi}$ is sufficiently small (implying that the difference $E - \hat{E}^{(0)}$ becomes small compared to $E^{(0)}$) so that the Born approximation $E^{(1)}$, defined by

$$\begin{aligned} \hat{E}^{(1)}(\omega, x) &= \hat{E}^{(0)}(\omega, x) + \left(\frac{\omega^2}{c^2} \mathbb{1} + \operatorname{grad}_x \operatorname{div}_x \right) \\ &\quad \int_{\mathbb{R}^3} G(\omega, x - y) \hat{\chi}(\omega, y) \hat{E}^{(0)}(\omega, y) dy, \end{aligned} \tag{18}$$

is considered a good approximation for the electric field E , see [3]. To describe multiple scattering events, one considers higher order Born approximations. For different linearization techniques, the reader is referred to [1, 23]. Moreover, since the detector in OCT is typically quite far away from the sample, one can simplify the expression (18) for the electric field at the detector array by replacing it with its asymptotic behavior for $|x| \rightarrow \infty$, that is replace the formula for $E^{(1)}$ by its far field approximation (the far field approximation could also be applied to the solution E of the Lippmann–Schwinger equation (14)).

Proposition 5. *Consider, for a given function $\phi : \mathbb{R}^3 \rightarrow \mathbb{R}^3$ with compact support and some parameter $a \in \mathbb{R}$, the function*

$$g : \mathbb{R}^3 \rightarrow \mathbb{R}^3, \quad g(x) = \int_{\mathbb{R}^3} \frac{e^{ia|x-y|}}{|x-y|} \phi(y) dy.$$

Then, it follows, asymptotically for $\rho \rightarrow \infty$ and uniformly in $\vartheta \in S^2$, that

$$(a^2 + \operatorname{grad}_x \operatorname{div}_x) g(\rho \vartheta) \simeq -\frac{a^2 e^{ia\rho}}{\rho} \int_{\mathbb{R}^3} \vartheta \times (\vartheta \times \phi(y)) e^{-ia\langle \vartheta, y \rangle} dy \quad (19)$$

Proof. Consider the function

$$\Gamma : \mathbb{R}^3 \rightarrow \mathbb{C}, \quad \Gamma(x) = \frac{e^{ia|x|}}{|x|}.$$

Then

$$\begin{aligned} \frac{\partial^2 \Gamma}{\partial x_j \partial x_k}(x) &= \frac{\partial}{\partial x_j} \left[\left(\frac{ia}{|x|^2} - \frac{1}{|x|^3} \right) x_k e^{ia|x|} \right] \\ &= \left[\left(\frac{ia}{|x|^2} - \frac{1}{|x|^3} \right) \delta_{jk} + \left(\frac{ia}{|x|^2} - \frac{1}{|x|^3} \right) \frac{ia x_j x_k}{|x|} \right. \\ &\quad \left. + \left(-2 \frac{ia}{|x|^3} + 3 \frac{1}{|x|^4} \right) \frac{x_j x_k}{|x|} \right] e^{ia|x|}. \end{aligned}$$

Therefore, writing x in spherical coordinates: $x = \rho \vartheta$ with $\rho > 0$, $\vartheta \in S^2$, for $\rho \rightarrow \infty$ uniformly in ϑ , it can be seen that

$$\frac{\partial^2 \Gamma}{\partial x_j \partial x_k}(\rho \vartheta) = -\frac{a^2 e^{ia\rho}}{\rho} \vartheta_j \vartheta_k + \mathcal{O}\left(\frac{1}{\rho^2}\right),$$

The approximation (locally uniformly in $y \in \mathbb{R}^3$)

$$|\rho \vartheta - y| = \rho \sqrt{|\vartheta|^2 - \frac{2}{\rho} \langle \vartheta, y \rangle + \frac{1}{\rho^2} |y|^2} = \rho - \langle \vartheta, y \rangle + \mathcal{O}\left(\frac{1}{\rho}\right),$$

implies that (again uniformly in $\vartheta \in S^2$)

$$\frac{\partial^2 \Gamma}{\partial x_j \partial x_k}(\rho \vartheta - y) = -\frac{a^2 e^{ia(\rho - \langle \vartheta, y \rangle)}}{\rho} \vartheta_j \vartheta_k + \mathcal{O}\left(\frac{1}{\rho}\right).$$

Now, considering the compact support of ϕ and using that $x \in \mathbb{R}^3 \setminus \operatorname{supp} \phi$

$$(\operatorname{grad}_x \operatorname{div}_x g)_j(x) = \sum_{k=1}^3 \frac{\partial}{\partial x_j} \int_{\mathbb{R}^3} \frac{\partial \Gamma}{\partial x_k}(x - y) \phi_k(y) dy$$

$$= \int_{\mathbb{R}^3} \sum_{k=1}^3 \frac{\partial^2 \Gamma}{\partial x_j \partial x_k}(x-y) \phi_k(y) dy.$$

Asymptotically for $|x| \rightarrow \infty$ (again using the compact support of ϕ) one obtains

$$a^2 g_j(\rho \vartheta) + (\text{grad}_x \text{div}_x g)_j(\rho \vartheta) \simeq a^2 \int_{\mathbb{R}^3} \sum_{k=1}^3 \frac{e^{ia(\rho - \langle \vartheta, y \rangle)}}{\rho} (\delta_{jk} - \vartheta_j \vartheta_k) \phi_k(y) dy.$$

The approximation (19) follows from the vector identity $\vartheta \times (\vartheta \times \phi) = \langle \vartheta, \phi \rangle \vartheta - |\vartheta|^2 \phi$ and $|\vartheta| = 1$. \square

The application of both the far field and the Born approximation, this means **Proposition 5** for the expression (18) of $E^{(1)}$, that is setting $a = \omega/c$ and $\phi = \frac{1}{4\pi} \hat{\chi} \hat{E}^{(0)}$ in **Proposition 5**, imply the asymptotic behavior

$$\hat{E}^{(1)}(\omega, \rho \vartheta) \simeq \hat{E}^{(0)}(\omega, \rho \vartheta) - \frac{\omega^2 e^{i\frac{\omega}{c}\rho}}{4\pi \rho c^2} \int_{\mathbb{R}^3} \vartheta \times (\vartheta \times (\hat{\chi}(\omega, y) \hat{E}^{(0)}(\omega, y))) e^{-i\frac{\omega}{c}\langle \vartheta, y \rangle} dy. \quad (20)$$

The Forward Operator

To obtain a forward model for the measurements described in Sect. 3, the (approximative) formula (20) is considered as a model for the solution of the scattering problem. To make this formula concrete, one has to plug in a function $E^{(0)}$ describing the initial illumination (recall that $E^{(0)}$ has to solve (6)).

The specific illumination is a laser pulse propagating in the direction $-e_3$, orthogonal to the detector surface $\mathcal{D} = \{x \in \mathbb{R}^3 \mid x_3 = d\}$, this means

$$E^{(0)}(t, x) = f(t + \frac{x_3}{c}) p, \quad (21)$$

which solves Maxwell's equations (1) with the assumptions (3) for some fixed vector $p \in \mathbb{R}^3$, with $p_3 = \langle p, e_3 \rangle = 0$, describing the polarization of the initial laser beam.

Proposition 6. *The function $E^{(0)}$, defined by (21) with $\langle p, e_3 \rangle = 0$, solves together with the magnetic field $H^{(0)}$, defined by*

$$H^{(0)}(t, x) = f(t + \frac{x_3}{c}) p \times e_3,$$

Maxwell's equations (1) in the vacuum, that is with the additional assumptions (3).

Proof. The four equations of (1) can be directly verified:

$$\begin{aligned}
\operatorname{div}_x E^{(0)}(t, x) &= \frac{1}{c} f'(t + \frac{x_3}{c}) \langle e_3, p \rangle = 0, \\
\operatorname{div}_x H^{(0)}(t, x) &= \frac{1}{c} f'(t + \frac{x_3}{c}) \langle e_3, p \times e_3 \rangle = 0, \\
\operatorname{curl}_x E^{(0)}(t, x) &= \frac{1}{c} f'(t + \frac{x_3}{c}) e_3 \times p = -\frac{1}{c} \frac{\partial H^{(0)}}{\partial t}(t, x), \\
\operatorname{curl}_x H^{(0)}(t, x) &= \frac{1}{c} f'(t + \frac{x_3}{c}) e_3 \times (p \times e_3) = \frac{1}{c} f'(t + \frac{x_3}{c}) p = \frac{1}{c} \frac{\partial E^{(0)}}{\partial t}(t, x).
\end{aligned}$$

□

To guarantee that the initial field $E^{(0)}$ (and also the magnetic field $H^{(0)}$) does not interact with the sample or the mirror for $t \leq 0$ and neither contributes to the measurement at the detectors for $t \geq 0$ as required by (8) and (10) the vertical distribution $f : \mathbb{R} \rightarrow \mathbb{R}$ should satisfy (see Fig. 2)

$$\operatorname{supp} f \subset (\frac{R}{c}, \frac{d}{c}). \quad (22)$$

In the case of an illumination $E^{(0)}$ of the form (21), the electric field E_r produced by an ideal mirror at the position r is given by

$$E_r(t, x) = \begin{cases} \left(f(t + \frac{x_3}{c}) - f(t + \frac{x_3}{c} + 2 \frac{r-x_3}{c}) \right) p & \text{if } x_3 > r, \\ 0 & \text{if } x_3 \leq r. \end{cases} \quad (23)$$

This just corresponds to the superposition of the initial wave with the (orthogonally) reflected wave, which travels additionally the distance $2 \frac{x_3-r}{c}$. The change in polarization of the reflected wave (from p to $-p$) comes from the fact that the tangential components of the electric field have to be continuous across the border of the mirror.

The following proposition gives the form of the measurements M_r , described in Sect. 3, on the detector surface \mathcal{D} for the specific illumination (21).

Proposition 7. *Let $E^{(0)}$ be an initial illumination of the form (21) satisfying (22). Then, the equations for the measurements M_r from Proposition 3 are given by*

$$M_{r,j}(x) = -p_j \int_{-\infty}^{\infty} (E_j - E_j^{(0)})(t, x) f(t + \frac{2r-x_3}{c}) dt, \quad (24a)$$

$$= -\frac{p_j}{2\pi} \int_{-\infty}^{\infty} (\hat{E}_j - \hat{E}_j^{(0)})(\omega, x) \hat{f}(-\omega) e^{i\frac{\omega}{c}(2r-x_3)} d\omega \quad (24b)$$

for all $j \in \{1, 2, 3\}$, $r \in (-\infty, R)$, and $x \in \mathcal{D}$.

Proof. Since the electric field E_r reflected on a mirror at vertical position $r \in (-\infty, R)$ is according to (23) given by

$$E_r(t, x) = (f(t + \frac{x_3}{c}) - f(t + \frac{2r-x_3}{c}))p \quad \text{for all } t \in \mathbb{R}, x \in \mathcal{D},$$

the measurement functions M_r (defined by (12) and computed with (13a)) are simplified, for the particular initial illumination $E^{(0)}$ of the form (21), to (24a) for $x \in \mathcal{D}$.

Since formula (24a) is just a convolution, the electric field $E - E^{(0)}$ can be rewritten, in terms of its Fourier transform, in the form

$$M_{r,j}(x) = -\frac{p_j}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} (\hat{E}_j - \hat{E}_j^{(0)})(\omega, x) e^{-i\omega t} f(t + \frac{2r-x_3}{c}) d\omega dt.$$

Interchanging the order of integration and applying the Fourier transform \hat{f} of f , it follows Eq. (24b). \square

In the limiting case of a delta impulse as initial wave, that is for $f(\xi) = \delta(\xi - \xi_0)$ with some constant $\xi_0 \in (\frac{R}{c}, \frac{d}{c})$ satisfying (22), the measurements provide directly the electric field. Indeed, it can be seen from (24a) that

$$M_{r,j}(x) = -p_j(E_j - E_j^{(0)})\left(\frac{x_3-2r}{c} + \xi_0, x\right).$$

By varying $r \in (-\infty, R)$, the electric field E can be obtained (to be more precise, its component in direction of the initial polarization) as a function of time at every detector position.

The following assumptions are made:

Assumption 5. *The susceptibility χ is sufficiently small so that the Born approximation $E^{(1)}$ for the solution E of the Lippmann–Schwinger equation (14) can be applied.*

Assumption 6. *The detectors are sufficiently far away from the object so that one can use the far field asymptotics (20) for the measured field.*

Under these assumptions, one can approximate the electric field by the far field expression of the Born approximation $E^{(1)}$ and plug in the expression in (20) to obtain the measurements $M_{r,j}$, $j \in \{1, 2, 3\}$.

The above analysis, introducing appropriate operators, can then be formulated as an operator equation. The integral equation (20) can be formally written as

$$(\hat{E}^{(1)} - \hat{E}^{(0)})(\omega, x) = (\mathcal{K}_0 \hat{\chi})(\omega, x),$$

for a given $\hat{E}^{(0)}$ where the operator $\mathcal{K}_0 : \hat{\chi} \mapsto \hat{E}^{(1)} - \hat{E}^{(0)}$ is given by

$$(\mathcal{K}_0 v)(\omega, \rho \vartheta) = -\frac{\omega^2 e^{i \frac{\omega}{c} \rho}}{4\pi \rho c^2} \int_{\mathbb{R}^3} \vartheta \times (\vartheta \times (v(\omega, y) \hat{E}^{(0)}(\omega, y))) e^{-i \frac{\omega}{c} \langle \vartheta, y \rangle} dy,$$

$$\rho > 0, \vartheta \in S^2.$$

It is emphasized that $\hat{\chi} : \mathbb{R} \times \mathbb{R}^3 \rightarrow \mathbb{C}^{3 \times 3}$ and $\hat{E}^{(1)} - \hat{E}^{(0)} : \mathbb{R} \times \mathbb{R}^3 \rightarrow \mathbb{C}^3$, that is $\mathcal{K}_0 v$ is a function from $\mathbb{R} \times \mathbb{R}^3$ into \mathbb{C}^3 . Equivalently, considering the Eq. (13b), one has

$$M(r, x) = (M_{r,j}(x))_{j=1}^3 = (\mathcal{M}(\hat{E}^{(1)} - \hat{E}^{(0)}))(r, x),$$

where the operator \mathcal{M} is defined by

$$(\mathcal{M}v)(r, x) = \left(\int_{-\infty}^{\infty} v_j(\omega, x) \overline{(\hat{E}_{r,j} - \hat{E}_j^{(0)})(\omega, x)} d\omega \right)_{j=1}^3, \quad x \in \mathcal{D}.$$

Here, $\mathcal{M}v$ is a function from $\mathbb{R} \times \mathcal{D}$ to \mathbb{R}^3 . Thus, combining the operators \mathcal{K}_0 and \mathcal{M} , the forward operator $\mathcal{F} : \hat{\chi} \mapsto M$, $\mathcal{F} = \mathcal{M}\mathcal{K}_0$ models the direct problem. The inverse problem of OCT is then formulated as an operator equation

$$\mathcal{F}\hat{\chi} = M. \quad (25)$$

For the specific illumination (21), one has

$$\hat{E}^{(0)}(\omega, x) = \left(\int_{-\infty}^{\infty} f(t + \frac{x_3}{c}) e^{i\omega t} dt \right) p = \hat{f}(\omega) e^{-i \frac{\omega}{c} x_3} p. \quad (26)$$

Then, the operators \mathcal{K}_0 and \mathcal{M} simplify to

$$(\mathcal{K}_0 v)(\omega, \rho \vartheta) = -\frac{\omega^2 e^{i \frac{\omega}{c} \rho}}{4\pi \rho c^2} \hat{f}(\omega) \int_{\mathbb{R}^3} \vartheta \times (\vartheta \times (v(\omega, y) p)) e^{-i \frac{\omega}{c} \langle \vartheta, y \rangle} dy \quad (27)$$

and, recalling that $M_{r,3} = 0$ since $p_3 = 0$ (the polarization in the incident direction is zero),

$$(\mathcal{M}v)(r, x) = \left(-\frac{p_j}{2\pi} \int_{-\infty}^{\infty} v_j(\omega, x) \hat{f}(-\omega) e^{i \frac{\omega}{c} (2r - x_3)} d\omega \right)_{j=1}^2. \quad (28)$$

The operator \mathcal{K}_0 is derived from the Born approximation taking into account the far field approximation for the solution of the Lippmann–Schwinger equation (14). But, one could also neglect Assumption 5 and Assumption 6 and use the operator \mathcal{K} corresponding to Eq. (14), that is,

$$(\mathcal{K}v)(\omega, x) = \left(\frac{\omega^2}{c^2} \mathbb{1} + \text{grad}_x \text{div}_x \right) \int_{\mathbb{R}^3} G(\omega, x - y) v(\omega, y) \hat{E}(\omega, y) dy,$$

and considering the nonlinear forward operator $\mathcal{F} = \mathcal{M}\mathcal{K}$.

The next section focuses on the solution of (25), considering the operators \mathcal{K}_0 and \mathcal{M} , given by (27) and (28), respectively. The inversion of \mathcal{F} is performed in two steps, first \mathcal{M} is inverted and then \mathcal{K}_0 .

5 The Inverse Scattering Problem

In optical coherence tomography, the susceptibility χ of the sample is imaged from the measurements $M_r(x)$, $r \in (-\infty, R)$, $x \in \mathcal{D}$. In a first step, it is shown that the measurements allow us to reconstruct the scattered field on the detector \mathcal{D} , that is inverting the operator (28).

The vertical distribution $f : \mathbb{R} \rightarrow \mathbb{R}$ should additionally satisfy (see Fig. 2)

$$\text{supp } f \subset (\frac{R}{c}, \frac{R}{c} + \frac{2\delta}{c}) \subset (\frac{R}{c}, \frac{d}{c}) \quad \text{for some } \delta > 0. \quad (29)$$

This guarantees that the initial field $E^{(0)}$ (and also the magnetic field $H^{(0)}$) not interact with the sample or the mirror for $t \leq 0$ and neither contribute to the measurement at the detectors for $t \geq 0$ as required by (8) and (10).

The condition that the length of the support of $E^{(0)}$ is at most 2δ (the assumption that the support starts at $\frac{R}{c}$ is only made to simplify the notation) is required for **Proposition 8**. It ensures that the formula (13a) for the measurement data $M_r(x)$, $x \in \mathcal{D}$, vanishes for values $r \geq R$ so that the integral on the right hand side of (30) is only over the interval $(-\infty, R)$ where measurement data are obtained (recall that measurements are only performed for positions $r < R$ of the mirror).

Proposition 8. *Let $E^{(0)}$ be an initial illumination of the form (21) satisfying (29). Then, the measurements M_r from Proposition 7 imply for the electric field E :*

$$(\hat{E}_j - \hat{E}_j^{(0)})(\omega, x) \overline{\hat{f}(\omega)} p_j = -\frac{2}{c} \int_{-\infty}^R M_{r,j}(x) e^{-i\frac{\omega}{c}(2r-x_3)} dr \quad (30)$$

for all $j \in \{1, 2, 3\}$, $\omega \in \mathbb{R}$, and $x \in \mathcal{D}$.

Proof. Remark that the formula (24a) can be extended to all $r \in \mathbb{R}$ by setting $M_{r,j}(x) = 0$ for $r \geq R$. Indeed, from (29) it follows that $E(t, \cdot) = E^{(0)}(t, \cdot)$ for all $t < \frac{\delta}{c}$. Since E is a solution of the linear wave equation with constant wave speed c on the half space given by $x_3 > R - \delta$, the difference between E and $E^{(0)}$ caused by the sample needs at least time $\frac{d-R+\delta}{c}$ to travel from the point at $x_3 = R - \delta$ to the detector at $x_3 = d$, so:

$$E(t, x) = E^{(0)}(t, x) \quad \text{for all } x \in \mathbb{R}^3 \text{ with } x_3 = d \text{ and } ct < 2\delta + d - R.$$

This means that the integrand vanishes for $t < \frac{2\delta+d-R}{c}$. In the case of $t \geq \frac{2\delta+d-R}{c}$, it holds for $r \geq R$ that

$$ct + 2r - d \geq 2\delta + d - R + 2R - d = R + 2\delta,$$

so that $f(t + \frac{2r-d}{c}) = 0$ by the assumption (29) on the support of f . Therefore, for $r \geq R$, always one of the factors in the integrand in (24a) is zero which implies that $M_r(x) = 0$ for $r \geq R$ and $x \in \mathcal{D}$.

Thus, Eq. (24b) holds for all $r \in \mathbb{R}$ and applying the inverse Fourier transform with respect to r , using that $\hat{f}(-\omega) = \overline{\hat{f}(\omega)}$ because f is real valued, yields

$$\frac{2}{c} \int_{-\infty}^{\infty} M_{r,j}(x) e^{-i\frac{2\omega r}{c}} dr = -p_j(\hat{E}_j - \hat{E}_j^{(0)})(\omega, x) \overline{\hat{f}(\omega)} e^{-i\frac{\omega}{c}x_3},$$

which can equivalently be written as (30). \square

This means that one can calculate from the Fourier transform of the measurements $r \mapsto M_r(x)$ at some frequency ω the Fourier transform of the electric field at ω as long as the Fourier transform of the initial wave $E^{(0)}$ does not vanish at ω , that is for $\hat{f}(\omega) \neq 0$. Thus, under the Assumption 5 and Assumption 6, Eq. (30) can be solved for the electric field \hat{E} . Proposition 8 thus provides the inverse of the operator \mathcal{M} defined by (28). Now, the inversion of the operator \mathcal{K}_0 given by (27) is performed considering the optical properties of the sample.

Proposition 9. *Let $E^{(0)}(t, x)$ be given by the form (21) with $p_3 = 0$ and the additional assumption (29). Then, for every $\omega \in \mathbb{R} \setminus \{0\}$ with $\hat{f}(\omega) \neq 0$, the formula*

$$p_j \left[\vartheta \times (\vartheta \times \tilde{\chi}(\omega, \frac{\omega}{c}(\vartheta + e_3)) p) \right]_j \simeq \frac{8\pi\rho c}{\omega^2 |\hat{f}(\omega)|^2} \int_{-\infty}^R M_{r,j}(\rho\vartheta) e^{-i\frac{\omega}{c}(2r - \rho(\vartheta_3 - 1))} dr \quad (31)$$

holds for all $j \in \{1, 2\}$, $\vartheta \in S_+^2 := \{\eta \in S^2 \mid \eta_3 > 0\}$, and $\rho = \frac{d}{\vartheta_3}$ (asymptotically for $\chi \rightarrow 0$ and $\rho \rightarrow \infty$).

Here $\tilde{\chi}$ denotes the Fourier transform of χ with respect to time and space, that is

$$\tilde{\chi}(\omega, k) = \int_{-\infty}^{\infty} \int_{\mathbb{R}^3} \chi(t, x) e^{-i\langle k, x \rangle} e^{i\omega t} dx dt = \int_{\mathbb{R}^3} \hat{\chi}(\omega, x) e^{-i\langle k, x \rangle} dx. \quad (32)$$

Proof. Because of (26), the Fourier transform of the electric field $E - E^{(0)}$ can be approximated, using (20) with $E \simeq E^{(1)}$ (by Assumption 5 and Assumption 6), by

$$(\hat{E} - \hat{E}^{(0)})(\omega, \rho\vartheta) \simeq -\frac{\omega^2 \hat{f}(\omega) e^{i\frac{\omega}{c}\rho}}{4\pi\rho c^2} \int_{\mathbb{R}^3} e^{-i\frac{\omega}{c}(\langle y, \vartheta \rangle + y_3)} \vartheta \times (\vartheta \times \hat{\chi}(\omega, y) p) dy.$$

Then, applying (32), one obtains

$$(\hat{E} - \hat{E}^{(0)})(\omega, \rho\vartheta) \simeq -\frac{\omega^2 \hat{f}(\omega) e^{i\frac{\omega}{c}\rho}}{4\pi\rho c^2} \vartheta \times (\vartheta \times \tilde{\chi}(\omega, \frac{\omega}{c}(\vartheta + e_3)) p). \quad (33)$$

From (30), it is known that, for $\hat{f}(\omega) \neq 0$ and $p_j \neq 0$,

$$(\hat{E}_j - \hat{E}_j^{(0)})(\omega, \rho\vartheta) = -\frac{2}{p_j c \hat{f}(\omega)} \int_{-\infty}^R M_{r,j}(\rho\vartheta) e^{-i\frac{\omega}{c}(2r - \rho\vartheta_3)} dr.$$

This identity together with (33), asymptotically for $\omega \neq 0$, yields the statement (31). \square

To derive reconstruction formulas, [Proposition 9](#) is used, which states that from the measurements M_r (under the [Assumption 5](#) and [Assumption 6](#)) the expression

$$p_j [\vartheta \times (\vartheta \times \tilde{\chi}(\omega, \frac{\omega}{c}(\vartheta + e_3)) p)]_j, \quad j = 1, 2, \quad (34)$$

can be calculated. Here, $p \in \mathbb{R}^2 \times \{0\}$ denotes the polarization of the initial illumination $E^{(0)}$, see (21), and $\vartheta \in S_+^2$ is the direction from the origin (where the sample is located) to a detector.

The Isotropic Case

This section analyzes the special case of an isotropic medium, meaning that the susceptibility matrix χ is just a multiple of the unit matrix, so in the following χ is identified with a scalar.

Then, from the sum of the measurements $M_{r,1}$ and $M_{r,2}$, using the formula (31), one obtains the expression

$$\tilde{\chi}(\omega, \frac{\omega}{c}(\vartheta + e_3)) \langle p, \vartheta \times (\vartheta \times p) \rangle = \tilde{\chi}(\omega, \frac{\omega}{c}(\vartheta + e_3)) (\langle \vartheta, p \rangle^2 - |p|^2).$$

Since $\langle \vartheta, p \rangle^2 < |p|^2$ for every combination of $p \in \mathbb{R}^2 \times \{0\}$ and $\vartheta \in S_+^2$, one has direct access to the spatial and temporal Fourier transform

$$\tilde{\chi}(\omega, \frac{\omega}{c}(\vartheta + e_3)), \quad \omega \in \mathbb{R} \setminus \{0\}, \quad \vartheta \in S_+^2, \quad (35)$$

of χ in a subset of $\mathbb{R} \times \mathbb{R}^3$.

However, it remains the problem of reconstructing the four-dimensional susceptibility data χ from the three-dimensional measurement data (35). In the following, some different additional assumptions are discussed to compensate the lack of dimension, see Table 1.

Table 1 Different assumptions about the susceptibility and the corresponding reconstruction formulas

| Assumptions | Reconstruction method | Section |
|--|--|---|
| $\tilde{\chi}(\omega, k) = \tilde{\chi}(k)$ | Reconstruction from partial (three dimensional) Fourier data: $\tilde{\chi}(k), k \in \mathbb{R}^3$, $\Delta(k, e_3) \in (-\frac{\pi}{4}, \frac{\pi}{4})$ | Non-dispersive Medium in Full Field OCT |
| $\tilde{\chi}(\omega, k) = \tilde{\chi}(k_3)$ | Reconstruction from full (one dimensional) Fourier data: $\tilde{\chi}(k_3), k_3 \in \mathbb{R} \setminus \{0\}$ | Non-dispersive Medium with Focused Illumination |
| $\text{supp } \chi(\cdot, x) \subset [0, T]$ $\mathcal{R}(\chi(\tau, \cdot))(\cdot, \varphi)$ is piecewise constant | Recursive formula to get limited angle Radon data $\mathcal{R}(\chi(\tau, \cdot))(\sigma, \varphi), \sigma \in \mathbb{R}, \varphi \in S^2$ with $\Delta(\varphi, e_3) \in (-\frac{\pi}{4}, \frac{\pi}{4})$ | Dispersive Medium |
| $\chi(\tau, x) = \delta(x_1)\delta(x_2)\chi(\tau, x_3)$, $\text{supp } \chi(\cdot, x) \subset [0, T]$, and $\chi(\tau, \cdot)$ is piecewise constant | Recursive formula to reconstruct χ | Dispersive Layered Medium with Focused Illumination |

Here, $(\mathcal{R}g)(\sigma, \varphi) = \int_{\{x \in \mathbb{R}^3 | \langle x, \varphi \rangle = \sigma\}} g(y) ds(y)$, $\sigma \in \mathbb{R}, \varphi \in S^2$, denotes the Radon transform of a function $g : \mathbb{R}^3 \rightarrow \mathbb{R}$.

Non-dispersive Medium in Full Field OCT

The model is simplified by assuming an immediate reaction of the sample to the exterior electric field in (2a). This means that χ can be considered as a delta distribution in time so that its temporal Fourier transform $\hat{\chi}$ does not depend on frequency, that is $\hat{\chi}(\omega, x) = \hat{\chi}(x)$. Thus, the reconstruction reduces to the problem of finding $\hat{\chi}$ from its partial (spatial) Fourier data

$$\begin{aligned} \tilde{\chi}(k) \quad \text{for } k \in \left\{ \frac{\omega}{c}(\vartheta + e_3) \in \mathbb{R}^3 \mid \vartheta \in S^2_+, \omega \in \mathbb{R} \setminus \{0\} \right\} \\ = \left\{ \kappa \in \mathbb{R}^3 \setminus \{0\} \mid \arccos\left(\left\langle \frac{\kappa}{|\kappa|}, e_3 \right\rangle\right) \in \left(-\frac{\pi}{4}, \frac{\pi}{4}\right) \right\}. \end{aligned}$$

Thus, only the Fourier data of χ in the right circular cone \mathcal{C} with axis along e_3 and aperture $\frac{\pi}{2}$ are observed (see Fig. 3). In practice, these data are usually only available for a small range of frequencies ω .

Inverse scattering for full field OCT, under the Born approximation, has been considered by Marks et al. [28, 29] where algorithms to recover the scalar susceptibility were proposed.

Non-dispersive Medium with Focused Illumination

In standard OCT, the illumination is focused to a small region inside the object so that the function χ can be assumed to be constant in the directions e_1 and e_2 (locally the illumination is still assumed to be properly described by a plane wave). Then, the problem can be reduced by two dimensions assuming that the illumination is described by a delta distribution in these two directions. As before, χ is assumed to be frequency independent, so that

$$\hat{\chi}(\omega, x) = \delta(x_1)\delta(x_2)\hat{\chi}(x_3),$$

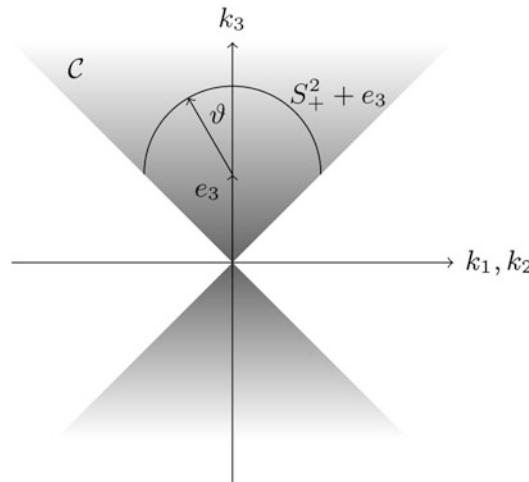

Fig. 3 Region $\mathcal{C} \cong \mathbb{R} \times (S_+^2 + e_3)$ of the available Fourier data of χ

this means that the spatial and temporal Fourier transform (32) fulfils $\tilde{\chi}(\omega, k) = \tilde{\chi}(k_3)$. In this case, the two-dimensional detector array can be replaced by a single point detector located at de_3 .

Then, the measurement data (35) in direction $\vartheta = e_3$ provide the Fourier transform

$$\tilde{\chi}\left(\frac{2\omega}{c}\right) \quad \text{for all } \omega \in \mathbb{R} \setminus \{0\}.$$

Therefore, the reconstruction of the (one dimensional) susceptibility $x_3 \mapsto \hat{\chi}(x_3)$ can be simply obtained by an inverse Fourier transform.

This one-dimensional analysis, has been used initially by Fercher et al. [18], reviewed in [13] and by Hellmuth [22] to describe time domain OCT. Ralston et al. [34,35] described the OCT system using a single backscattering model. The solution was given through numerical simulation using regularized least squares methods.

Dispersive Medium

However, in the case of a dispersive medium, that is frequency-dependent $\hat{\chi}$, the difficulty is to reconstruct the four-dimensional function $\chi : \mathbb{R} \times \mathbb{R}^3 \rightarrow \mathbb{C}$ from the three-dimensional data

$$\hat{m} : \mathbb{R} \times S_+^2 \rightarrow \mathbb{C}, \quad \hat{m}(\omega, \vartheta) = \tilde{\chi}\left(\omega, \frac{\omega}{c}(\vartheta + e_3)\right). \quad (36)$$

Lemma 1. Let \hat{m} be given by (36). Then its inverse Fourier transform $m : \mathbb{R} \times S_+^2 \rightarrow \mathbb{C}$ with respect to the first variable is given by

$$m(t, \vartheta) = \frac{c}{\sqrt{2(1 + \vartheta_3)}} \int_{-\infty}^{\infty} \bar{\chi}(\tau; \tau - t, \vartheta) d\tau, \quad t \in \mathbb{R}, \vartheta \in S_+^2, \quad (37)$$

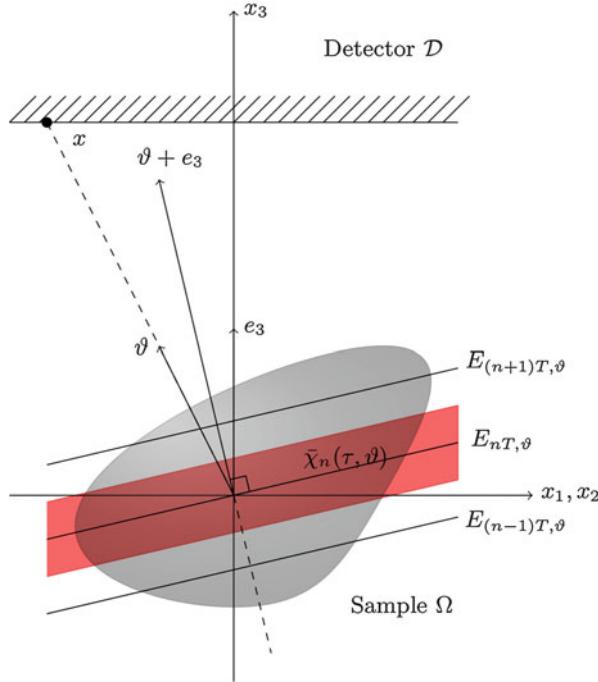

Fig. 4 Discretization of χ with respect to the detection points

where

$$\bar{\chi}(\tau; \sigma, \vartheta) = \int_{E_{\sigma, \vartheta}} \chi(\tau, y) ds(y), \quad \tau, \sigma \in \mathbb{R}, \vartheta \in S^2_+,$$

and $E_{\sigma, \vartheta}$ denotes the plane

$$E_{\sigma, \vartheta} = \{y \in \mathbb{R}^3 \mid \langle \vartheta + e_3, y \rangle = c\sigma\}, \quad \sigma \in \mathbb{R}, \vartheta \in S^2_+. \quad (38)$$

Proof. Taking the inverse temporal Fourier transform of \hat{m} and using (32), it follows that

$$\begin{aligned} m(t, \vartheta) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{\chi}(\omega, \frac{\omega}{c}(\vartheta + e_3)) e^{-i\omega t} d\omega \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{\mathbb{R}^3} \hat{\chi}(\omega, x) e^{-i\frac{\omega}{c} \langle \vartheta + e_3, x \rangle} e^{-i\omega t} dx d\omega. \end{aligned}$$

Interchanging the order of integration, the integral over ω is again described by an inverse Fourier transform and the previous equation becomes

$$m(t, \vartheta) = \int_{\mathbb{R}^3} \chi(t + \frac{1}{c} \langle \vartheta + e_3, x \rangle, x) dx.$$

Substituting then the variable x_3 by $\tau = t + \frac{1}{c} \langle \vartheta + e_3, x \rangle$, this can be written as

$$m(t, \vartheta) = \frac{c}{1 + \vartheta_3} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \chi(\tau, \psi_{\tau-t, \vartheta}(x_1, x_2)) dx_1 dx_2 d\tau \quad (39)$$

with the function

$$\psi_{\sigma, \vartheta} : \mathbb{R}^2 \rightarrow \mathbb{R}^3, \quad \psi_{\sigma, \vartheta}(x_1, x_2) = \left(x_1, x_2, \frac{c\sigma}{1 + \vartheta_3} - \frac{\vartheta_1 x_1 + \vartheta_2 x_2}{1 + \vartheta_3} \right).$$

Now, $\psi_{\sigma, \vartheta}$ is seen to be the parametrization of the plane

$$E_{\sigma, \vartheta} = \{y \in \mathbb{R}^3 \mid \langle v_{\vartheta}, y \rangle = a_{\sigma, \vartheta}\} \quad \text{with} \quad v_{\vartheta} = \begin{pmatrix} \frac{\vartheta_1}{1 + \vartheta_3} \\ \frac{\vartheta_2}{1 + \vartheta_3} \\ 1 \end{pmatrix} \quad \text{and} \quad a_{\sigma, \vartheta} = \frac{c\sigma}{1 + \vartheta_3},$$

see Fig. 4. The square root of the Gram determinant of the parametrization $\psi_{\sigma, \vartheta}$ is now given by the length of the vector $v_{\vartheta} = \frac{\partial \psi_{\sigma, \vartheta}}{\partial x_1} \times \frac{\partial \psi_{\sigma, \vartheta}}{\partial x_2}$, which implies that

$$\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \chi(\tau, \psi_{\tau-t, \vartheta}(x_1, x_2)) dx_1 dx_2 = \sqrt{\frac{1 + \vartheta_3}{2}} \int_{E_{t-t, \vartheta}} \chi(\tau, y) ds(y).$$

Plugging this into (39) yields the claim. \square

Thus, the measurements give the combination (37) of values $\bar{\chi}$ of the Radon transform of the function $\chi(\tau, \cdot)$. It seems, however, impossible to recover the values $\bar{\chi}(\tau; \sigma, \vartheta)$ from this combination

$$m(t, \vartheta) = \frac{c}{\sqrt{2(1 + \vartheta_3)}} \int_{-\infty}^{\infty} \bar{\chi}(\tau; \tau - t, \vartheta) d\tau,$$

since (for every fixed angle $\vartheta \in S_+^2$) one would have to reconstruct a function on \mathbb{R}^2 from one dimensional data.

To overcome this problem, the function $\bar{\chi}(\tau; \cdot, \vartheta)$ is going to be discretized for every $\tau \in \mathbb{R}$ and $\vartheta \in S_+^2$, where the step size will depend on the size of the support of $\chi(\cdot, x)$.

Let us therefore consider the following assumption.

Assumption 7. *The support of χ in the time variable is contained in a small interval $[0, T]$ for some $T > 0$:*

$$\text{supp} \chi(\cdot, x) \subset [0, T] \quad \text{for all } x \in \mathbb{R}^3.$$

Then, the following discretization

$$\bar{\chi}_n(\tau, \vartheta) = \int_{E_{nT,\vartheta}} \chi(\tau, y) ds(y), \quad n \in \mathbb{Z}, \tau \in (0, T), \vartheta \in S_+^2,$$

of the Radon transform of the functions $\chi(\tau, \cdot)$ is considered, where $E_{\sigma,\vartheta}$ denotes the plane defined in (38).

Assumption 8. *The value $\bar{\chi}_n(\tau, \vartheta)$ is a good approximation for the integral of the function $\chi(\tau, \cdot)$ over the planes $E_{nT+\varepsilon,\vartheta}$ for all $\varepsilon \in [-\frac{T}{2}, \frac{T}{2})$ (see Fig. 4), that is*

$$\bar{\chi}_n(\tau, \vartheta) \approx \int_{E_{nT+\varepsilon,\vartheta}} \chi(\tau, y) ds(y), \quad \varepsilon \in [-\frac{T}{2}, \frac{T}{2}), n \in \mathbb{Z}, \tau \in (0, T), \vartheta \in S_+^2.$$

Under the Assumption 8, Eq. (37) can be rewritten in the form

$$m(t, \vartheta) \approx \frac{c}{\sqrt{2(1 + \vartheta_3)}} \int_0^T \bar{\chi}_{N(\tau-t)}(\tau, \vartheta) d\tau,$$

where $N(\sigma) = \lfloor \frac{\sigma}{T} + \frac{1}{2} \rfloor$ denotes the integer closest to $\frac{\sigma}{T}$. This (approximate) identity can now be iteratively solved for $\bar{\chi}$.

Proposition 10. *Let*

$$\bar{m}(t, \vartheta) = \frac{c}{\sqrt{2(1 + \vartheta_3)}} \int_0^T \bar{\chi}_{N(\tau-t)}(\tau, \vartheta) d\tau, \quad \vartheta \in S_+^2, t \in \mathbb{R},$$

for some constant $T > 0$ with the integer-valued function $N(\sigma) = \lfloor \frac{\sigma}{T} + \frac{1}{2} \rfloor$.

Then, $\bar{\chi}$ fulfills the recursion relation

$$\begin{aligned} \bar{\chi}_n(\tau, \vartheta) &= \bar{\chi}_{n+1}(\tau, \vartheta) + \frac{\sqrt{2(1 + \vartheta_3)}}{c} \frac{\partial \bar{m}}{\partial t}(\tau - (n + \frac{1}{2})T, \vartheta), \\ n \in \mathbb{Z}, \tau \in (0, T), \vartheta \in S_+^2. \end{aligned} \tag{40}$$

Proof. Let $t = -nT + \varepsilon$ with $\varepsilon \in [-\frac{T}{2}, \frac{T}{2})$ and $n \in \mathbb{Z}$, then

$$N(\tau - t) = \begin{cases} n & \text{if } \tau \in (0, \frac{T}{2} + \varepsilon), \\ n + 1 & \text{if } \tau \in [\frac{T}{2} + \varepsilon, T). \end{cases}$$

Taking an arbitrary $\varepsilon \in [-\frac{T}{2}, \frac{T}{2})$ and $n \in \mathbb{Z}$, \bar{m} can be formulated as

$$\bar{m}(-nT + \varepsilon, \vartheta) = \frac{c}{\sqrt{2(1 + \vartheta_3)}} \left(\int_0^{\frac{T}{2} + \varepsilon} \bar{\chi}_n(\tau, \vartheta) d\tau + \int_{\frac{T}{2} + \varepsilon}^T \bar{\chi}_{n+1}(\tau, \vartheta) d\tau \right).$$

Differentiating this equation with respect to ε , it follows that

$$\frac{\partial \bar{m}}{\partial t}(-nT + \varepsilon, \vartheta) = \frac{c}{\sqrt{2(1 + \vartheta_3)}} (\bar{\chi}_n(\frac{T}{2} + \varepsilon, \vartheta) - \bar{\chi}_{n+1}(\frac{T}{2} + \varepsilon, \vartheta)),$$

which (with $\tau = \frac{T}{2} + \varepsilon$) is equivalent to (40). \square

Thus, given that $\bar{\chi}_n(t, \vartheta) = 0$ for sufficiently large $n \in \mathbb{Z}$ (recall that $\text{supp } \chi(\tau, \cdot) \subset \Omega$ for all $\tau \in (0, T)$), one can recursively reconstruct $\bar{\chi}$, to obtain the data

$$\int_{E_{\sigma, \vartheta}} \chi(\tau, y) ds(y) \quad \text{for all } \tau \in [0, T], \sigma \in \mathbb{R}, \vartheta \in S_+^2$$

for the Radon transform of $\chi(\tau, \cdot)$.

However, since the plane $E_{\sigma, \vartheta}$ is by its Definition (38) orthogonal to the vector $\vartheta + e_3$ for $\vartheta \in S_+^2$, this provides only the values of the Radon transform corresponding to planes which are orthogonal to a vector in the cone \mathcal{C} , see Fig. 3. For the reconstruction, one therefore still has to invert a limited angle Radon transform.

Dispersive Layered Medium with Focused Illumination

Except from ophthalmology, OCT is also widely used for investigation of skin deceases, such as cancer. From the mathematical point of view, this simplifies the main model since the human skin can be described as a multilayer structure with different optical properties and varying thicknesses in each layer.

Here the incident field is considered to propagate with normal incidence to the interface $x_3 = L$ and the detector array is replaced by a single point detector located at de_3 . The susceptibility is simplified as

$$\chi(t, x) = \delta(x_1)\delta(x_2)\chi(t, x_3),$$

and therefore the measurements provide the data, see (37) with $\tilde{\chi}(\omega, k) = \tilde{\chi}(\omega, k_3)$,

$$\hat{m}(\omega) = \tilde{\chi}(\omega, \frac{\omega}{c}2e_3), \quad \omega \in \mathbb{R} \setminus \{0\}.$$

Considering the special structure of a layered medium, the susceptibility is described by a piecewise constant function in x_3 . This means explicitly that χ has the form

$$\chi(t, x_3) = \begin{cases} \chi_0 := 0, & x_3 \notin [0, L] \\ \chi_n(t), & x_3 \in [L_n, L_{n+1}) \end{cases}, \quad n = 1, \dots, N \quad (41)$$

with (unknown) parameters $L = L_1 > L_2 > \dots > L_{N+1} = 0$ characterizing the thicknesses of the N layers and (unknown) functions χ_n .

Lemma 1, for $\vartheta = e_3$, gives

$$m(t) = \frac{c}{2} \int_{-\infty}^{\infty} \bar{\chi}(\tau; \tau - t) d\tau, \quad \text{where } \bar{\chi}(\tau; \sigma) = \chi(\tau, \frac{c\sigma}{2}).$$

Remarking that $\bar{\chi}$ is piecewise constant (41) and additionally assuming that $\chi(\cdot, x_3)$ has compact support, see [Assumption 7](#), with $T < \frac{2}{c} \min_n (L_n - L_{n+1})$ [Proposition 10](#) can be applied for $\vartheta = e_3$ to iteratively reconstruct χ starting from $\chi_0 = 0$.

Modified Born Approximation

In the proposed iteration scheme, [Proposition 10](#), the traveling of the incident field through the sample before reaching a “specific” layer, where the susceptibility is to be reconstructed, is not considered. To do so, a modified iteration method is presented describing the traveling of the light through the different layers using Frensel’s equations.

The main idea is to consider, for example, in the second step of the recursive formula, given χ_1 to find χ_2 , as incident the field $\hat{E}^{(0)}$, given by (26), traveled also through the first layer. This process can be continued to the next steps.

Let us first introduce some notations which will be used in the following. The fields $\hat{E}_n^{(r)}$ and $\hat{E}_n^{(t)}$ denote the reflected and the transmitted fields, with respect to the boundary L_n , respectively. The transmitted field $\hat{E}_n^{(t)}$ after traveling through the n -th layer is incident on the L_{n+1} boundary and is denoted by $\hat{E}_{n+1}^{(0)}$. The reflected field by the L_{n+1} boundary back to the L_n boundary will be denoted by $\hat{E}_{n+1}^{(r)}$ and by $\hat{E}_n^{(r')}$ after traveling through the n -th layer (see Fig. 5). To simplify this model, multiple reflections are not included and the electric fields are taken to be tangential to the interface planes.

Lemma 2. *Let the sample have susceptibility given by (41) and let ρ_n and τ_n denote the reflection and the corresponding transmission coefficients for the L_n boundary, respectively. Then, the field incident on the n -th layer with respect to the initial incident field $\hat{E}^{(0)} := \hat{E}_1^{(0)}$ is given by*

$$\begin{pmatrix} \hat{E}_n^{(0)} \\ 0 \end{pmatrix} = (\mathcal{M}_1 \cdot \mathcal{M}_2 \cdot \dots \cdot \mathcal{M}_{n-1})^{-1} \begin{pmatrix} \hat{E}^{(0)} \\ \hat{E}_1^{(r)} \end{pmatrix} \quad \text{for } n = N-1, \dots, 2$$

assuming no backward field in the n -th layer, where

$$\mathcal{M}_n = \frac{1}{\tau_n} \begin{pmatrix} e^{i\frac{\omega}{c}\sqrt{\chi_n+1}(L_n-L_{n+1})} & \rho_n e^{-i\frac{\omega}{c}\sqrt{\chi_n+1}(L_n-L_{n+1})} \\ \rho_n e^{i\frac{\omega}{c}\sqrt{\chi_n+1}(L_n-L_{n+1})} & e^{-i\frac{\omega}{c}\sqrt{\chi_n+1}(L_n-L_{n+1})} \end{pmatrix}.$$

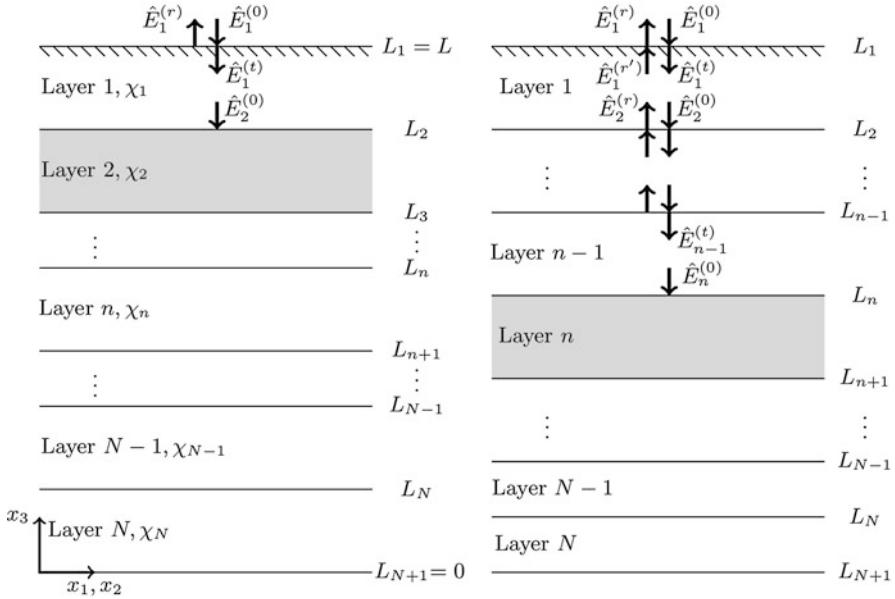

Fig. 5 Layered medium. Propagation of the initial field through the sample incident on the second layer (*left image*) and in general on the n -th layer, for $n = 3, \dots, N$ (*right image*)

Proof. Because of the assumptions (normal incidence, $\hat{E}^{(0)}$ tangential to the boundary) the boundary conditions require the continuity of the total (upward and downward) electric and magnetic fields. Then, the reflection ρ_n and the corresponding transmission τ_n coefficients for the L_n boundary in terms of the susceptibility are given by [21]

$$\rho_n = \frac{\sqrt{\chi_{n-1} + 1} - \sqrt{\chi_n + 1}}{\sqrt{\chi_{n-1} + 1} + \sqrt{\chi_n + 1}}, \quad \tau_n = 1 + \rho_n.$$

To determine the propagation equations for the electric fields, the transfer matrices formulation is applied [30]. In particular, the fields at the top of the n -th layer can be computed with respect to the fields at the top of the $(n + 1)$ th using

$$\begin{pmatrix} \hat{E}_n^{(0)} \\ \hat{E}_n^{(r)} \end{pmatrix} = \mathcal{M}_n \begin{pmatrix} \hat{E}_{n+1}^{(0)} \\ \hat{E}_{n+1}^{(r)} \end{pmatrix} \quad \text{for } n = N-1, \dots, 1.$$

and with respect to the incident field,

$$\begin{pmatrix} \hat{E}_1^{(0)} \\ \hat{E}_1^{(r)} \end{pmatrix} = \mathcal{M}_1 \cdot \dots \cdot \mathcal{M}_{n-1} \begin{pmatrix} \hat{E}_n^{(0)} \\ \hat{E}_n^{(r)} \end{pmatrix} \quad \text{for } n = N-1, \dots, 2.$$

□

From the previous result, given χ_n (by the recursion relation of [Proposition 10](#)), the matrix \mathcal{M}_{n+1} is computed to obtain the update $\hat{E}_{n+1}^{(0)}$ which is then incident to the rest part of the sample. This means that $\hat{E}^{(0)}$ is replaced by $\hat{E}_{n+1}^{(0)}$ in the derivation of the measurements and the recursion relation ([Lemma 1](#) and [Proposition 10](#)) for computing χ_{n+1} . For example, in the second step to reconstruct χ_2 , the incident field is simply given by

$$\hat{E}_2^{(0)} = \tau_1 e^{-i\frac{\omega}{c}\sqrt{\chi_1+1}(L_1-L_2)} \hat{E}^{(0)}.$$

The only unknown in this representation is the boundary L_2 which can be approximated considering the point where change in the value of the measured function \tilde{m} is observed. The following analysis can be also extended for anisotropic media, but in a more complicated context since the displacement D and the electric field E are not always parallel.

A simplification usually made here is to consider the sample field as the sum of all the discrete reflections and neglect dispersion. This mathematical model was adopted by Bruno and Chaubell [[7](#)] for solving the inverse scattering problem of determining the refractive index and the width of each layer from the output data. The solution was obtained using the Gauss–Newton method and the effect of the initial guesses was also considered.

In conclusion, the traveling of the scattered field from the n -th layer through the sample could also be considered. Since the spherical waves can be represented as a superposition of plane waves by using similar techniques, in a more complicated form, one can obtain the transmitted scattered field.

The Anisotropic Case

In the anisotropic case, the susceptibility χ cannot be considered a multiple of the identity. Therefore, the problem is to reconstruct from the expressions

$$p_j [\vartheta \times (\vartheta \times \tilde{\chi}(\omega, \frac{\omega}{c}(\vartheta + e_3)) p)]_j, \quad j = 1, 2,$$

see ([34](#)), the matrix-valued function $\chi : \mathbb{R} \times \mathbb{R}^3 \rightarrow \mathbb{R}^{3 \times 3}$, where it is assumed that measurements for every polarization $p \in \mathbb{R}^2 \times \{0\}$ of the initial field $E^{(0)}$ are available.

Introducing in analogy to ([36](#)) the function

$$\hat{m}_{p,j} : \mathbb{R} \times S_+^2 \rightarrow \mathbb{C}, \quad \hat{m}_{p,j}(\omega, \vartheta) = \tilde{\chi}_{\vartheta, p, j}(\omega, \frac{\omega}{c}(\vartheta + e_3)),$$

where $\tilde{\chi}_{\vartheta, p, j}$ is for every $\vartheta \in S_+^2$, $p \in \mathbb{R}^2 \times \{0\}$, and $j \in \{1, 2\}$ the (spatial and temporal) Fourier transform of

$$\chi_{\vartheta, p, j} : \mathbb{R} \times \mathbb{R}^3 \rightarrow \mathbb{R}, \quad \chi_{\vartheta, p, j}(t, x) = p_j [\vartheta \times (\vartheta \times \chi(t, x) p)]_j,$$

Lemma 1 (with m replaced by $m_{p,j}$ and χ replaced by $\chi_{\vartheta,p,j}$) can be applied to find that the inverse Fourier transform of $\hat{m}_{p,j}$ with respect to its first variable fulfills

$$m_{p,j}(t, \vartheta) = \frac{c}{\sqrt{2(1 + \vartheta_3)}} \int_{-\infty}^{\infty} \int_{E_{\tau-t,\vartheta}} \chi_{\vartheta,p,j}(\tau, y) ds(y) d\tau.$$

Now, the same assumptions as in the isotropic case are considered, namely **Assumption 7** and similar to **Assumption 8**:

Assumption 9. *The approximation*

$$\int_{E_{nT,\vartheta}} \chi_{\vartheta,p,j}(\tau, y) ds(y) \approx \int_{E_{nT+\varepsilon,\vartheta}} \chi_{\vartheta,p,j}(\tau, y) ds(y) \quad \text{for all } \varepsilon \in [-\frac{T}{2}, \frac{T}{2}]$$

is for every $\tau \in \mathbb{R}$, $\vartheta \in S_+^2$, $n \in \mathbb{Z}$, $p \in \mathbb{R}^2 \times \{0\}$, and $j \in \{1, 2\}$ justified.

Then, **Proposition 10** provides an approximate reconstruction formula for the functions

$$\bar{\chi}_{p,j}(\tau; \sigma, \vartheta) = \int_{E_{\sigma,\vartheta}} \chi_{\vartheta,p,j}(\tau, y) ds(y) = p_j [\vartheta \times (\vartheta \times \bar{\chi}(\tau; \sigma, \vartheta) p)]_j \quad (42)$$

for all $p \in \mathbb{R}^2 \times \{0\}$, $\tau \in \mathbb{R}$, $\sigma \in \mathbb{R}$, $\vartheta \in S_+^2$, and $j \in \{1, 2\}$, where

$$\bar{\chi}(\tau; \sigma, \vartheta) = \int_{E_{\sigma,\vartheta}} \chi(\tau, y) ds(y) \quad (43)$$

denotes the two-dimensional Radon transform data of the function $\chi(\tau, \cdot)$.

Proposition 11. *Let $\vartheta \in S_+^2$ be fixed and $a_{p,j}$, $p \in \mathbb{R}^2 \times \{0\}$, $j = 1, 2$, be such that the equations*

$$p_j [\vartheta \times (\vartheta \times X p)]_j = a_{p,j} \quad \text{for all } p \in \mathbb{R}^2 \times \{0\}, \quad j \in \{1, 2\}, \quad (44)$$

for the matrix $X \in \mathbb{R}^{3 \times 3}$ have a solution.

Then $X \in \mathbb{R}^{3 \times 3}$ is a solution of (44) if and only if

$$(P_\vartheta X)_{k\ell} = B_{k\ell}, \quad B = \begin{pmatrix} -a_{e_1,1} & a_{e_1,1} - a_{e_1+e_2,1} \\ a_{e_2,2} - a_{e_1+e_2,2} & -a_{e_2,2} \end{pmatrix}, \quad k, \ell \in \{1, 2\}, \quad (45)$$

where $P_\vartheta \in \mathbb{R}^{3 \times 3}$ denotes the orthogonal projection in direction ϑ .

Proof. First, remark that the equation system (44) is equivalent to the four equations

$$\begin{aligned} a_{e_1,1} &= [\vartheta \times (\vartheta \times X e_1)]_1, & a_{e_1+e_2,1} &= a_{e_1,1} + [\vartheta \times (\vartheta \times X e_2)]_1, \\ a_{e_2,2} &= [\vartheta \times (\vartheta \times X e_2)]_2, & a_{e_1+e_2,2} &= a_{e_2,2} + [\vartheta \times (\vartheta \times X e_1)]_2, \end{aligned} \quad (46)$$

which correspond to the Eq. (44) for $(p, j) \in \{(e_1, 1), (e_2, 2), (e_1 + e_2, 1), (e_1 + e_2, 2)\}$. Indeed, for arbitrary polarization $p = p_1 e_1 + p_2 e_2$, the expression $p_j [\vartheta \times (\vartheta \times X p)]_j$ can be written as a linear combination of the four expressions $[\vartheta \times (\vartheta \times X e_i)]_k$, $i, k = 1, 2$:

$$\begin{aligned} p_1 [\vartheta \times (\vartheta \times X p)]_1 &= p_1^2 [\vartheta \times (\vartheta \times X e_1)]_1 + p_1 p_2 [\vartheta \times (\vartheta \times X e_2)]_1, \\ p_2 [\vartheta \times (\vartheta \times X p)]_2 &= p_1 p_2 [\vartheta \times (\vartheta \times X e_1)]_2 + p_2^2 [\vartheta \times (\vartheta \times X e_2)]_2, \end{aligned}$$

and is thus determined by (46).

Now, the equation system (46) written in matrix form reads

$$[\vartheta \times (\vartheta \times X p)]_k = - \left[B \begin{pmatrix} p_1 \\ p_2 \end{pmatrix} \right]_k, \quad k \in \{1, 2\}, \quad (47)$$

for all $p \in \mathbb{R}^2 \times \{0\}$ with B defined by (45).

Decomposing $X p = \langle \vartheta, X p \rangle \vartheta + P_\vartheta X p$, where $P_\vartheta \in \mathbb{R}^{3 \times 3}$ denotes the orthogonal projection in direction ϑ , and using that

$$\vartheta \times (\vartheta \times X p) = \vartheta \times (\vartheta \times P_\vartheta X p) = \langle \vartheta, P_\vartheta X p \rangle \vartheta - P_\vartheta X p = -P_\vartheta X p,$$

the Eq. (47) can be written in the form (45). \square

Proposition 11 applied to the Eq. (42) for the matrix $X = \bar{\chi}(\tau; \sigma, \vartheta)$ for some fixed values $\tau, \sigma \in \mathbb{R}$ and $\vartheta \in S_+^2$ shows that the data $a_{p,j} = p_j [\vartheta \times (\vartheta \times \bar{\chi}(\tau; \sigma, \vartheta))]_j$ for $j = 1, 2$ and the three different polarization vectors $p = e_1$, $p = e_2$, and $p = e_1 + e_2$ uniquely determine with Eq. (45) the projection

$$(P_\vartheta \bar{\chi}(\tau; \sigma, \vartheta))_{k,\ell} = \int_{E_{\sigma,\vartheta}} (P_\vartheta \chi(\tau, y))_{k,\ell} ds(y) \quad \text{for } k, \ell \in \{1, 2\}.$$

Moreover, measurements for additional polarizations p do not provide any further information so that at every detector point, corresponding to a direction $\vartheta \in S_+^2$, only the four elements $(P_\vartheta \chi)_{k,\ell}$, $k, \ell = 1, 2$, of the projection $P_\vartheta \chi$ influence the measurements.

To obtain additional data which make a full reconstruction of χ possible, one can carry out extra measurements after slight rotations of the sample.

So, let $R \in \text{SO}(3)$ describe the rotation of the sample. Then the transformed susceptibility χ_R is given by

$$\chi_R(t, y) = R \chi(t, R^T y) R^T. \quad (48)$$

Lemma 3. Let $\chi : \mathbb{R} \times \mathbb{R}^3 \rightarrow \mathbb{R}^{3 \times 3}$ be the susceptibility of the sample and $\vartheta \in S_+^2$ be given. Furthermore, let $R \in \text{SO}(3)$ be such that there exists a constant $\alpha_R > 0$ and a direction $\vartheta_R \in S_+^2$ with

$$\vartheta_R + e_3 = \alpha_R R(\vartheta + e_3) \quad (49)$$

and define the susceptibility χ_R of the rotated sample by (48).

Then, the data

$$\bar{\chi}_{R,p,j}(\tau; \sigma, \vartheta_R) = p_j \left[\vartheta_R \times \left(\vartheta_R \times \int_{E_{\sigma,\vartheta_R}} \chi_R(\tau, y) ds(y) \right) \right]_j, \quad (50)$$

corresponding to the measurements of the rotated sample at the detector in direction ϑ_R , see (42), fulfil that

$$\bar{\chi}_{R,p,j}(\tau; \alpha_R \sigma, \vartheta_R) = p_j [\vartheta_R \times (\vartheta_R \times R \bar{\chi}(\tau; \sigma, \vartheta) R^T)]_j \quad (51)$$

for all $\tau, \sigma \in \mathbb{R}$, $p \in \mathbb{R}^2 \times \{0\}$, $j = 1, 2$, where $\bar{\chi}$ is given by (43).

Proof. Inserting Definition (48) and substituting $z = R^T y$, formula (50) becomes

$$\bar{\chi}_{R,p,j}(\tau; \sigma, \vartheta_R) = p_j \left[\vartheta_R \times \left(\vartheta_R \times \int_{R^T E_{\sigma,\vartheta_R}} R \chi(\tau, z) R^T ds(z) \right) \right]_j.$$

Since now, by the Definition (38) of the plane $E_{\sigma,\vartheta}$ and by the Definition (49) of ϑ_R ,

$$\begin{aligned} R^T E_{\sigma,\vartheta_R} &= \{R^T y \in \mathbb{R}^3 \mid \langle \vartheta_R + e_3, y \rangle = c\sigma\} \\ &= \{z \in \mathbb{R}^3 \mid \langle R^T(\vartheta_R + e_3), z \rangle = c\sigma\} \\ &= \{z \in \mathbb{R}^3 \mid \alpha_R \langle \vartheta + e_3, z \rangle = c\sigma\} = E_{\frac{\sigma}{\alpha_R}, \vartheta}, \end{aligned}$$

it follows (51). \square

This means that the data $\bar{\chi}_{R,p,j}(\tau; \alpha_R \sigma, \vartheta_R)$ obtained from a detector placed in the direction ϑ_R , defined by (49), depends only on the Radon transform data $\bar{\chi}(\tau; \sigma, \vartheta)$. However, it still remains the algebraic problem of solving the Eq. (51) for different rotations R to obtain the matrix $\bar{\chi}(\tau; \sigma, \vartheta) \in \mathbb{R}^{3 \times 3}$.

Proposition 12. Let $A \in \mathbb{R}^{3 \times 3}$ and $\vartheta \in S_+^2$ be given. Moreover, let $R_0, R_1, R_2 \in \text{SO}(3)$ be rotations so that every proper subset of $\{R_0^T e_3, R_1^T e_3, R_2^T e_3, \vartheta + e_3\}$ is linearly independent and such that there exist for every $R \in \{R_0, R_1, R_2\}$ constants $\alpha_R > 0$ and $\vartheta_R \in S_+^2$ fulfilling (49).

Let further $P \in \mathbb{R}^{2 \times 3}$ be the orthogonal projection in direction e_3 , $P_\theta \in \mathbb{R}^{3 \times 3}$ the orthogonal projection in direction $\vartheta \in \mathbb{R}^3$, and

$$B_R = \begin{pmatrix} -a_{R,e_1,1} & a_{R,e_1,1} - a_{R,e_1+e_2,1} \\ a_{R,e_2,2} - a_{R,e_1+e_2,2} & -a_{R,e_2,2} \end{pmatrix},$$

$$a_{R,p,j} = p_j [\vartheta_R \times (\vartheta_R \times RAR^\top p)]_j,$$

for every $R \in \{R_0, R_1, R_2\}$.

Then, the equations

$$PP_{\vartheta_R}RXR^\top P^\top = B_R, \quad R \in \{R_0, R_1, R_2\} \quad (52)$$

have the unique solution $X = A$.

Proof. Using that $\vartheta_R = \alpha_R R(\vartheta + e_3) - e_3$, see (49), it follows with $Pe_3 = 0$ that

$$PP_{\vartheta_R} = P(\mathbb{1} - \vartheta_R \vartheta_R^\top) = P - \alpha_R PR(\vartheta + e_3)\vartheta_R^\top.$$

With this identity, the Eq. (52) can be written in the form

$$PR(X - \alpha_R(\vartheta + e_3)\vartheta_R^\top RX)R^\top P^\top = B_R. \quad (53)$$

Let now $\eta_R \in \mathbb{R}^3$ denote a unit vector orthogonal to $\vartheta + e_3$ and orthogonal to $R^\top e_3$. Then $R\eta_R$ is orthogonal to e_3 and therefore, with $P^\top P = Pe_3$,

$$(PR\eta_R)^\top PR = (Pe_3 R\eta_R)^\top R = (R\eta_R)^\top R = \eta_R^\top.$$

Thus, multiplying the Eq. (53) from the left with $(PR\eta_R)^\top$, it follows that

$$\eta_R^\top (X - \alpha_R(\vartheta + e_3)\vartheta_R^\top RX)R^\top P^\top = (PR\eta_R)^\top B_R.$$

Since now η_R is orthogonal to $\vartheta + e_3$, this simplifies to

$$\eta_R^\top XR^\top P^\top = (PR\eta_R)^\top B_R. \quad (54)$$

Remarking that the orthogonal projection onto the line $\mathbb{R}\eta_R$ can be written as the composition of two orthogonal projections onto orthogonal planes with intersection $\mathbb{R}\eta_R$:

$$\eta_R \eta_R^\top = P_{v_R} P_{\vartheta+e_3},$$

where v_R is a unit vector orthogonal to η_R and $\vartheta + e_3$, and multiplying Eq. (54) from the left with η_R , one finds that

$$P_{v_R}(P_{\vartheta+e_3}X)R^T P^T = \eta_R(PR\eta_R)^T B_R.$$

Applying then the projection P from the right and using that $R^T P^T P = R^T P_{e_3} = P_{R^T e_3} R^T$, this can be written in the form

$$P_{v_R}(P_{\vartheta+e_3}X)P_{R^T e_3} = \eta_R(PR\eta_R)^T B_R PR. \quad (55)$$

Evaluating this equation now for $R = R_0, R_1, R_2$ and remarking that $\{v_{R_0}, v_{R_1}, v_{R_2}\}$ and $\{R_0^T e_3, R_1^T e_3, R_2^T e_3\}$ are linearly independent, one concludes that the 3×3 matrix $P_{\vartheta+e_3} X$ is uniquely determined by (55).

However, it is also possible to calculate X (and not only its projection $P_{\vartheta+e_3}X$) from Eq. (53). Because

$$X = P_{\vartheta+e_3}X + \frac{1}{|\vartheta+e_3|^2}(\vartheta+e_3)(\vartheta+e_3)^T X,$$

it follows from (53) that

$$\begin{aligned} PR \left(\frac{\vartheta+e_3}{|\vartheta+e_3|^2} (1 - \alpha_R \vartheta_R^T R (\vartheta+e_3)) (\vartheta+e_3)^T X \right) R^T P^T \\ = B_R - PR(1 - \alpha_R (\vartheta+e_3) \vartheta_R^T R) P_{\vartheta+e_3} X R^T P^T. \end{aligned} \quad (56)$$

Plugging in the identity

$$\alpha_R \vartheta_R^T R (\vartheta+e_3) = \vartheta_R^T (\vartheta_R + e_3) = 1 + \vartheta_{R,3},$$

which follows from the Definition (49) of ϑ_R , applying P^T from the left and P from the right, and using as before $R^T P^T P = P_{R^T e_3} R^T$, the Eq. (56) yields

$$\begin{aligned} -\vartheta_{R,3} P_{R^T e_3} \left(\frac{\vartheta+e_3}{|\vartheta+e_3|^2} (\vartheta+e_3)^T X \right) P_{R^T e_3} \\ = R^T P^T B_R P R - P_{R^T e_3} (1 - \alpha_R (\vartheta+e_3) \vartheta_R^T R) P_{\vartheta+e_3} X P_{R^T e_3}. \end{aligned} \quad (57)$$

Since the right hand side is already known (it depends only on $P_{\vartheta+e_3}X$), the equation system (57) for $R = R_0, R_1, R_2$ can be uniquely solved for

$$\frac{\vartheta+e_3}{|\vartheta+e_3|^2} (\vartheta+e_3)^T X.$$

Therefore, the Eq. (52) uniquely determine X and because A is by construction a solution of the equations, this implies that $X = A$. \square

Thus, applying [Proposition 12](#) to the matrix $A = \bar{\chi}(\tau; \sigma, \vartheta)$ shows that the measurements $a_{R,p,j}$ obtained at the detectors ϑ_R for the polarizations $p = e_1, e_2, e_1 + e_2$ and rotations $R = R_0, R_1, R_2$, fulfilling the assumptions of [Proposition 12](#) provide sufficient information to reconstruct the Radon data $\bar{\chi}(\tau; \sigma, \vartheta)$. Calculating these two-dimensional Radon data for all directions ϑ in some subset of S^2_+ (by considering some additional rotations so that for every direction ϑ , there exist three rotations fulfilling the assumptions of [Proposition 12](#)), it is possible via an inversion of a limited angle Radon transform to finally recover the susceptibility χ .

6 Conclusion

In this chapter, a general mathematical model of OCT based on Maxwell's equations has been presented. As a consequence of this modeling, OCT was formulated as an inverse scattering problem for the susceptibility χ . It was shown that without additional assumptions about the optical properties of the medium, in general, χ cannot be reconstructed due to lack of measurements. Some reasonable physical assumptions were presented, under which the medium can, in fact, be reconstructed. For instance, if the medium is isotropic, iterative schemes to reconstruct the susceptibility were developed. Dispersion and focus illumination are also considered. For an anisotropic medium, it follows that different incident fields, with respect to direction (rotating the sample) and polarization, should be considered to completely recover χ .

Acknowledgments The authors would like to thank Wolfgang Drexler and Boris Hermann from the Medical University Vienna for their valuable comments and stimulating discussions. Abstract

This chapter discusses imaging methods related to wave phenomena, and in particular, inverse problems for the wave equation will be considered. The first part of the chapter explains the boundary control method for determining a wave speed of a medium from the response operator, which models boundary measurements. The second part discusses the scattering relation and travel times, which are different types of boundary data contained in the response operator. The third part gives a brief introduction to curvelets in wave imaging for media with nonsmooth wave speeds. The focus will be on theoretical results and methods.

1 Introduction

This chapter discusses imaging methods related to wave phenomena. Of the different types of waves that exist, we will focus on acoustic waves and problems which can be modeled by the acoustic wave equation. In the simplest case, this is the second-order linear hyperbolic equation

$$\partial_t^2 u(x, t) - c(x)^2 \Delta u(x, t) = 0$$

for a sound speed $c(x)$. This equation can be considered as a model for other hyperbolic equations, and the methods presented here can in some cases be extended to study wave phenomena in other fields such as electromagnetism or elasticity.

We will mostly be interested in inverse problems for the wave equation. In these problems, one has access to certain measurements of waves (the solutions u) on the surface of a medium, and one would like to determine material parameters (the sound speed c) of the interior of the medium from these boundary measurements. A typical field where such problems arise is seismic imaging, where one wishes to determine the interior structure of Earth by making various measurements of waves at the surface. We will not describe seismic imaging applications in more detail here, since they are discussed elsewhere in this volume.

Another feature in this chapter is that we will consistently consider *anisotropic* materials, where the sound speed depends on the direction of propagation. This means that the scalar sound speed $c(x)$, where $x = (x^1, x^2, \dots, x^n) \in \Omega \subset \mathbb{R}^n$, is replaced by a positive definite symmetric matrix $(g^{jk}(x))_{j,k=1}^n$, and the wave equation becomes

$$\partial_t^2 u(x, t) - \sum_{j,k=1}^n g^{jk}(x) \frac{\partial^2 u}{\partial x^j \partial x^k}(x, t) = 0.$$

Anisotropic materials appear frequently in applications such as in seismic imaging.

It will be convenient to interpret the anisotropic sound speed (g^{jk}) as the inverse of a Riemannian metric, thus modeling the medium as a *Riemannian manifold*. The benefits of such an approach are twofold. First, the well-established methods of Riemannian geometry become available to study the problems, and second, this provides an efficient way of dealing with the invariance under changes of coordinates present in many anisotropic wave imaging problems. The second point means that in inverse problems in anisotropic media, one can often only expect to recover the matrix (g^{jk}) up to a change of coordinates given by some diffeomorphism. In practice, this ambiguity could be removed by some a priori knowledge of the medium properties (such as the medium being in fact isotropic, see section “From Boundary Distance Functions to Riemannian Metric”).

2 Background

This chapter contains three parts which discuss different topics related to wave imaging. The first part considers the inverse problem of determining a sound speed in a wave equation from the response operator, also known as the hyperbolic Dirichlet-to-Neumann map, by using the boundary control method; see [5, 7, 42]. The second part considers other types of boundary measurements of waves, namely, the scattering relation and boundary distance function, and discusses corresponding inverse problems. The third part is somewhat different in nature and does not consider any inverse problems but rather gives an introduction to the use of curvelet decompositions in wave imaging for nonsmooth sound speeds. We briefly describe these three topics.

Wave Imaging and Boundary Control Method

Let us consider an isotropic wave equation. Let $\Omega \subset \mathbb{R}^n$ be an open, bounded set with smooth boundary $\partial\Omega$, and let $c(x)$ be a scalar-valued positive function in $C^\infty(\overline{\Omega})$ modeling the wave speed in Ω . First, we consider the wave equation

$$\begin{aligned} \partial_t^2 u(x, t) - c(x)^2 \Delta u(x, t) &= 0 && \text{in } \Omega \times \mathbb{R}_+, \\ u|_{t=0} &= 0, & u_t|_{t=0} &= 0, \\ c(x)^{-n+1} \partial_n u &= f(x, t) && \text{in } \partial\Omega \times \mathbb{R}_+, \end{aligned} \tag{1}$$

where ∂_n denotes the Euclidean normal derivative and n is the unit interior normal. We denote by $u^f = u^f(x, t)$ the solution of (1) corresponding to the boundary source term f .

Let us assume that the domain $\Omega \subset \mathbb{R}^n$ is known. The inverse problem is to reconstruct the wave speed $c(x)$ when we are given the set

$$\{(f|_{\partial\Omega \times (0, 2T)}, u^f|_{\partial\Omega \times (0, 2T)}) : f \in C_0^\infty(\partial\Omega \times \mathbb{R}_+)\},$$

that is, the Cauchy data of solutions corresponding to all possible boundary sources $f \in C_0^\infty(\partial\Omega \times \mathbb{R}_+)$, $T \in (0, \infty]$. If $T = \infty$, then this data is equivalent to the *response operator*

$$\Lambda_\Omega : f \mapsto u^f|_{\partial\Omega \times \mathbb{R}_+}, \tag{2}$$

which is also called the *nonstationary Neumann-to-Dirichlet map*. Physically, $\Lambda_\Omega f$ describes the measurement of the medium response to any applied boundary source f , and it is equivalent to various physical measurements. For instance, measuring how much energy is needed to force the boundary value $c(x)^{-n+1} \partial_n u|_{\partial\Omega \times \mathbb{R}_+}$ to be equal to any given boundary value $f \in C_0^\infty(\partial\Omega \times \mathbb{R}_+)$ is equivalent to

measuring the map Λ_Ω on $\partial\Omega \times \mathbb{R}_+$; see [42, 44]. Measuring Λ_Ω is also equivalent to measuring the corresponding Neumann-to-Dirichlet map for the heat or the Schrödinger equations or measuring the eigenvalues and the boundary values of the normalized eigenfunctions of the elliptic operator $-c(x)^2 \Delta$; see [44].

The inverse problems for the wave equation and the equivalent inverse problems for the heat or the Schrödinger equations go back to works of M. Krein at the end of the 1950s, who used the causality principle in dealing with the one-dimensional inverse problem for an inhomogeneous string, $u_{tt} - c^2(x)u_{xx} = 0$; see, for example, [46]. In his works, causality was transformed into analyticity of the Fourier transform of the solution. A more straightforward hyperbolic version of the method was suggested by A. Blagovestchenskii at the end of 1960s to 1970s [12, 13]. The multidimensional case was studied by M. Belishev [4] in the late 1980s who understood the role of the PDE control for these problems and developed the boundary control method for hyperbolic inverse problems in domains of Euclidean space. Of crucial importance for the boundary control method was the result of D. Tataru in 1995 [77, 79] concerning a Holmgren-type uniqueness theorem for nonanalytic coefficients. The boundary control method was extended to the anisotropic case by M. Belishev and Y. Kurylev [7]. The geometric version of the boundary control method which we consider in this chapter was developed in [7, 41, 42, 47]. We will consider the inverse problem in the more general setting of an anisotropic wave equation in an unbounded domain or on a non-compact manifold. These problems have been studied in detail in [39, 43] also in the case when the measurements are done only on a part of the boundary. In this paper we present a simplified construction method applicable for non-compact manifolds in the case when measurements are done on the whole boundary. We demonstrate these results in the case when we have an isotropic wave speed $c(x)$ in a bounded domain of Euclidean space. For this, we use the fact that in the Euclidean space, the only conformal deformation of a compact domain fixing the boundary is the identity map. This implies that after the abstract manifold structure (M, g) corresponding to the wave speed $c(x)$ in a given domain Ω is constructed, we can construct in an explicit way the embedding of the manifold M to the domain Ω and determine $c(x)$ at each point $x \in \Omega$. We note on the history of this result that using Tataru's unique continuation result [77], Theorem 2 concerning this case can be proven directly using the boundary control method developed for domains in Euclidean space in [4].

The reconstruction of non-compact manifolds has been considered also in [11, 27] with different kind of data, using iterated time reversal for solutions of the wave equation. We note that the boundary control method can be generalized also for Maxwell and Dirac equations under appropriate geometric conditions [50, 51], and its stability has been analyzed in [1, 45].

Travel Times and Scattering Relation

The problem considered in the previous section of recovering a sound speed from the response operator is highly overdetermined in dimensions $n \geq 2$. The Schwartz

kernel of the response operator depends on $2n$ variables, and the sound speed c depends on n variables.

In section “Travel Times and Scattering Relation,” we will show that other types of boundary measurements in wave imaging can be directly obtained from the response operator. One such measurement is the *boundary distance function*, a function of $2n - 2$ variables, which measures the travel times of shortest geodesics between boundary points. The problem of determining a sound speed from the travel times of shortest geodesics is the *inverse kinematic problem*. The more general problem of determining a Riemannian metric (corresponding to an anisotropic sound speed) up to isometry from the boundary distance function is the *boundary rigidity problem*. The problem is formally determined if $n = 2$ but overdetermined for $n \geq 3$.

This problem arose in geophysics in an attempt to determine the inner structure of the Earth by measuring the travel times of seismic waves. It goes back to Herglotz [37] and Wiechert and Zoeppritz [84] who considered the case of a radial metric conformal to the Euclidean metric. Although the emphasis has been in the case that the medium is isotropic, the anisotropic case has been of interest in geophysics since the Earth is anisotropic. It has been found that even the inner core of the Earth exhibits anisotropic behavior [24].

To give a proper definition of the boundary distance function, we will consider a bounded domain $\Omega \subset \mathbb{R}^n$ with smooth boundary to be equipped with a Riemannian metric g , that is, a family of positive definite symmetric matrices $g(x) = (g_{jk}(x))_{j,k=1}^n$ depending smoothly on $x \in \overline{\Omega}$. The length of a smooth curve $\gamma : [a, b] \rightarrow \overline{\Omega}$ is defined to be

$$L_g(\gamma) = \int_a^b \left(\sum_{j,k=1}^n g_{jk}(\gamma(t)) \dot{\gamma}^j(t) \dot{\gamma}^k(t) \right)^{1/2} dt.$$

The distance function $d_g(x, y)$ for $x, y \in \overline{\Omega}$ is the infimum of the lengths of all piecewise smooth curves in $\overline{\Omega}$ joining x and y . The boundary distance function is $d_g(x, y)$ for $x, y \in \partial\Omega$.

In the boundary rigidity problem, one would like to determine a Riemannian metric g from the boundary distance function d_g . In fact, since $d_g = d_{\psi^* g}$ for any diffeomorphism $\psi : \overline{\Omega} \rightarrow \overline{\Omega}$ which fixes each boundary point, we are looking to recover from d_g the metric g up to such a diffeomorphism. Here, $\psi^* g(y) = D\psi(y)^t g(\psi(y)) D\psi(y)$ is the pullback of g by ψ .

It is easy to give counterexamples showing that this cannot be done in general; consider, for instance, the closed hemisphere, where boundary distances are given by boundary arcs so making the metric larger in the interior does not change d_g . Michel [55] conjectured that a *simple* metric g is uniquely determined, up to an action of a diffeomorphism fixing the boundary, by the boundary distance function $d_g(x, y)$ known for all x and y on $\partial\Omega$. A metric is called simple if for any two

points in $\overline{\Omega}$, there is a unique length minimizing geodesic joining them, and if the boundary is strictly convex.

The conjecture of Michel has been proved for two-dimensional simple manifolds [60]. In higher dimensions, it is open, but several partial results are known, including the recent results of Burago and Ivanov for metrics close to Euclidean [15] and close to hyperbolic [16] (see the survey [40]). Earlier and related works include results for simple metrics conformal to each other [8, 10, 26, 56–58], for flat metrics [34], for locally symmetric spaces of negative curvature [9], for two-dimensional simple metrics with negative curvature [25, 59], a local result [70], a semiglobal solvability result [54], and a result for generic simple metrics [71].

In case the metric is not simple, instead of the boundary distance function, one can consider the more general *scattering relation* which encodes, for any geodesic starting and ending at the boundary, the start point and direction, the end point and direction, and the length of the geodesic. We will see in section “Travel Times and Scattering Relation” that also this information can be determined directly from the response operator. If the metric is simple, then the scattering relation and boundary distance function are equivalent, and either one is determined by the other.

The *lens rigidity problem* is to determine a metric up to isometry from the scattering relation. There are counterexamples of manifolds which are trapping, and the conjecture is that on a nontrapping manifold the metric is determined by the scattering relation up to isometry. We refer to [72] and the references therein for known results on this problem.

Curvelets and Wave Equations

In section “Curvelets and Wave Equations,” we describe an alternative approach to the analysis of solutions of wave equations, based on a decomposition of functions into basic elements called *curvelets* or *wave packets*. This approach also works for wave speeds of limited smoothness unlike some of the approaches presented earlier. Furthermore, the curvelet decomposition yields efficient representations of functions containing sharp wave fronts along curves or surfaces, thus providing a common framework for representing such data and analyzing wave phenomena and imaging operators. Curvelets and related methods have been proposed as computational tools for wave imaging, and the numerical aspects of the theory are a subject of ongoing research.

A curvelet decomposition was introduced by Smith [67] to construct a solution operator for the wave equation with $C^{1,1}$ sound speed and to prove Strichartz estimates for such equations. This started a body of research on L^p estimates for low-regularity wave equations based on curvelet-type methods; see, for instance, Tataru [80–82], Smith [68], and Smith and Sogge [69]. Curvelet decompositions have their roots in harmonic analysis and the theory of Fourier integral operators,

where relevant works include Córdoba and Fefferman [23] and Seeger et al. [65] (see also Stein [73]).

In a rather different direction, curvelet decompositions came up in image analysis as an optimally sparse way of representing images with C^2 edges; see Candès and Donoho [20] (the name “curvelet” was introduced in [19]). The property that curvelets yield sparse representations for wave propagators was studied in Candès and Demanet [17, 18]. Numerical aspects of curvelet-type methods in wave computation are discussed in [21, 30]. Finally, both theoretical and practical aspects of curvelet methods related to certain seismic imaging applications are studied in [2, 14, 29, 31, 64].

3 Mathematical Modeling and Analysis

Boundary Control Method

Inverse Problems on Riemannian Manifolds

Let $\Omega \subset \mathbb{R}^n$ be an open, bounded set with smooth boundary $\partial\Omega$ and let $c(x)$ be a scalar-valued positive function in $C^\infty(\overline{\Omega})$, modeling the wave speed in Ω . We consider the closure $\overline{\Omega}$ as a differentiable manifold M with a smooth, nonempty boundary. We consider also a more general case, and allow (M, g) to be a possibly non-compact, complete manifold with boundary. This means that the manifold contains its boundary ∂M and M is complete with metric d_g defined below. Moreover, near each point $x \in M$, there are coordinates (U, X) , where $U \subset M$ is a neighborhood of x and $X : U \rightarrow \mathbb{R}^n$ if x is an interior point, or $X : U \rightarrow \mathbb{R}^{n-1} \times [0, \infty)$ if x is a boundary point such that for any coordinate neighborhoods (U, X) and (\tilde{U}, \tilde{X}) , the transition functions $X \circ \tilde{X}^{-1} : \tilde{X}(U \cap \tilde{U}) \rightarrow X(U \cap \tilde{U})$ are C^∞ -smooth. Note that all compact Riemannian manifolds are complete according to this definition. Usually we denote the components of X by $X(y) = (x^1(y), \dots, x^n(y))$.

Let u be the solution of the wave equation

$$\begin{aligned} u_{tt}(x, t) + Au(x, t) &= 0 \quad \text{in } M \times \mathbb{R}_+, \\ u|_{t=0} &= 0, \quad u_t|_{t=0} = 0, \\ B_{v, \eta} u|_{\partial M \times \mathbb{R}_+} &= f. \end{aligned} \tag{3}$$

Here, $f \in C_0^\infty(\partial M \times \mathbb{R}_+)$ is a real-valued function, and $A = A(x, D)$ is an elliptic partial differential operator of the form

$$Av = - \sum_{j,k=1}^n \mu(x)^{-1} |g(x)|^{-\frac{1}{2}} \frac{\partial}{\partial x^j} \left(\mu(x) |g(x)|^{\frac{1}{2}} g^{jk}(x) \frac{\partial v}{\partial x^k}(x) \right) + q(x)v(x), \tag{4}$$

where $g^{jk}(x)$ is a smooth, symmetric, real, positive definite matrix, $|g| = \det(g^{jk}(x))^{-1}$, and $\mu(x) > 0$ and $q(x)$ are smooth real-valued functions. On

existence and properties of the solutions of Eq.(3), see [52]. The inverse of the matrix $(g^{jk}(x))_{j,k=1}^n$, denoted $(g_{jk}(x))_{j,k=1}^n$ defines a Riemannian metric on M . The tangent space of M at x is denoted by $T_x M$, and it consists of vectors p which in local coordinates (U, X) , $X(y) = (x^1(y), \dots, x^n(y))$ are written as $p = \sum_{k=1}^n p^k \frac{\partial}{\partial x^k}$. Similarly, the cotangent space $T_x^* M$ of M at x consists of covectors which are written in the local coordinates as $\xi = \sum_{k=1}^n \xi_k dx^k$. The inner product which g determines in the cotangent space $T_x^* M$ of M at the point x is denoted by $\langle \xi, \eta \rangle_g = g(\xi, \eta) = \sum_{j,k=1}^n g^{jk}(x) \xi_j \eta_k$ for $\xi, \eta \in T_x^* M$. We use the same notation for the inner product at the tangent space $T_x M$, that is, $\langle p, q \rangle_g = g(p, q) = \sum_{j,k=1}^n g_{jk}(x) p^j q^k$ for $p, q \in T_x M$.

The metric defines a distance function, which we call also the travel time function,

$$d_g(x, y) = \inf |\mu|, \quad |\mu| = \int_0^1 \langle \partial_s \mu(s), \partial_s \mu(s) \rangle_g^{1/2} ds,$$

where $|\mu|$ denotes the length of the path μ , and the infimum is taken over all piecewise C^1 -smooth paths $\mu : [0, 1] \rightarrow M$ with $\mu(0) = x$ and $\mu(1) = y$.

We define the space $L^2(M, dV_\mu)$ with inner product

$$\langle u, v \rangle_{L^2(M, dV_\mu)} = \int_M u(x) v(x) dV_\mu(x),$$

where $dV_\mu = \mu(x)|g(x)|^{1/2} dx^1 dx^2 \dots dx^n$. By the above assumptions, A is formally self-adjoint, that is,

$$\langle Au, v \rangle_{L^2(M, dV_\mu)} = \langle u, Av \rangle_{L^2(M, dV_\mu)} \quad \text{for } u, v \in C_0^\infty(M^{\text{int}}).$$

Furthermore, let

$$B_{v,\eta} v = -\partial_v v + \eta v,$$

where $\eta : \partial M \rightarrow \mathbb{R}$ is a smooth function and

$$\partial_v v = \sum_{j,k=1}^n \mu(x) g^{jk}(x) v_k \frac{\partial}{\partial x^j} v(x),$$

where $v(x) = (v_1, v_2, \dots, v_m)$ is the interior conormal vector field of ∂M , satisfying $\sum_{j,k=1}^n g^{jk} v_j \xi_k = 0$ for all cotangent vectors of the boundary, $\xi \in T^*(\partial M)$. We assume that v is normalized, so that $\sum_{j,k=1}^n g^{jk} v_j v_k = 1$. If M is compact, then the operator A in the domain $\mathcal{D}(A) = \{v \in H^2(M) : \partial_v v|_{\partial M} = 0\}$, where $H^s(M)$ denotes the Sobolev spaces on M , is an unbounded self-adjoint operator in $L^2(M, dV_\mu)$.

An important example is the operator

$$A_0 = -c^2(x)\Delta + q(x) \quad (5)$$

on a bounded smooth domain $\Omega \subset \mathbb{R}^n$ with $\partial_\nu v = c(x)^{-n+1}\partial_{\mathbf{n}} v$, where $\partial_{\mathbf{n}} v$ is the Euclidean normal derivative of v .

We denote the solutions of (3) by

$$u(x, t) = u^f(x, t).$$

For the initial boundary value problem (3), we define the nonstationary Robin-to-Dirichlet map or the response operator Λ by

$$\Lambda f = u^f|_{\partial M \times \mathbb{R}_+}. \quad (6)$$

The finite time response operator Λ^T corresponding to the finite observation time $T > 0$ is given by

$$\Lambda^T f = u^f|_{\partial M \times (0, T)}. \quad (7)$$

For any set $B \subset \partial M \times \mathbb{R}_+$, we denote $L^2(B) = \{f \in L^2(\partial M \times \mathbb{R}_+) : \text{supp}(f) \subset B\}$. This means that we identify the functions and their zero continuations.

By [78], the map Λ^T can be extended to bounded linear map $\Lambda^T : L^2(B) \rightarrow H^{1/3}(\partial M \times (0, T))$ when $B \subset \partial M \times (0, T)$ is compact. Here, $H^s(\partial M \times (0, T))$ denotes the Sobolev space on $\partial M \times (0, T)$. Below we consider Λ^T also as a linear operator $\Lambda^T : L^2_{cpt}(\partial M \times (0, T)) \rightarrow L^2(\partial M \times (0, T))$, where $L^2_{cpt}(\partial M \times (0, T))$ denotes the compactly supported functions in $L^2(\partial M \times (0, T))$.

For $t > 0$ and a relatively compact open set $\Gamma \subset \partial M$, let

$$M(\Gamma, t) = \{x \in M : d_g(x, \Gamma) < t\}. \quad (8)$$

This set is called the domain of influence of Γ at time t .

When $\Gamma \subset \partial M$ is an open relatively compact set and $f \in C_0^\infty(\Gamma \times \mathbb{R}_+)$, it follows from finite speed of wave propagation (see, e.g., [38]) that the wave $u^f(t) = u^f(\cdot, t)$ is supported in the domain $M(\Gamma, t)$, that is,

$$u^f(t) \in L^2(M(\Gamma, t)) = \{v \in L^2(M) : \text{supp}(v) \subset M(\Gamma, t)\}. \quad (9)$$

We will consider the boundary of the manifold ∂M with the metric $g_{\partial M} = \iota^* g$ inherited from the embedding $\iota : \partial M \rightarrow M$. We assume that we are given the *boundary data*, that is, the collection

$$(\partial M, g_{\partial M}) \text{ and } \Lambda, \quad (10)$$

where $(\partial M, g_{\partial M})$ is considered as a smooth Riemannian manifold with a known differentiable and metric structure and Λ is the nonstationary Robin-to-Dirichlet map given in (6).

Our goal is to reconstruct the isometry type of the Riemannian manifold (M, g) , that is, a Riemannian manifold which is isometric to the manifold (M, g) . This is often stated by saying that we reconstruct (M, g) up to an isometry. Our next goal is to prove the following result:

Theorem 1. *Let (M, g) to be a smooth, complete Riemannian manifold with a nonempty boundary. Assume that we are given the boundary data (10). Then it is possible to determine the isometry type of manifold (M, g) .*

From Boundary Distance Functions to Riemannian Metric

In order to reconstruct (M, g) , we use a special representation, the *boundary distance representation*, $R(M)$, of M and later show that the boundary data (10) determine $R(M)$. We consider next the (possibly unbounded) continuous functions $h : C(\partial M) \rightarrow \mathbb{R}$. Let us choose a specific point $Q_0 \in \partial M$ and a constant $C_0 > 0$ and using these, endow $C(\partial M)$ with the metric

$$d_C(h_1, h_2) = |h_1(Q_0) - h_2(Q_0)| + \sup_{z \in \partial M} \min(C_0, |h_1(z) - h_2(z)|). \quad (11)$$

Consider a map $R : M \rightarrow C(\partial M)$,

$$R(x) = r_x(\cdot); \quad r_x(z) = d_g(x, z), \quad z \in \partial M, \quad (12)$$

that is, $r_x(\cdot)$ is the *distance function* from $x \in M$ to the points on ∂M . The image $R(M) \subset C(\partial M)$ of R is called the boundary distance representation of M . The set $R(M)$ is a metric space with the distance inherited from $C(\partial M)$ which we denote by d_C , too. The map R , due to the triangular inequality, is Lipschitz,

$$d_C(r_x, r_y) \leq 2d_g(x, y). \quad (13)$$

We note that when M is compact and $C_0 = \text{diam}(M)$, the metric $d_C : C(\partial M) \rightarrow \mathbb{R}$ is a norm which is equivalent to the standard norm $\|f\|_\infty = \max_{x \in \partial M} |f(x)|$ of $C(\partial M)$.

We will see below that the map $R : M \rightarrow R(M) \subset C(\partial M)$ is an embedding. Many results of differential geometry, such as Whitney or Nash embedding theorems, concern the question how an abstract manifold can be embedded to some simple space such as a higher dimensional Euclidean space. In the inverse problem, we need to construct a “copy” of the unknown manifold in some known space, and as we assume that the boundary is given, we do this by embedding the manifold M to the known, although infinite dimensional function space $C(\partial M)$.

Next we recall some basic definitions on Riemannian manifolds; see, for example, [22] for an extensive treatment. A path $\mu : [a, b] \rightarrow N$ is called a

geodesic if, for any $c \in [a, b]$, there is $\varepsilon > 0$ such that if $s, t \in [a, b]$ such that $c - \varepsilon < s < t < c + \varepsilon$, the path $\mu([s, t])$ is a shortest path between its endpoints, that is,

$$|\mu([s, t])| = d_g(\mu(s), \mu(t)).$$

In the future, we will denote a geodesic path μ by γ and parameterize γ with its arclength s , so that $|\mu([s_1, s_2])| = d_g(\mu(s_1), \mu(s_2))$. Let $x(s)$,

$$x(s) = (x^1(s), \dots, x^n(s)),$$

be the representation of the geodesic γ in local coordinates (U, X) . In the interior of the manifold, that is, for $U \subset M^{\text{int}}$ the path $x(s)$ satisfies the second-order differential equations

$$\frac{d^2 x^k(s)}{ds^2} = - \sum_{i,j=1}^n \Gamma_{ij}^k(x(s)) \frac{dx^i(s)}{ds} \frac{dx^j(s)}{ds}, \quad (14)$$

where Γ_{ij}^k are the Christoffel symbols, given in local coordinates by the formula

$$\Gamma_{ij}^k(x) = \sum_{p=1}^n \frac{1}{2} g^{kp}(x) \left(\frac{\partial g_{jp}}{\partial x^i}(x) + \frac{\partial g_{ip}}{\partial x^j}(x) - \frac{\partial g_{ij}}{\partial x^p}(x) \right).$$

Let $y \in M$ and $\xi \in T_y M$ be a unit vector satisfying the condition $g(\xi, v(y)) > 0$ in the case when $y \in \partial M$. Then, we can consider the solution of the initial value problem for the differential equation (14) with the initial data

$$x(0) = y, \quad \frac{dx}{ds}(0) = \xi.$$

This initial value problem has a unique solution $x(s)$ on an interval $[0, s_0(y, \xi))$ such that $s_0(y, \xi) > 0$ is the smallest value $s_0 > 0$ for which $x(s_0) \in \partial M$, or $s_0(y, \xi) = \infty$ in case no such s_0 exists. We will denote $x(s) = \gamma_{y, \xi}(s)$ and say that the geodesic is a normal geodesic starting at y if $y \in \partial M$ and $\xi = v(y)$.

Example 1. In the case when (M, g) is such a compact manifold that all geodesics are the shortest curves between their endpoints and all geodesics can be continued to geodesics that hit the boundary, we can see that the metric spaces (M, d_g) and $(R(M), \|\cdot\|_\infty)$ are isometric. Indeed, for any two points $x, y \in M$, there is a geodesic γ from x to a boundary point z , which is a continuation of the geodesic from x to y . As in the considered case the geodesics are distance minimizing curves, we see that

$$r_x(z) - r_y(z) = d_g(x, z) - d_g(y, z) = d_g(x, y),$$

and thus $\|r_x - r_y\|_\infty \geq d_g(x, y)$. Combining this with the triangular inequality, we see that $\|r_x - r_y\|_\infty = d_g(x, y)$ for $x, y \in M$ and R is isometry of (M, d_g) and $(R(M), \|\cdot\|_\infty)$.

Notice that when even M is a compact manifold, the metric spaces (M, d_g) and $(R(M), \|\cdot\|_\infty)$ are not always isometric. As an example, consider a unit sphere in \mathbb{R}^3 with a small circular hole near the South pole of, say, diameter ε . Then, for any x, y on the equator and $z \in \partial M$, $\pi/2 - \varepsilon \leq r_x(z) \leq \pi/2$ and $\pi/2 - \varepsilon \leq r_y(z) \leq \pi/2$. Then $d_C(r_x, r_y) \leq \varepsilon$, while $d_g(x, y)$ may be equal to π .

Next, we introduce the *boundary normal coordinates* on M . For a normal geodesic $\gamma_{z,v}(s)$ starting from $z \in \partial M$ consider $d_g(\gamma_{z,v}(s), \partial M)$. For small s ,

$$d_g(\gamma_{z,v}(s), \partial M) = s, \quad (15)$$

and z is the unique nearest point to $\gamma_{z,v}(s)$ on ∂M . Let $\tau(z) \in (0, \infty]$ be the largest value for which (15) is valid for all $s \in [0, \tau(z)]$. Then for $s > \tau(z)$,

$$d_g(\gamma_{z,v}(s), \partial M) < s,$$

and z is no more the nearest boundary point for $\gamma_{z,v}(s)$. The function $\tau(z) \in C(\partial M)$ is called the cut locus distance function, and the set

$$\omega = \{\gamma_{z,v}(\tau(z)) \in M : z \in \partial M, \text{ and } \tau(z) < \infty\}, \quad (16)$$

is the *cut locus of M with respect to ∂M* . The set ω is a closed subset of M having zero measure. In particular, $M \setminus \omega$ is dense in M . In the remaining domain $M \setminus \omega$, we can use the coordinates

$$x \mapsto (z(x), t(x)), \quad (17)$$

where $z(x) \in \partial M$ is the unique nearest point to x and $t(x) = d_g(x, \partial M)$. (Strictly speaking, one also has to use some local coordinates of the boundary, $y : z \mapsto (y^1(z), \dots, y^{(n-1)}(z))$ and define that

$$x \mapsto (y(z(x)), t(x)) = (y^1(z(x)), \dots, y^{(n-1)}(z(x)), t(x)) \in \mathbb{R}^n, \quad (18)$$

are the boundary normal coordinates.) Using these coordinates, we show that $R : M \rightarrow C(\partial M)$ is an embedding. The result of Lemma 1 is considered in detail for compact manifolds in [42].

Lemma 1. Let (M, d_g) be the metric space corresponding to a complete Riemannian manifold (M, g) with a nonempty boundary. The map $R : (M, d_g) \rightarrow (R(M), d_C)$ is a homeomorphism. Moreover, given $R(M)$ as a subset of $C(\partial M)$, it is possible to construct a distance function d_R on $R(M)$ that makes the metric space $(R(M), d_R)$ isometric to (M, d_g) .

Proof. We start by proving that R is a homeomorphism. Recall the following simple result from topology:

Assume that X and Y are Hausdorff spaces, X is compact, and $F : X \rightarrow Y$ is a continuous, bijective map from X to Y . Then $F : X \rightarrow Y$ is a homeomorphism.

Let us next extend this principle. Assume that (X, d_X) and (Y, d_Y) are metric spaces and let $X_j \subset X$, $j \in \mathbb{Z}_+$ be compact sets such that $\bigcup_{j \in \mathbb{Z}_+} X_j = X$. Assume that $F : X \rightarrow Y$ is a continuous, bijective map. Moreover, let $Y_j = F(X_j)$ and assume that there is a point $p \in Y$ such that

$$a_j = \inf_{y \in Y \setminus Y_j} d_Y(y, p) \rightarrow \infty \text{ as } j \rightarrow \infty. \quad (19)$$

Then by the above, the maps $F : \bigcup_{j=1}^n X_j \rightarrow \bigcup_{j=1}^n Y_j$ are homeomorphisms for all $n \in \mathbb{Z}_+$. Next, consider a sequence $y_k \in Y$ such that $y_k \rightarrow y$ in Y as $k \rightarrow \infty$. By removing first elements of the sequence $(y_k)_{k=1}^\infty$ if needed, we can assume that $d_Y(y_k, y) \leq 1$. Let now $N \in \mathbb{Z}_+$ be such that for $j > N$, we have $a_j > b := d_Y(y, p) + 1$. Then $y_k \in \bigcup_{j=1}^N Y_j$ and as the map $F : \bigcup_{j=1}^N X_j \rightarrow \bigcup_{j=1}^N Y_j$ is a homeomorphism, we see that $F^{-1}(y_k) \rightarrow F^{-1}(y)$ in X as $k \rightarrow \infty$. This shows that $F^{-1} : Y \rightarrow X$ is continuous, and thus $F : X \rightarrow Y$ is a homeomorphism.

By definition, $R : M \rightarrow R(M)$ is surjective and, by (13), continuous. In order to prove the injectivity, assume the contrary, that is, $r_x(\cdot) = r_y(\cdot)$ but $x \neq y$. Denote by z_0 any point where

$$\min_{z \in \partial M} r_x(z) = r_x(z_0).$$

Then

$$\begin{aligned} d_g(x, \partial M) &= \min_{z \in \partial M} r_x(z) = r_x(z_0) \\ &= r_y(z_0) = \min_{z \in \partial M} r_y(z) = d_g(y, \partial M), \end{aligned} \quad (20)$$

and $z_0 \in \partial M$ is a nearest boundary point to x . Let μ_x be the shortest path from z_0 to x . Then, the path μ_x is a geodesic from x to z_0 which intersects ∂M first time at z_0 . By using the first variation on length formula, we see that μ_x has to hit to z_0 normally; see [22]. The same considerations are true for the point y with the same point z_0 . Thus, both x and y lie on the normal geodesic $\gamma_{z_0, v}(s)$ to ∂M . As the geodesics are unique solutions of a system of ordinary differential equations (the Hamilton–Jacobi equation (14)), they are uniquely determined by their initial points

and directions, that is, the geodesics are non-branching. Thus, we see that

$$x = \gamma_{z_0}(s_0) = y,$$

where $s_0 = r_x(z_0) = r_y(z_0)$. Hence, $R : M \rightarrow C(\partial M)$ is injective.

Next, we consider the condition (19) for $R : M \rightarrow R(M)$. Let $z \in M$ and consider closed sets $X_j = \{x \in M : d_C(R(x), R(z)) \leq j\}$, $j \in \mathbb{Z}_+$. Then for $x \in X_j$, we have by definition (11) of the metric d_C that

$$d_g(x, Q_0) \leq j + d_g(z, Q_0),$$

implying that the sets X_j , $j \in \mathbb{Z}_+$ are compact. Clearly, $\bigcup_{j \in \mathbb{Z}_+} X_j = X$. Let next $Y_j = R(X_j) \subset Y = R(M)$ and $p = R(Q_0) \in R(M)$. Then for $r_x \in Y \setminus Y_j$, we have

$$\begin{aligned} d_C(r_x, p) &\geq r_x(Q_0) - p(Q_0) = d_g(x, Q_0) \\ &\geq j - d_g(z, Q_0) - C_0 \rightarrow \infty \text{ as } j \rightarrow \infty \end{aligned}$$

and thus the condition (19) is satisfied. As $R : M \rightarrow R(M)$ is a continuous, bijective map, it implies that $R : M \rightarrow R(M)$ is a homeomorphism.

Next we introduce a differentiable structure and a metric tensor, g_R , on $R(M)$ to have an isometric diffeomorphism

$$R : (M, g) \rightarrow (R(M), g_R). \quad (21)$$

Such structures clearly exists – the map R pushes the differentiable structure of M and the metric g to some differentiable structure on $R(M)$ and the metric $g_R := R_*g$ which makes the map (21) an isometric diffeomorphism. Next we construct these coordinates and the metric tensor in those on $R(M)$ using the fact that $R(M)$ is known as a subset of $C(\partial M)$.

We will start by construction of the differentiable and metric structures on $R(M) \setminus R(\omega)$, where ω is the cut locus of M with respect to ∂M . First, we show that we can identify in the set $R(M)$ all the elements of the form $r = r_x \in R(M)$ where $x \in M \setminus \omega$. To do this, we observe that $r = r_x$ with $x = \gamma_{z,v}(s)$, $s < \tau(z)$ if and only if:

1. $r(\cdot)$ has a unique global minimum at some point $z \in \partial M$;
2. There is $\tilde{r} \in R(M)$ having a unique global minimum at the same z and $r(z) < \tilde{r}(z)$. This is equivalent to saying that there is y with $r_y(\cdot)$ having a unique global minimum at the same z and $r_x(z) < r_y(z)$.

Thus, we can find $R(M \setminus \omega)$ by choosing all those $r \in R(M)$ for which the above conditions (1) and (2) are valid.

Next, we choose a differentiable structure on $R(M \setminus \omega)$ which makes the map $R : M \setminus \omega \rightarrow R(M \setminus \omega)$ a diffeomorphism. This can be done by introducing coordinates near each $r^0 \in R(M \setminus \omega)$. In a sufficiently small neighborhood $W \subset R(M)$ of r^0 the coordinates

$$r \mapsto (Y(r), T(r)) = \left(y(\operatorname{argmin}_{z \in \partial M} r), \min_{z \in \partial M} r \right)$$

are well defined. These coordinates have the property that the map $x \mapsto (Y(r_x), T(r_x))$ coincides with the boundary normal coordinates (17) and (18). When we choose the differential structure on $R(M \setminus \omega)$ that corresponds to these coordinates, the map

$$R : M \setminus \omega \rightarrow R(M \setminus \omega)$$

is a diffeomorphism.

Next we construct the metric g_R on $R(M)$. Let $r^0 \in R(M \setminus \omega)$. As above, in a sufficiently small neighborhood $W \subset R(M)$ of r^0 , there are coordinates $r \mapsto X(r) := (Y(r), T(r))$ that correspond to the boundary normal coordinates. Let $(y^0, t^0) = X(r^0)$. We consider next the evaluation function

$$K_w : W \rightarrow \mathbb{R}, \quad K_w(r) = r(w),$$

where $w \in \partial M$. The inverse of $X : W \rightarrow \mathbb{R}^n$ is well defined in a neighborhood $U \subset \mathbb{R}^n$ of (y^0, t^0) , and thus we can define the function

$$E_w = K_w \circ X^{-1} : U \rightarrow \mathbb{R}$$

that satisfies

$$E_w(y, t) := d_g(w, \gamma_{z(y), v(y)}(t)), \quad (y, t) \in U, \quad (22)$$

where $\gamma_{z(y), v(y)}(t)$ is the normal geodesic starting from the boundary point $z(y)$ with coordinates $y = (y^1, \dots, y^{n-1})$ and $v(y)$ is the interior unit normal vector at y .

Let now $g_R = R_* g$ be the push-forward of g to $R(M \setminus \omega)$. We denote its representation in X -coordinates by $g_{jk}(y, t)$. Since X corresponds to the boundary normal coordinates, the metric tensor satisfies

$$g_{mm} = 1, \quad g_{\alpha m} = 0, \quad \alpha = 1, \dots, n-1.$$

Consider the function $E_w(y, t)$ as a function of (y, t) with a fixed w . Then its differential, dE_w at point (y, t) defines a covector in $T_{(y,t)}^*(U) = \mathbb{R}^n$. Since the gradient of a distance function is a unit vector field, we see from (22) that

$$\|dE_w(y, t)\|_{(g_{jk})}^2 := \left(\frac{\partial}{\partial t} E_w(y, t) \right)^2 + \sum_{\alpha, \beta=1}^{n-1} (g_R)^{\alpha\beta}(y, t) \frac{\partial E_w}{\partial y^\alpha}(y, t) \frac{\partial E_w}{\partial y^\beta}(y, t) = 1.$$

Let us next fix a point $(y^0, t^0) \in U$. Varying the point $w \in \partial M$, we obtain a set of covectors $dE_w(y^0, t^0)$ in the unit ball of $(T_{(y^0, t^0)}^* U, g_{jk})$ which contains an open neighborhood of $(0, \dots, 0, 1)$. This determines uniquely the tensor $g^{jk}(y^0, t^0)$. Thus, we can construct the metric tensor in the boundary normal coordinates at arbitrary $r \in R(M \setminus \omega)$. This means that we can find the metric g_R on $R(M \setminus \omega)$ when $R(M)$ is given.

To complete the reconstruction, we need to find the differentiable structure and the metric tensor near $R(\omega)$. Let $r^{(0)} \in R(\omega)$ and $x^{(0)} \in M^{\text{int}}$ be such a point that $r^{(0)} = r_{x^{(0)}} = R(x^{(0)})$. Let z_0 be some of the closest points of ∂M to the point $x^{(0)}$. Then there are points z_1, \dots, z_{n-1} on ∂M , given by $z_j = \mu_{z_0, \theta_j}(s_0)$, where $\mu_{z_0, \theta_j}(s)$ are geodesics of $(\partial M, g_{\partial M})$ and $\theta_1, \dots, \theta_{n-1}$ are orthonormal vectors of $T_{z_0}(\partial M)$ with respect to metric $g_{\partial M}$ and $s_0 > 0$ is sufficiently small, so that the distance functions $y \mapsto d_g(z_i, y)$, $i = 0, 1, 2, \dots, n-1$ form local coordinates $y \mapsto (d_g(z_i, y))_{i=0}^{n-1}$ on M in some neighborhood of the point $x^{(0)}$ (we omit here the proof which can be found in [42, Lemma 2.14]).

Let now $W \subset R(M)$ be a neighborhood of $r^{(0)}$ and let $\tilde{r} \in W$. Moreover, let $V = R^{-1}(W) \subset M$ and $\tilde{x} = R^{-1}(\tilde{r}) \in V$. Let us next consider arbitrary points z_1, \dots, z_{n-1} on ∂M . Our aim is to verify whether the functions $x \mapsto X^i(x) = d_g(x, z_i)$, $i = 0, 1, \dots, n-1$ form smooth coordinates in V . As $M \setminus \omega$ is dense on M and we have found topological structure of $R(M)$ and constructed the metric g_R on $R(M \setminus \omega)$, we can choose $r^{(j)} \in R(M \setminus \omega)$ such that $\lim_{j \rightarrow \infty} r^{(j)} = \tilde{r}$ in $R(M)$. Let $x^{(j)} \in M \setminus \omega$ be the points for which $r^{(j)} = R(x^{(j)})$. Now the function $x \mapsto (X^i(x))_{i=0}^{n-1}$ defines smooth coordinates near \tilde{x} if and only if for functions $Z^i(r) = K_{z_i}(r)$, we have

$$\begin{aligned} & \lim_{j \rightarrow \infty} \det \left((g_R(dZ^i(r), dZ^l(r)))_{i,l=0}^{n-1} \right) |_{r=r^{(j)}} \\ &= \lim_{j \rightarrow \infty} \det \left((g(dX^i(x), dX^l(x)))_{i,l=0}^{n-1} \right) |_{x=x^{(j)}} \neq 0. \end{aligned} \tag{23}$$

Thus, for all $\tilde{r} \in W$ we can verify for any points $z_1, \dots, z_{n-1} \in \partial M$ whether the condition (23) is valid or not and this condition is valid for all $\tilde{r} \in W$ if and only if the functions $x \mapsto X^i(x) = d_g(x, z_i)$, $i = 0, 1, \dots, n-1$ form smooth coordinates in V . Moreover, by the above reasoning, we know that any $r^{(0)} \in R(\omega)$ has some neighborhood W and some points $z_1, \dots, z_{n-1} \in \partial M$ for which the condition (23) is valid for all $\tilde{r} \in W$. By choosing such points, we find also near $r^{(0)} \in (\omega)$ smooth coordinates $r \mapsto (Z^i(r))_{i=0}^{n-1}$ which make the map $R : M \rightarrow R(M)$ a diffeomorphism near $x^{(0)}$.

Summarizing, we have constructed differentiable structure (i.e., local coordinates) on the whole set $R(M)$, and this differentiable structure makes the map $R : M \rightarrow R(M)$ a diffeomorphism. Moreover, since the metric $g_R = R_* g$ is a smooth tensor, and we have found it in a dense subset $R(M \setminus \omega)$ of $R(M)$, we can continue it in the local coordinates. This gives us the metric g_R on the whole $R(M)$, which makes the map $R : M \rightarrow R(M)$ an isometric diffeomorphism. ■

In the above proof, the reconstruction of the metric tensor in the boundary normal coordinates can be considered as finding the image of the metric in the travel time coordinates.

Let us next consider the case when we have an unknown isotropic wave speed $c(x)$ in a bounded domain $\Omega \subset \mathbb{R}^n$. We will assume that we are given the set Ω and an abstract Riemannian manifold (M, g) , which is isometric to Ω endowed with its travel time metric corresponding to the wave speed $c(x)$. Also, we assume that we are given a map $\psi : \partial\Omega \rightarrow \partial M$, which gives the correspondence between the boundary points of Ω and M . Next we show that it is then possible to find an embedding from the manifold M to Ω which gives us the wave speed $c(x)$ at each point $x \in \Omega$. This construction is presented in detail, e.g., in [42].

For this end, we need first to reconstruct a function σ on M which corresponds to the function $c(x)^2$ on Ω . This is done on the following lemma.

Lemma 2. *Assume we are given a Riemannian manifold (M, g) such that there exists an open set $\Omega \subset \mathbb{R}^n$ and an isometry $\Psi : (\Omega, (\sigma(x))^{-1}\delta_{ij}) \rightarrow (M, g)$ and a function α on M such that $\alpha(\Psi(x)) = \sigma(x)$. Then knowing the Riemannian manifold (M, g) , the restriction $\psi = \Psi|_{\partial\Omega} : \partial\Omega \rightarrow \partial M$, and the boundary value $\sigma|_{\partial\Omega}$, we can determine the function α .*

Proof. First, observe that we are given the boundary value $\alpha|_{\partial M}$ of $\alpha(\Psi(x)) = \sigma(x)$. By assumption, the metric g on M is conformally Euclidean, that is, the metric tensor, in some coordinates, has the form $g_{jk}(x) = \sigma(x)^{-1}\delta_{jk}$, where $\sigma(x) > 0$. Hence, the function $\beta = \frac{1}{2}\ln(\alpha)$, when $n = 2$, and $\beta = \alpha^{(n-2)/4}$, when $n \geq 3$, satisfies the so-called scalar curvature equation

$$\Delta_g \beta - k_g = 0 \quad (n = 2), \quad (24)$$

$$\frac{4(n-1)}{n-2} \Delta_g \beta - k_g \beta = 0 \quad (n \geq 3), \quad (25)$$

where k_g is the scalar curvature of (M, g) ,

$$k_g(x) = \sum_{k,j,l=1}^n g^{jl}(x) R_{jkl}^k(x)$$

where R_{jkl}^i is the curvature tensor given in terms of the Christoffel symbols as

$$R_{jkl}^i(x) = \frac{\partial}{\partial x^k} \Gamma_{lj}^i(x) - \frac{\partial}{\partial x^l} \Gamma_{kj}^i(x) + \sum_{r=1}^n \left(\Gamma_{lj}^r(x) \Gamma_{kr}^i(x) - \Gamma_{kj}^r(x) \Gamma_{lr}^i(x) \right).$$

The idea of these equations is that if β satisfies, for example, Eq. (25) in the case $m \geq 3$, then the metric $\beta^{4/(n-2)}g$ has zero scalar curvature. Together with boundary data (10) being given, we obtain Dirichlet boundary value problem for β in M .

Clearly, Dirichlet problem for Eq. (24) has a unique solution that gives α when $n = 2$. In the case $n \geq 3$, to show that this boundary value problem has a unique solution, it is necessary to check that 0 is not an eigenvalue of the operator $\frac{4(n-1)}{n-2} \Delta_g - k_g$ with Dirichlet boundary condition. Now, the function $\beta = \alpha^{(n-2)/4}$ is a positive solution of the Dirichlet problem for Eq. (25) with boundary condition $\beta|_{\partial M} = \alpha^{(n-2)/4}|_{\partial M}$. Assume that there is another possible solution of this problem,

$$\tilde{\beta} = v\beta, \quad v > 0, \quad v|_{\partial M} = 1. \quad (26)$$

Then both $(M, \beta^{4/(n-2)}g)$ and $(M, \tilde{\beta}^{4/(n-2)}g)$ have zero scalar curvatures. Denoting $g_1 = \beta^{4/(n-2)}g$, $g_2 = \tilde{\beta}^{4/(n-2)}g$, we obtain that v should satisfy the scalar curvature equation

$$\frac{4(n-1)}{n-2} \Delta_{g_1} v - k_{g_1} v = 0.$$

Here, we have $k_{g_1} = 0$ as g_1 has vanishing scalar curvature. Together with boundary condition (26), this equation implies that $v \equiv 1$, that is, $\beta = \tilde{\beta}$. This immediately yields that 0 is not the eigenvalue of the Dirichlet operator (25) because, otherwise, we could obtain a positive solution $\tilde{\beta} = \beta + c_0 \psi_0$, where ψ_0 is the Dirichlet eigenfunction, corresponding to zero eigenvalue, and $|c_0|$ is sufficiently small. Thus, β , and henceforth α , can be uniquely determined by solving Dirichlet boundary value problems for (24) and (25). ■

Our next goal is to embed the abstract manifold (M, g) with conformally Euclidean metric into Ω with metric $(\sigma(x))^{-1} \delta_{ij}$. To achieve this goal, we use the a priori knowledge that such embedding exists and the fact that we have already constructed α corresponding to $\sigma(x)$ on M .

Lemma 3. *Let (M, g) be a compact Riemannian manifold, $\alpha(x)$ a positive smooth function on M , and $\psi : \partial\Omega \rightarrow \partial M$ a diffeomorphism. Assume also that there is a diffeomorphism $\Psi : \overline{\Omega} \rightarrow M$ such that*

$$\Psi|_{\partial\Omega} = \psi, \quad \Psi^* g = (\alpha(\Psi(x)))^{-1} \delta_{ij}.$$

Then, if Ω , (M, g) , α , and ψ are known, it is possible to construct the diffeomorphism Ψ by solving ordinary differential equations.

Proof. Let $\zeta = (z, \tau)$ be the boundary normal coordinates on $M \setminus \omega$. Our goal is to construct the coordinate representation for $\Psi^{-1} = X$,

$$X : M \setminus \omega \rightarrow \Omega,$$

$$X(z, \tau) = (x^1(z, \tau), \dots, x^n(z, \tau)).$$

Denote by $h_{ij}(x) = \alpha(\Psi(x))^{-1} \delta_{ij}$ the metric tensor in Ω . Let $\Gamma_{i,jk} = \sum_p g_{ip} \Gamma_{jk}^p$ be the Christoffel symbols of (Ω, h_{ij}) in the Euclidean coordinates and let $\tilde{\Gamma}_{\sigma,\mu\nu}$ be Christoffel symbols of (M, g) , in ζ -coordinates. Next, we consider functions h_{ij} , $\Gamma_{k,ij}$, etc., as functions on $M \setminus \omega$ in (z, τ) -coordinates evaluated at the point $x = x(z, \tau)$, for example, $\Gamma_{k,ij}(z, \tau) = \Gamma_{k,ij}(x(z, \tau))$. Then, since Ψ is an isometry, the transformation rule of Christoffel symbols with respect to the change of coordinates implies

$$\tilde{\Gamma}_{\sigma,\mu\nu} = \sum_{i,j,k=1}^n \Gamma_{k,ij} \frac{\partial x^i}{\partial \zeta^\mu} \frac{\partial x^j}{\partial \zeta^\nu} \frac{\partial x^k}{\partial \zeta^\sigma} + \sum_{i,j=1}^n h_{ij} \frac{\partial x^i}{\partial \zeta^\sigma} \frac{\partial^2 x^j}{\partial \zeta^\mu \partial \zeta^\nu}, \quad (27)$$

where

$$h_{ij}(z, \tau) = \frac{1}{\alpha(\Psi(z, \tau))} \delta_{ij}. \quad (28)$$

Using Eqs. (27) and (28), we can write $\frac{\partial^2 x^j}{\partial \zeta^\mu \partial \zeta^\nu}$ in the form

$$\begin{aligned} \frac{\partial^2 x^j}{\partial \zeta^\mu \partial \zeta^\nu}(\zeta) &= \sum_{p,\sigma,\mu,v=1}^n \alpha(\zeta) \delta^{jp} \left(\tilde{\Gamma}_{\sigma,\mu\nu} \frac{\partial \zeta^\sigma}{\partial x^p} - \sum_{n=1}^n \frac{1}{2} \frac{\partial \alpha^{-1}}{\partial \zeta^\sigma} \right. \\ &\quad \times \left. \left[\frac{\partial \zeta^\sigma}{\partial x^n} \delta_{pi} + \frac{\partial \zeta^\sigma}{\partial x^i} \delta_{pn} - \frac{\partial \zeta^\sigma}{\partial x^p} \delta_{ni} \right] \frac{\partial x^i}{\partial \zeta^\mu} \frac{\partial x^n}{\partial \zeta^\nu} \right). \end{aligned} \quad (29)$$

As α and $\tilde{\Gamma}_{\sigma,\mu\nu}$ are known as a function of ζ , the right-hand side of (29) can be written in the form

$$\frac{\partial^2 x^j}{\partial \zeta^\mu \partial \zeta^\nu} = F_{\mu,\nu}^j \left(\zeta, \frac{\partial x}{\partial \zeta} \right), \quad (30)$$

where $F_{\mu,\nu}^j$ are known functions. Choose $\nu = m$, so that

$$\frac{\partial^2 x^j}{\partial \zeta^\mu \partial \zeta^m} = \frac{d}{d\tau} \left(\frac{\partial x^j}{\partial \zeta^\mu} \right).$$

Then, Eq.(30) becomes a system of ordinary differential equations along normal geodesics for the matrix $\left(\frac{\partial x^j}{\partial \zeta^\mu}(\tau)\right)_{j,\mu=1}^n$. Moreover, since diffeomorphism $\Psi : \partial\Omega \rightarrow \partial M$ is given, the boundary derivatives $\frac{\partial x^j}{\partial \zeta^\mu}$, $\mu = 1, \dots, n-1$, are known for $\zeta^n = \tau = 0$. By relation (28),

$$\frac{\partial x^j}{\partial \zeta^n} = \frac{\partial x^j}{\partial \tau} = \alpha^{-1} \frac{\partial x^j}{\partial \mathbf{n}} = -\alpha^{-1} \mathbf{n}^j$$

for $\zeta^n = \tau = 0$ where $\mathbf{n} = (\mathbf{n}^1, \dots, \mathbf{n}^n)$ is the Euclidean unit exterior normal vector. Thus, $\frac{\partial x^j}{\partial \tau}(z, 0)$ are also known. Solving a system of ordinary differential equations (30) with these initial conditions at $\tau = 0$, we can construct $\frac{\partial x^j}{\partial \zeta^\mu}(z, \tau)$ everywhere on $M \setminus \omega$. In particular, taking $\mu = n$, we find $\frac{dx^j}{d\tau}(z, \tau)$. Using again the fact that $(x^1(z, 0), \dots, x^n(z, 0)) = \psi(z)$ are known, we obtain the functions $x^j(z, \tau)$, z fixed, $0 \leq \tau \leq \tau_{\partial M}(z)$, that is, reconstruct all normal geodesics on Ω with respect to metric h_{ij} . Clearly, this gives us the embedding of (M, g) onto (Ω, h_{ij}) . ■

Combining the above results, we get the following result for the isotropic wave equation.

Theorem 2. *Let $\Omega \subset \mathbb{R}^n$ to be a bounded, open set with smooth boundary and $c(x) \in C^\infty(\overline{\Omega})$ be a strictly positive function. Assume that we know Ω , $c|_{\partial\Omega}$, and the nonstationary Robin-to-Neumann map $\Lambda_{\partial\Omega}$. Then it is possible to determine the function $c(x)$.*

We note that in Theorem 2, the boundary value $c|_{\partial\Omega}$ of the wave speed $c(x)$ can be determined using the finite velocity of wave propagation (9) and the knowledge of Ω and $\Lambda_{\partial\Omega}$, but we will not consider this fact in this chapter.

From Boundary Data to Inner Products of Waves

Let $u^f(x, t)$ denote the solutions of the hyperbolic equation (3), Λ^{2T} be the finite time Robin-to-Dirichlet map for Eq. (3) and let dS_g denote the Riemannian volume form on the manifold $(\partial M, g_{\partial M})$. We start with the Blagovestchenskii identity.

Lemma 4. *Let $f, h \in C_0^\infty(\partial M \times \mathbb{R}_+)$. Then*

$$\int_M u^f(x, T) u^h(x, T) dV_\mu(x) = \quad (31)$$

$$= \frac{1}{2} \int_L \int_{\partial M} (f(x, t)(\Lambda^{2T} h)(x, s) - (\Lambda^{2T} f)(x, t)h(x, s)) dS_g(x) dt ds,$$

where

$$L = \{(s, t) : 0 \leq t + s \leq 2T, t < s, t, s > 0\}.$$

Proof. Let

$$w(t, s) = \int_M u^f(x, t)u^h(x, s) dV_\mu(x).$$

Then, by integration by parts, we see that

$$\begin{aligned} (\partial_t^2 - \partial_s^2) w(t, s) &= \int_M [\partial_t^2 u^f(x, t)u^h(x, s) - u^f(x, t)\partial_s^2 u^h(x, s)] dV_\mu(x) = \\ &= - \int_M [Au^f(x, t)u^h(x, s) - u^f(x, t)Au^h(x, s)] dV_\mu(x) = \\ &= - \int_{\partial M} [B_{v, \eta} u^f(t)u^h(s) - u^f(t)B_{v, \eta} u^h(s)] dS_g(x) = \\ &= \int_{\partial M} [\Lambda^{2T} u^f(x, t)u^h(x, s) - u^f(x, t)\Lambda^{2T} u^h(x, s)] dS_g(x). \end{aligned}$$

Moreover,

$$w|_{t=0} = w|_{s=0} = 0,$$

$$\partial_t w|_{t=0} = \partial_s w|_{s=0} = 0.$$

Thus, w is the solution of the initial boundary value problem for the one-dimensional wave equation in the domain $(t, s) \in [0, 2T] \times [0, 2T]$ with known source and zero initial and boundary data (10). Solving this problem, we determine $w(t, s)$ in the domain where $t + s \leq 2T$ and $t < s$ (see Fig. 1). In particular, $w(T, T)$ gives the assertion. ■

The other result is based on the following fundamental theorem by D. Tataru [77, 79].

Theorem 3. *Let $u(x, t)$ solve the wave equation $u_{tt} + Au = 0$ in $M \times \mathbb{R}$ and $u|_{\Gamma \times (0, 2T_1)} = \partial_v u|_{\Gamma \times (0, 2T_1)} = 0$, where $\emptyset \neq \Gamma \subset \partial M$ is open. Then*

$$u = 0 \text{ in } K_{\Gamma, T_1}, \tag{32}$$

where

$$K_{\Gamma, T_1} = \{(x, t) \in M \times \mathbb{R} : d_g(x, \Gamma) < T_1 - |t - T_1|\}$$

Fig. 1 Domain of integration in the Blagovestchenskii identity

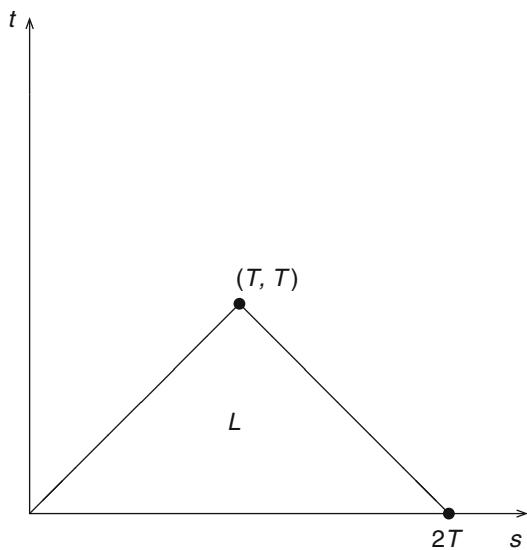

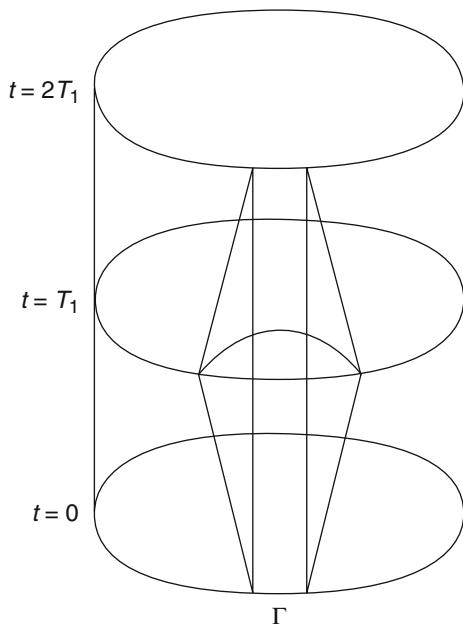

Fig. 2 Double cone of influence

is the double cone of influence (see Fig. 2).

(The proof of this theorem, in full generality, is in [77]. A simplified proof for the considered case is in [42].)

The observability Theorem 3 gives rise to the following approximate controllability:

Corollary 1. *For any open $\Gamma \subset \partial M$ and $T_1 > 0$,*

$$\text{cl}_{L^2(M)} \{u^f(\cdot, T_1) : f \in C_0^\infty(\Gamma \times (0, T_1))\} = L^2(M(\Gamma, T_1)).$$

Here,

$$M(\Gamma, T_1) = \{x \in M : d_g(x, \Gamma) < T_1\} = K_{\Gamma, T_1} \cap \{t = T_1\}$$

is the domain of influence of Γ at time T_1 and $L^2(M(\Gamma, T_1)) = \{a \in L^2(M) : \text{supp}(a) \subset M(\Gamma, T_1)\}$.

Proof. Let us assume that $a \in L^2(M(\Gamma, T_1))$ is orthogonal to all $u^f(\cdot, T_1)$, $f \in C_0^\infty(\Gamma \times (0, T_1))$. Denote by v the solution of the wave equation

$$\begin{aligned} (\partial_t^2 + A)v = 0; \quad v|_{t=T_1} = 0, & \quad \text{in } M \times \mathbb{R}, \\ \partial_t v|_{t=T_1} = a; \quad B_{v,\eta} v|_{\partial M \times \mathbb{R}} = 0. & \end{aligned}$$

Using integration by parts, we obtain for all $f \in C_0^\infty(\Gamma \times (0, T_1))$

$$\int_0^{T_1} \int_{\partial M} f(x, s)v(x, s) dS_g(x) ds = \int_M a(x)u^f(x, T_1) dV_\mu(x) = 0,$$

due to the orthogonality of a and the solutions $u^f(t)$. Thus, $v|_{\Gamma \times (0, T_1)} = 0$. Moreover, as v is odd with respect to $t = T_1$, that is, $v(x, T_1+s) = -v(x, T_1-s)$, we see that $v|_{\Gamma \times (T_1, 2T_1)} = 0$. As u satisfies the wave equation, standard energy estimates yield that $u \in C(\mathbb{R}; H^1(M))$, and hence $u|_{\partial M \times \mathbb{R}} \in C(\mathbb{R}; H^{1/2}(\partial M))$. Combining the above, we see that $v|_{\Gamma \times (0, 2T_1)} = 0$, and as $B_{v,\eta} v|_{\Gamma \times (0, 2T_1)} = 0$, we see using Theorem 3 that $a = 0$. ■

Recall that we denote $u^f(t) = u^f(\cdot, t)$.

Lemma 5. *Let $T > 0$ and $\Gamma_j \subset \partial M$, $j = 1, \dots, J$, be nonempty, relatively compact open sets, $0 \leq T_j^- < T_j^+ \leq T$. Assume we are given $(\partial M, g_{\partial M})$ and the response operator Λ^{2T} . This data determines the inner product*

$$J_N^T(f_1, f_2) = \int_N u^{f_1}(x, t)u^{f_2}(x, t) dV_\mu(x)$$

for given $t > 0$ and $f_1, f_2 \in C_0^\infty(\partial M \times \mathbb{R}_+)$, where

$$N = \bigcap_{j=1}^J \left(M(\Gamma_j, T_j^+) \setminus M(\Gamma_j, T_j^-) \right) \subset M.$$

Proof. Let us start with the case when $f_1 = f_2 = f$ and $T_j^- = 0$ for all $j = 1, 2, \dots, J$.

Let $B = \bigcup_{j=1}^J (\Gamma_j \times [T - T_j, T])$. For all $h \in C_0^\infty(B)$, it holds by (9) that $\text{supp}(u^h(\cdot, T)) \subset N$, and thus

$$\begin{aligned} & \|u^f(T) - u^h(T)\|_{L^2(M, dV_\mu)}^2 \\ &= \int_N (u^f(x, T) - u^h(x, T))^2 dV_\mu(x) + \int_{M \setminus N} (u^f(x, T))^2 dV_\mu(x). \end{aligned}$$

Let $\chi_N(x)$ be the characteristic function of the set N . By Corollary 1, there is $h \in C_0^\infty(B)$ such that the norm $\|\chi_N u^f(T) - u^h(T)\|_{L^2(M, dV_\mu)}$ is arbitrarily small. This shows that $J_N^T(f_1, f_2)$ can be found by

$$J_N^T(f, f) = \|u^f(T)\|_{L^2(M, dV_\mu)}^2 - \inf_{h \in C_0^\infty(B)} F(h), \quad (33)$$

where

$$F(h) = \|u^f(T) - u^h(T)\|_{L^2(M, dV_\mu)}^2.$$

As $F(h)$ can be computed with the given data (10) by Lemma 4, it follows that we can determine $J_N^T(f, f)$ for any $f \in C_0^\infty(\partial M \times \mathbb{R}_+)$. Now, since

$$J_N^T(f_1, f_2) = \frac{1}{4} (J_N^T(f_1 + f_2, f_1 + f_2) - J_N^T(f_1 - f_2, f_1 - f_2)),$$

the claim follows in the case when $T_j^- = 0$ for all $j = 1, 2, \dots, J$.

Let us consider the general case when T_j^- may be nonzero. We observe that we can write the characteristic function $\chi_N(x)$ of the set $N = \bigcap_{j=1}^J (M(\Gamma_j, T_j^+) \setminus M(\Gamma_j, T_j^-))$ as

$$\chi_N(x) = \sum_{k=1}^{K_1} c_k \chi_{N_k}(x) - \sum_{k=K_1+1}^{K_2} c_k \chi_{N_k}(x),$$

where $c_k \in \mathbb{R}$ are constants which can be determined by solving a simple linear system of equations and the sets N_k are of the form

$$N_k = \bigcup_{j \in I_k} M(\Gamma_j, t_j),$$

where $I_k \subset \{1, 2, \dots, J\}$ and $t_j \in \left\{T_j^+ : j = 1, 2, \dots, J\right\} \cup \left\{T_j^- : j = 1, 2, \dots, J\right\}$. Thus,

$$J_N^T(f_1, f_2) = \sum_{k=1}^{K_1} c_k J_{N_k}^T(f_1, f_2) - \sum_{k=K_1+1}^{K_2} c_k J_{N_k}^T(f_1, f_2),$$

where all the terms $J_{N_k}^T(f_1, f_2)$ can be computed using the boundary data (10). ■

From Inner Products of Waves to Boundary Distance Functions

Let us consider open sets $\Gamma_j \subset \partial M$, $j = 1, 2, \dots, J$ and numbers $T_j^+ > T_j^- \geq 0$. For a collection $\left\{(\Gamma_j, T_j^+, T_j^-) : j = 1, \dots, J\right\}$, we define the number

$$P\left(\left\{(\Gamma_j, T_j^+, T_j^-) : j = 1, \dots, J\right\}\right) = \sup_f J_N^T(f, f),$$

where $T = \left(\max_j T_j^+\right) + 1$,

$$N = \bigcap_{j=1}^J \left(M\left(\Gamma_j, T_j^+\right) \setminus M\left(\Gamma_j, T_j^-\right) \right)$$

and the supremum is taken over functions $f \in C_0^\infty(\partial M \times (0, T))$ satisfying $\|u^f(T)\|_{L^2(M)} \leq 1$. When $\Gamma_j^q \subset \partial M$, $j = 1, 2, \dots, J$, are open sets, so that $\Gamma_j^q \rightarrow \{z_j\}$ as $q \rightarrow \infty$, that is, $\{z_j\} \subset \Gamma_j^q \subset \Gamma_j^{q-1}$ for all q and $\bigcap_{q=1}^\infty \overline{\Gamma}_j^q = \{z_j\}$, we denote

$$P\left(\left\{(z_j, T_j^+, T_j^-) : j = 1, \dots, J\right\}\right) = \lim_{q \rightarrow \infty} P\left(\left\{(\Gamma_j^q, T_j^+, T_j^-) : j = 1, \dots, J\right\}\right).$$

Theorem 4. Let $\{z_n\}_{n=1}^\infty$ be a dense set on ∂M and $r(\cdot) \in C(\partial M)$ be an arbitrary continuous function. Then $r \in R(M)$ if and only if for all $N > 0$ it holds that

$$P\left(\left\{\left(z_j, r(z_n) + \frac{1}{N}, r(z_n) - \frac{1}{N}\right) : j = 1, \dots, N\right\}\right) > 0. \quad (34)$$

Moreover, condition (34) can be verified using the boundary data (10). Hence, the boundary data determine uniquely the boundary distance representation $R(M)$ of (M, g) and therefore determine the isometry type of (M, g) .

Proof. “If”-part. Let $x \in M$ and denote for simplicity $r(\cdot) = r_x(\cdot)$. Consider a ball $B_{1/N}(x) \subset M$ of radius $1/N$ and center x in (M, g) . Then, for $z \in \partial M$

$$B_{1/N}(x) \subset M\left(z, r(z) + \frac{1}{N}\right) \setminus M\left(z, r(z) - \frac{1}{N}\right).$$

By Corollary 1, for any $T > r(z)$, there is $f \in C_0^\infty(\partial M \times (0, T))$ such that the function $u^f(\cdot, T)$ does not vanish a.e. in $B_{1/N}(x)$. Thus, for any $N \in \mathbb{Z}_+$ and $T = \max\{r(z_n) : n = 1, 2, \dots, N\}$, we have

$$\begin{aligned} P\left(\left\{\left(z_j, r(z_n) + \frac{1}{N}, r(z_n) - \frac{1}{N}\right) : j = 1, \dots, N\right\}\right) \\ \geq \int_{B_{1/N}(x)} |u^f(x, T)|^2 dV_\mu(x) > 0 \end{aligned}$$

“Only if”–part. Let (34) be valid. Then for all $N > 0$, there are points

$$x_N \in A_N = \bigcap_{n=1}^N \left(M\left(z_n, r(z_n) + \frac{1}{N}\right) \setminus M\left(z_n, r(z_n) - \frac{1}{N}\right) \right) \quad (35)$$

as the set A_N has to have a nonzero measure. By choosing a suitable subsequence of x_N (denoted also by x_N), there exists a limit $x = \lim_{N \rightarrow \infty} x_N$.

Let $j \in \mathbb{Z}_+$. It follows from (35) that

$$r(z_j) - \frac{1}{N} \leq d_g(x_N, z_j) \leq r(z_j) + \frac{1}{N} \quad \text{for all } N \geq j.$$

As the distance function d_g on M is continuous, we see by taking limit $N \rightarrow \infty$ that

$$d_g(x, z_j) = r(z_j), \quad j = 1, 2, \dots$$

Since $\{z_j\}_{j=1}^\infty$ are dense in ∂M , we see that $r(z) = d_g(x, z)$ for all $z \in \partial M$, that is, $r = r_x$. \blacksquare

Note that this proof provides an algorithm for construction of an isometric copy of (M, g) when the boundary data (10) are given.

Alternative Reconstruction of Metric via Gaussian Beams

Next we consider an alternative construction of the boundary distance representation $R(M)$, developed in [6, 41, 42]. In the previous considerations, we used in Lemma 5 the sets of type $N = \bigcap_{j=1}^J \left(M\left(\Gamma_j, T_j^+\right) \setminus M\left(\Gamma_j, T_j^-\right) \right) \subset M$ and studied the norms $\|\chi_N u^f(\cdot, T)\|_{L^2(M)}$. In the alternative construction considered below, we need to consider only the sets N of the form $N = M(\Gamma_0, T_0)$. For this end, we consider solutions $u^f(x, t)$ with special sources f which produce wave packets, called the Gaussian beams [3, 63]. For simplicity, we consider just the case when

$$A = -\Delta_g + q,$$

and give a very short exposition on the construction of the Gaussian beam solutions. Details can be found in, for example, Ref. [42], Chapter 2.4, where the properties of Gaussian beams are discussed in detail. In this section, we consider complex valued solutions $u^f(x, t)$.

Gaussian beams, called also “quasiphotons,” are a special class of solutions of the wave equation depending on a parameter $\varepsilon > 0$ which propagate in a neighborhood of a geodesic $\gamma = \gamma_{y, \xi}([0, L])$, $g(\xi, \xi) = 1$. Below, we consider first the construction in the case when γ is in the interior of M .

To construct Gaussian beams, we start by considering an asymptotic sum, called formal Gaussian beam,

$$U_\varepsilon(x, t) = M_\varepsilon \exp \{-(i\varepsilon)^{-1}\theta(x, t)\} \sum_{k=0}^N u_k(x, t)(i\varepsilon)^k, \quad (36)$$

where $x \in M$, $t \in [t_-, t_+]$, and $M_\varepsilon = (\pi\varepsilon)^{-n/4}$ is the normalization constant. The function $\theta(x, t)$ is called the phase function and $u_k(x, t)$, $k = 0, 1, \dots, N$ are the amplitude functions. A phase function $\theta(x, t)$ is associated with a geodesic $t \mapsto \gamma(t) \in M$ if

$$\operatorname{Im} \theta(\gamma(t), t) = 0, \quad (37)$$

$$\operatorname{Im} \theta(x, t) \geq C_0 d_g(x, \gamma(t))^2, \quad (38)$$

for $t \in [t_-, t_+]$. These conditions guarantee that for any t , the absolute value of $U_\varepsilon(x, t)$ looks like a Gaussian function in the x variable which is centered at $\gamma(t)$. Thus, the formal Gaussian beam can be considered to move in time along the geodesic $\gamma(t)$. The phase function can be constructed, so that it satisfies the eikonal equation

$$\left(\frac{\partial}{\partial t} \theta(x, t) \right)^2 - g^{jl}(x) \frac{\partial}{\partial x^j} \theta(x, t) \frac{\partial}{\partial x^l} \theta(x, t) \asymp 0, \quad (39)$$

where \asymp means the coincidence of the Taylor coefficients of both sides considered as functions of x at the points $\gamma(t)$, $t \in [t_-, t_+]$, that is,

$$v(x, t) \asymp 0 \quad \text{if } \partial_x^\alpha v(x, t)|_{x=\gamma(t)} = 0 \text{ for all } \alpha \in \mathbb{N}^n \text{ and } t \in [t_-, t_+].$$

The amplitude functions u_k , $k = 0, \dots, N$ can be constructed as solutions of the transport equations

$$\mathcal{L}_\theta u_k \asymp (\partial_t^2 - \Delta_g + q) u_{k-1}, \quad \text{with } u_{-1} = 0. \quad (40)$$

Here \mathcal{L}_θ is the transport operator

$$\mathcal{L}_\theta u = 2\partial_t \theta \partial_t u - 2\langle \nabla \theta, \nabla u \rangle_g + (\partial_t^2 - \Delta_g) \theta \cdot u, \quad (41)$$

where $\nabla u(x, t) = \sum_j g^{jk}(x) \frac{\partial u}{\partial x^k}(x, t) \frac{\partial}{\partial x^k}$ is the gradient on (M, g) and $\langle V, W \rangle_g = \sum_{j=1}^n g^{jk}(x) V_j(x) W_k(x)$. The following existence result is proven, for example, in [3, 42, 63].

Theorem 5. Let $y \in M^{\text{int}}$, $\xi \in T_y M$ be a unit vector and $\gamma = \gamma_{y, \xi}(t)$, $t \in [t_-, t_+] \subset \mathbb{R}$ be a geodesic lying in M^{int} when $t \in (t_-, t_+)$.

Then there are functions $\theta(x, t)$ and $u_k(x, t)$ satisfying (38)–(40) and a solution $u_\varepsilon(x, t)$ of equation

$$(\partial_t^2 - \Delta_g + q) u_\varepsilon(x, t) = 0, \quad (x, t) \in M \times [t_-, t_+], \quad (42)$$

such that

$$|u_\varepsilon(x, t) - \phi(x, t) U_\varepsilon(x, t)| \leq C_N \varepsilon^{\tilde{N}(N)}, \quad (43)$$

where $\tilde{N}(N) \rightarrow \infty$ when $N \rightarrow \infty$. Here $\phi \in C_0^\infty(M \times \mathbb{R})$ is a smooth cut-off function satisfying $\phi = 1$ near the trajectory $\{(\gamma(t), t) : t \in [t_-, t_+]\} \subset M \times \mathbb{R}$.

In the other words, for an arbitrary geodesic in the interior of M , there is a Gaussian beam that propagates along this geodesic.

Next we consider a class of boundary sources in (3) which generate Gaussian beams. Let $z_0 \in \partial M$, $t_0 > 0$, and let $x \mapsto z(x) = (z^1(x), \dots, z^{n-1}(x))$ be a local system of coordinates on $W \subset \partial M$ near z_0 . For simplicity, we denote these coordinates as $z = (z^1, \dots, z^{n-1})$ and make computations without reference to the point x . Consider a class of functions $f_\varepsilon = f_{\varepsilon, z_0, t_0}(z, t)$ on the boundary cylinder $\partial M \times \mathbb{R}$, where

$$f_\varepsilon(z, t) = B_{\nu, \eta} ((\pi \varepsilon)^{-n/4} \phi(z, t) \exp \{i \varepsilon^{-1} \Theta(z, t)\} V(z, t)). \quad (44)$$

Here $\phi \in C_0^\infty(\partial M \times \mathbb{R})$ is one near (z_0, t_0) and

$$\Theta(z, t) = -(t - t_0) + \frac{1}{2} \langle H_0(z - z_0), (z - z_0) \rangle + \frac{i}{2} (t - t_0)^2, \quad (45)$$

where $\langle \cdot, \cdot \rangle$ is the complexified Euclidean inner product, $\langle a, b \rangle = \sum a_j b_j$, and $H_0 \in \mathbb{C}^{n \times n}$ is a symmetric matrix with a positive definite imaginary part, that is, $(H_0)_{jk} = (H_0)_{kj}$ and $\text{Im } H_0 > 0$, where $(\text{Im } H_0)_{jk} = \text{Im } (H_0)_{jk}$. Finally, $V(z, t)$ is a smooth function supported in $W \times \mathbb{R}_+$, having nonzero value at (z_0, t_0) . The solution $u^{f_\varepsilon}(x, t)$ of the wave equation

$$\begin{aligned} \partial_t^2 u - \Delta_g u + qu &= 0, \quad \text{in } M \times \mathbb{R}_+, \\ u|_{t=0} = \partial_t u|_{t=0} &= 0, \\ B_{v,\eta} u|_{\partial M \times \mathbb{R}_+} &= f_\varepsilon(z, t) \end{aligned} \tag{46}$$

is a Gaussian beam propagating along the normal geodesic $\gamma_{z_0,v}$. Let $S(z_0) \in (0, \infty]$ be the smallest values $s > 0$, so that $\gamma_{z_0,v}(s) \in \partial M$, that is, the first time when the geodesic $\gamma_{z_0,v}$ hits to ∂M , or $S(z_0) = \infty$ if no such value $s > 0$ exists. Then the following result in valid (see, e.g., [42]).

Lemma 6. *For any function $V \in C_0^\infty(W \times \mathbb{R}_+)$ being one near (z_0, t_0) , $t_0 > 0$, and $0 < t_1 < S(z_0)$ and $N \in \mathbb{Z}_+$, there are C_N so that the solution $u^{f_\varepsilon}(x, t)$ of problem (46) satisfies estimates*

$$|u^{f_\varepsilon}(x, t) - \phi(x, t)U_\varepsilon(x, t)| \leq C_N \varepsilon^{\tilde{N}(N)}, \quad 0 \leq t < t_0 + t_1 \tag{47}$$

where $U_\varepsilon(x, t)$ is of the form (36), for all $0 < \varepsilon < 1$, where $\tilde{N}(N) \rightarrow \infty$ when $N \rightarrow \infty$ and $\phi \in C_0^\infty(M \times \mathbb{R})$ is ϕ one near the trajectory $\{(\gamma_{z_0,v}(t), t + t_0) : t \in [0, t_1]\} \subset M \times \mathbb{R}$.

Let us denote

$$P_{y,\tau} v(x) = \chi_{M(y,\tau)}(x)v(x).$$

Then, the boundary data $(\partial M, g_{\partial M})$ and the operator Λ uniquely determine the values $\|P_{y,\tau} u^f(t)\|_{L^2(M)}$ for any $f \in C_0^\infty(\partial M \times \mathbb{R}_+)$, $y \in \partial M$ and $t, \tau > 0$. Let f_ε be of form (44) and (45) and $u_\varepsilon(x, t) = u^f(x, t)$, $f = f_\varepsilon$ be a Gaussian beam propagating along $\gamma_{z_0,v}$ described in Lemma 6. The asymptotic expansion (36) of a Gaussian beam implies that for $s < S(z_0)$ and $\tau > 0$,

$$\lim_{\varepsilon \rightarrow 0} \|P_{y,\tau} u_\varepsilon(\cdot, s + t_0)\|_{L^2(M)} = \begin{cases} h(s), & \text{for } d_g(\gamma_{z_0,v}(s), y) < \tau, \\ 0, & \text{for } d_g(\gamma_{z_0,v}(s), y) > \tau, \end{cases} \tag{48}$$

where $h(s)$ is a strictly positive function. By varying $\tau > 0$, we can find $d_g(\gamma_{z_0,v}(s), y) = r_x(y)$, where $x = \gamma_{z_0,v}(t)$. Moreover, we see that $S(z_0)$ can be determined using the boundary data and (48) by observing that $S(z_0)$ is the smallest number $S > 0$ such that if $t_k \rightarrow S$ is an increasing sequence, then

$$d_g(\gamma_{z_0,v}(s_k), \partial M) = \inf_{y \in \partial M} d_g(\gamma_{z_0,v}(s_k), y) \rightarrow 0 \quad \text{as } k \rightarrow \infty.$$

Summarizing, for any $z_0 \in \partial M$, we can find $S(z_0)$, and furthermore, for any $0 \leq t < S(z_0)$, we can find the boundary distance function $r_x(y)$ with $x = \gamma_{z_0,v}(t)$. As

any point $x \in M$ can be represented in this form, we see that the boundary distance representation $R(M)$ can be constructed from the boundary data using the Gaussian beams.

Travel Times and Scattering Relation

We will show in this section that if $(\overline{\Omega}, g)$ is a simple Riemannian manifold, then by looking at the singularities of the response operator, we can determine the boundary distance function $d_g(x, y)$, $x, y \in \partial\Omega$, that is, the travel times of geodesics going through the domain. The boundary distance function is a function of $2n - 2$ variables. Thus, the inverse problem of determining the Riemannian metric from the boundary distance function is formally determined in two dimensions and formally overdetermined in dimensions $n \geq 3$.

Let $\Omega \subset \mathbb{R}^n$ be a bounded domain with smooth boundary. If the response operators for the two manifolds $(\overline{\Omega}, g_1)$ and $(\overline{\Omega}, g_2)$ are the same then we can assume, after a change of variables which is the identity at the boundary, the two metrics g_1 and g_2 have the same Taylor series at the boundary [76]. Therefore, we can extend both metrics smoothly to be equal outside Ω and Euclidean outside a ball of radius R . We denote the extensions to \mathbb{R}^n by g_j , $j = 1, 2$, as before. Let $u_j(t, x, \omega)$ be the solution of the continuation problem

$$\begin{cases} \frac{\partial^2 u}{\partial t^2} - \Delta_{g_j} u_j = 0, & \text{in } \mathbb{R}^n \times \mathbb{R} \\ u_j(x, t) = \delta(t - x \cdot \omega), & t < -R, \end{cases} \quad (49)$$

where $\omega \in \mathbb{S}^{n-1} = \{x \in \mathbb{R}^n; |x| = 1\}$.

It was shown in [76] that if the response operators for $(\overline{\Omega}, g_1)$ and $(\overline{\Omega}, g_2)$ are equal, then the two solutions coincide outside Ω , namely,

$$u_1(t, x, \omega) = u_2(t, x, \omega), \quad x \in \mathbb{R}^n \setminus \Omega. \quad (50)$$

In the case that the manifold (Ω, g_j) , $j = 1, 2$ is simple, we will use methods of geometrical optics to construct solutions of (49) to show that if the response operators of g_1 and g_2 are the same, then the boundary distance functions of the metrics g_1 and g_2 coincide.

Geometrical Optics

Let g denote a smooth Riemannian metric which is Euclidean outside a ball of radius R .

We will construct solutions to the continuation problem for the metric g (which is either g_1 or g_2). We fix ω . Let us assume that there is a solution to Eq. (49) of the form

$$u(x, t, \omega) = a(x, \omega)\delta(t - \phi(x, \omega)) + v(x, \omega), \quad u = 0, t < -R, \quad (51)$$

where a, ϕ are functions to be determined and $v \in L^2_{loc}$. Notice that in order to satisfy the initial conditions in (49), we require that

$$a = 1, \quad \phi(x, \omega) = x \cdot \omega \text{ for } x \cdot \omega < -R. \quad (52)$$

By replacing Eq. (51) in Eq. (49), it follows that

$$\begin{aligned} \frac{\partial^2 u}{\partial t^2} - \Delta_g u &= A\delta''(t - \phi(x, \omega)) + B\delta'(t - \phi(x, \omega)) \\ &\quad - (\Delta_g a)\delta(t - \phi(x, \omega)) + \frac{\partial^2 v}{\partial t^2} - \Delta_g v, \end{aligned} \quad (53)$$

where

$$A = a(x, \omega) \left(1 - \sum_{i,j=1}^n g^{ij} \frac{\partial \phi}{\partial x^i} \frac{\partial \phi}{\partial x^j} \right) \quad (54)$$

$$B = 2 \sum_{j,k=1}^n g^{jk} \frac{\partial a}{\partial x^k} \frac{\partial \phi}{\partial x^j} + a \Delta_g \phi. \quad (55)$$

We choose the functions ϕ, a in the expansion (53) to eliminate the singularities δ'' and δ' and then construct v , so that

$$\frac{\partial^2 v}{\partial t^2} - \Delta_g v = (\Delta_g a)\delta(t - \phi(x, \omega)), \quad v = 0, t < -R. \quad (56)$$

The Eikonal Equation

In order to solve the equation $A = 0$, it is sufficient to solve the equation

$$\sum_{i,j=1}^n g^{ij} \frac{\partial \phi}{\partial x^i} \frac{\partial \phi}{\partial x^j} = 1, \quad \phi(x, \omega) = x \cdot \omega, x \cdot \omega < -R. \quad (57)$$

Equation (57) is known as the *eikonal equation*. Here we will describe a method, using symplectic geometry, to solve this equation.

Let $H_g(x, \xi) = \frac{1}{2} \left(\sum_{i,j=1}^n g^{ij}(x) \xi_i \xi_j - 1 \right)$ the Hamiltonian associated to the metric g . Note that the metric induced by g in the cotangent space $T^*\mathbb{R}^n$ is given by the principal symbol of the Laplace–Beltrami operator $g^{-1}(x, \xi) = \sum_{i,j=1}^n g^{ij}(x) \xi_i \xi_j$. Equation (57) together with the initial condition can be rewritten as

$$H_g(x, d\phi) = 0, \quad \phi(x, \omega) = x \cdot \omega, x \cdot \omega < -R,$$

where $d\phi = \sum_{i=1}^n \frac{\partial \phi}{\partial x^i} dx^i$ is the differential of ϕ .

Let $S = \{(x, \xi) : H_g(x, \xi) = 0\}$, and let $M_\phi = \{(x, \nabla\phi(x)) : x \in \mathbb{R}^n\}$, then solving Eq. (57), is equivalent to finding ϕ such that

$$M_\phi \subset S, \text{ with } M_\phi = \{(x, \omega) : x \cdot \omega < -R\}. \quad (58)$$

In order to find ϕ so that (58) is valid, we need to find a Lagrangian submanifold L , so that $L \subset S$, $L = \{(x, \omega) : x \cdot \omega < -R\}$ and the projection of $T^*\mathbb{R}^n$ to \mathbb{R}^n is a diffeomorphism [32]. We will construct such a Lagrangian manifold by flowing out from $N = \{(x, \omega) : x \cdot \omega = s \text{ and } s < -R\}$ by the geodesic flow associated to the metric g . We recall the definition of geodesic flow.

We define the Hamiltonian vector field associated to H_g

$$V_g = \left(\frac{\partial H_g}{\partial \xi}, -\frac{\partial H_g}{\partial x} \right). \quad (59)$$

The bicharacteristics are the integral curves of H_g

$$\frac{d}{ds} x^m = \sum_{j=1}^n g^{mj} \xi_j, \quad \frac{d}{ds} \xi_m = -\frac{1}{2} \sum_{i,j=1}^n \frac{\partial g^{ij}}{\partial x^m} \xi_i \xi_j, \quad m = 1, \dots, n. \quad (60)$$

The projections of the bicharacteristics in the x variable are the geodesics of the metric g and the parameter s denotes arc length. We denote the associated geodesic flow by

$$X_g(s) = (x_g(s), \xi_g(s)).$$

If we impose the condition that the bicharacteristics are in S initially, then they belong to S for all time, since the Hamiltonian vector field V_g is tangent to S . The Hamiltonian vector field is transverse to N ; then the resulting manifold obtained by flowing N along the integral curves of V_g will be a Lagrangian manifold L contained in S . We shall write $L = X_g(N)$.

Now the projection of N into the base space is a diffeomorphism, so that $L = \{(x, d_x \phi)\}$ locally near a point of N . We can construct a global solution of (58) near Ω if the manifold is simple. We recall the definition of simple domains.

Definition 1. Let Ω be a bounded domain of Euclidean space with smooth boundary and g a Riemannian metric on $\bar{\Omega}$. We say that $(\bar{\Omega}, g)$ is simple if given two points on the boundary there is a unique minimizing geodesic joining the two points on the boundary and, moreover, $\partial\Omega$ is geodesically convex.

If $(\bar{\Omega}, g)$ is simple, then we extend the metric smoothly in a small neighborhood, so that the metric g is still simple. In this case we can solve the eikonal equation globally in a neighborhood of Ω .

The Transport Equation

The equation $B = 0$ is equivalent to solving the following equation:

$$\sum_{i,j=1}^n g^{ij} \frac{\partial \phi}{\partial x^j} \frac{\partial a}{\partial x^i} + \frac{a}{2} \Delta_g \phi = 0. \quad (61)$$

Equation (61) is called the *transport equation*. It is a vector field equation for $a(x, \omega)$, which is solved by integrating along the integral curves of the vector field $v = \sum_{i,j=1}^n g^{ij} \frac{\partial \phi}{\partial x^j} \frac{\partial}{\partial x^i}$. It is an easy computation to prove that v has length 1 and that the integral curves of v are the geodesics of the metric g .

The solution of the transport equation (61) is then given by

$$a(x, \omega) = \exp\left(-\frac{1}{2} \int_\gamma \Delta_g \phi\right), \quad (62)$$

where γ is the unique geodesic such that $\gamma(0) = y$, $\dot{\gamma}(0) = \omega$, $y \cdot \omega = 0$ and γ passes through x . If (Ω, g) is a simple manifold, then $a \in C^\infty(\mathbb{R}^n)$.

To end the construction of the geometrical optics solutions, we observe that the function $v(t, x, \omega) \in L^2_{\text{loc}}$ by using standard regularity results for hyperbolic equations.

Now we state the main result of this section in the following theorem.

Theorem 6. *Let $(\overline{\Omega}, g_i)$, $i = 1, 2$ be simple manifolds, and assume that the response operators for $(\overline{\Omega}, g_1)$ and $(\overline{\Omega}, g_2)$ are equal. Then $d_{g_1} = d_{g_2}$.*

Sketch of proof 1. Assume that we have two metrics g_1, g_2 with the same response operator. Then by (50), the solutions of (49) are the same outside Ω . Therefore, the main singularity of the solutions in the geometrical optics expansion must be the same outside Ω . Thus, we conclude that

$$\phi_1(x, \omega) = \phi_2(x, \omega), \quad x \in \mathbb{R}^n \setminus \Omega. \quad (63)$$

Now $\phi_j(x, \omega)$ measures the geodesic distance to the hyperplane $x \cdot \omega = -R$ in the metric g . From this, we can easily conclude that the geodesic distance between two points in the boundary for the two metrics is the same, that is, $d_{g_1}(x, y) = d_{g_2}(x, y)$, $x, y \in \partial\Omega$.

This type of argument was used in [61] to study a similar inverse problem for the more complicated system of elastodynamics. In particular, it is proven in [61] that from the response operator associated to the equations of isotropic elastodynamics, one can determine, under the assumption of simplicity of the metrics, the lengths of geodesics of the metrics defined by

$$ds^2 = c_p(x) ds_e^2, \quad ds^2 = c_s(x)^2 ds_e^2, \quad (64)$$

where ds_e is the length element corresponding to the Euclidean metric and $c_p(x) = \sqrt{\frac{(\lambda+2\mu)}{\rho}}$, $c_s(x) = \sqrt{\frac{\mu}{\rho}}$ denote the speed of compressional waves and shear waves, respectively. Here λ, μ are the Lamé parameters and ρ the density.

Using Mukhometov's result [56, 57], we can recover both speeds from the response operator. This shows in particular that if we know the density, one can determine the Lamé parameters from the response operator. By using the transport equation of geometrical optics, similar to (61), and the results on the ray transform (see, e.g., [66]), Rachele shows that under certain a priori conditions one can also determine the density ρ [62].

Scattering Relation

In the presence of caustics (i.e., the exponential map is not a diffeomorphism), the expansion (51) is not valid since we cannot solve the eikonal equation globally in Ω . The solution of (50) is globally a Lagrangian distribution (see, e.g., [38]). These distributions can locally be written in the form

$$u(t, x, \omega) = \int_{\mathbb{R}^m} e^{i\phi(t, x, \omega, \theta)} a(t, x, \omega, \theta) d\theta, \quad (65)$$

where ϕ is a phase function and $a(t, x, \omega)$ is a classical symbol.

Every Lagrangian distribution is determined (up to smoother terms) by a Lagrangian manifold and its symbol. The Lagrangian manifold associated to $u(t, x, \omega)$ is the flow out from $t = x \cdot \omega, t < -R$ by the Hamilton vector field of $p_g(t, x, \tau, \xi) = \tau^2 - \sum_{j,k=1}^n g_{jk}(x)\xi^j \xi^k$. Here (τ, ξ) are the dual variables to (t, x) , respectively. The projection in the (x, ξ) variables of the flow is given by the flow out from N by geodesic flow, that is, the Lagrangian submanifold L described above.

The *scattering relation* (also called lens map) $C_g \subset (T^*(\mathbb{R} \times \partial\Omega) \setminus 0) \times (T^*(\mathbb{R} \times \partial\Omega) \setminus 0)$ of a metric $g = (g^{ij})$ on $\overline{\Omega}$ with dual metric $g^{-1} = (g_{ij})$ is defined as follows. Consider bicharacteristic curves, $\gamma : [a, b] \rightarrow T^*(\overline{\Omega} \times \mathbb{R})$, of the Hamilton function $p_g(t, x, \tau, \xi)$, which satisfy the following: $\gamma([a, b])$ lies in the interior, γ intersects the boundary non-tangentially at $\gamma(a)$ and $\gamma(b)$, and time increases along γ . Then the canonical projection from $(T_{\mathbb{R} \times \partial\Omega}^*(\mathbb{R} \times \Omega) \setminus 0) \times (T_{\mathbb{R} \times \partial\Omega}^*(\mathbb{R} \times \Omega) \setminus 0)$ onto $(T^*(\mathbb{R} \times \partial\Omega) \setminus 0) \times (T^*(\mathbb{R} \times \partial\Omega) \setminus 0)$ maps the endpoint pair $(\gamma(b), \gamma(a))$ to a point in C_g . In other words, C_g gives the geodesic distance between points in the boundary and also the points of exit and direction of exit of the geodesic if we know the point of entrance and direction of entrance.

It is well known that C_g is a homogeneous canonical relation on $((T^*(\mathbb{R} \times \partial\Omega) \setminus 0) \times (T^*(\mathbb{R} \times \partial\Omega) \setminus 0))$. (See [35] for the concept of a scattering relation.) C_g is, in fact, a diffeomorphism between open subsets of $T^*(\mathbb{R} \times \partial\Omega) \setminus 0$.

In analogy with Theorem 6, we have the following theorem.

Theorem 7. *Let $g_i, i = 1, 2$ be Riemannian metrics on $\overline{\Omega}$ such that the response operators for $(\overline{\Omega}, g_1)$ and $(\overline{\Omega}, g_2)$ are equal. Then*

$$C_{g_1} = C_{g_2}.$$

Sketch of proof 2. Since by (49), we know the solutions of (48) outside Ω . Therefore, the associated Lagrangian manifolds to the Lagrangian distributions u_j must be the same outside Ω . By taking the projection of these Lagrangians onto the boundary, we get the desired claim.

In the case that $(\bar{\Omega}, g)$ is simple, the scattering relation does not give any new information. In fact $((t_1, x_1, \tau, \xi_1), (t_0, x_0, \tau, \xi_0)) \in C_g$ if $t_1 - t_0 = d_g(x_1, x_0)$ and $\xi_j = -\tau \frac{\partial d_g(x_1, x_0)}{\partial x^j}$, $j = 0, 1$. In other words d_g is the generating function of the scattering relation.

This result was generalized in [36] to the case of the equations of elastodynamics with residual stress. It is shown that knowing the response operator, we can recover the scattering relations associated to P and S waves. For this, one uses Lagrangian distributions with appropriate polarization.

The scattering relation contains all travel time data; not just information about minimizing geodesics as is the case of the boundary distance function. The natural conjecture is that on a nontrapping manifold, this is enough to determine the metric up to isometry. We refer to [72] and the references therein for results on this problem.

Curvelets and Wave Equations

In this section we will discuss in more detail the use of curvelets in wave imaging. We begin by explaining the curvelet decomposition of functions, using the standard second dyadic decomposition of phase space. The curvelets provide tight frames of $L^2(\mathbb{R}^n)$ and give efficient representations of sharp wave fronts. We then discuss why curvelets are useful for solving the wave equation. This is best illustrated in terms of the half-wave equation (a first-order hyperbolic equation), where a good approximation to the solution is obtained by decomposing the initial data in curvelets and then by translating each curvelet along the Hamilton flow for the equation. Then we explain how one deals with wave speeds of limited smoothness, and how one can convert the approximate solution operator into an exact one by doing a Volterra iteration.

The treatment below follows the original approach of Smith [67] and focuses on explaining the theoretical aspects of curvelet methods for solving wave equations. We refer to the works mentioned in the introduction for applications and more practical considerations.

Curvelet Decomposition

We will explain the curvelet decomposition in its most standard form, as given in [67]. In a nutshell, curvelets are functions which are frequency localized in certain frequency shells and certain directions, according to the second dyadic

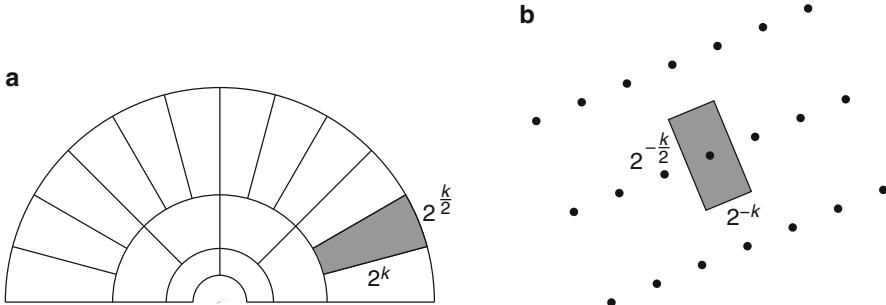

Fig. 3 A curvelet φ_γ , with $\gamma = (k, \omega, x)$ is concentrated (a) in the frequency domain near a box of length $\sim 2^k$ and width $\sim 2^{k/2}$ and (b) in the spatial side near a box of length $\sim 2^{-k}$ and width $\sim 2^{-k/2}$

decomposition and parabolic scaling. On the spatial side, curvelets are concentrated near lattice points which correspond to the frequency localization.

To make this more precise, we recall the *dyadic decomposition* of the frequency space $\{\xi \in \mathbb{R}^n\}$ into the ball $\{|\xi| \leq 1\}$ and dyadic shells $\{2^k \leq |\xi| \leq 2^{k+1}\}$. The *second dyadic decomposition* further subdivides each frequency shell $\{2^k \leq |\xi| \leq 2^{k+1}\}$ into slightly overlapping “boxes” of width roughly $2^{k/2}$ (thus each box resembles a rectangle whose major axis has length $\sim 2^k$ and all other axes have length $\sim 2^{k/2}$). See Fig. 3a for an illustration. The convention that the width ($2^{k/2}$) of the boxes is the square root of the length (2^k) is called *parabolic scaling*; this scaling is crucial for the wave equation as will be explained later.

In the end, the second dyadic decomposition amounts to having a collection of nonnegative functions $h_0, h_k^\omega \in C_c^\infty(\mathbb{R}^n)$, which form a partition of unity in the sense that

$$1 = h_0(\xi)^2 + \sum_{k=0}^{\infty} \sum_{\omega} h_k^\omega(\xi)^2.$$

Here, for each k, ω runs over roughly $2^{(n-1)k/2}$ unit vectors uniformly distributed over the unit sphere, and h_k^ω is supported in the set

$$2^{k-1/2} \leq |\xi| \leq 2^{k+3/2}, \quad \left| \frac{\xi}{|\xi|} - \omega \right| \leq 2^{-k/2}.$$

We also require a technical estimate for the derivatives

$$|\langle \omega, \partial_\xi \rangle^j \partial_\xi^\alpha h_k^\omega(\xi)| \leq C_{j,\alpha} 2^{-k(j+|\alpha|/2)},$$

with $C_{j,\alpha}$ independent of k and ω . Such a partition of unity is not hard to construct; we refer to [73, Sect. 20.9.4] for the details.

On the frequency side, a curvelet at frequency level 2^k with direction ω will be supported in a rectangle with side length $\sim 2^k$ in direction ω and side lengths $\sim 2^{k/2}$ in the orthogonal directions. By the uncertainty principle, on the spatial side, one expects a curvelet to be concentrated in a rectangle with side length $\sim 2^{-k}$ in direction ω and $\sim 2^{-k/2}$ in other directions. Motivated by this, we define a rectangular lattice Ξ_k^ω in \mathbb{R}^n , which has spacing 2^{-k} in direction ω and spacing $2^{-k/2}$ in the orthogonal directions, thus

$$\Xi_k^\omega = \left\{ x \in \mathbb{R}^n ; x = a2^{-k}\omega + \sum_{j=2}^n b_j 2^{-k/2}\omega_j \text{ where } a, b_j \in \mathbb{Z} \right\}$$

and $\{\omega, \omega_2, \dots, \omega_n\}$ is a fixed orthonormal basis of \mathbb{R}^n . See Fig. 3b.

We are now ready to give a definition of the curvelet frame.

Definition 2. For a triplet $\gamma = (k, \omega, x)$ with ω as described above and for $x \in \Xi_k^\omega$, we define the corresponding *fine-scale curvelet* φ_γ in terms of its Fourier transform by

$$\hat{\varphi}_\gamma(\xi) = (2\pi)^{-n/2} 2^{-k(n+1)/4} e^{-ix \cdot \xi} h_k^\omega(\xi).$$

The *coarse-scale curvelets* for $\gamma = (0, x)$ with $x \in \mathbb{Z}^n$ are given by

$$\hat{\varphi}_\gamma(\xi) = (2\pi)^{-n/2} e^{-ix \cdot \xi} h_0(\xi).$$

The distinction between coarse- and fine-scale curvelets is analogous to the case of wavelets. The coarse-scale curvelets are used to represent data at low frequencies $\{|\xi| \leq 1\}$, and they are direction independent, whereas the fine-scale curvelets depend on the direction ω .

The next list collects some properties of the (fine-scale) curvelets φ_γ .

- *Frequency localization.* The Fourier transform $\hat{\varphi}_\gamma(\xi)$ is supported in the shell $\{2^{k-1/2} < |\xi| < 2^{k+3/2}\}$ and in a rectangle with side length $\sim 2^k$ in the ω direction and side length $\sim 2^{k/2}$ in directions orthogonal to ω .
- *Spatial localization.* The function $\varphi_\gamma(y)$ is concentrated in (i.e., decays away from) a rectangle centered at $x \in \Xi_k^\omega$, having side length 2^{-k} in the ω direction and side lengths $2^{-k/2}$ in directions orthogonal to ω .
- *Tight frame.* Any function $f \in L^2(\mathbb{R}^n)$ may be written in terms of curvelets as

$$f(y) = \sum_\gamma c_\gamma \varphi_\gamma(y),$$

where c_γ are the curvelet coefficients of f :

$$c_\gamma = \int_{\mathbb{R}^n} f(y) \overline{\varphi_\gamma(y)} dy.$$

One has the Plancherel identity

$$\int_{\mathbb{R}^n} |f(y)|^2 dy = \sum_\gamma |c_\gamma|^2.$$

The last statement about how to represent a function $f \in L^2(\mathbb{R}^n)$ in terms of curvelets can be proved by writing

$$\hat{f}(\xi) = h_0(\xi)^2 \hat{f}(\xi) + \sum_{k=0}^{\infty} \sum_{\omega} h_k^\omega(\xi)^2 \hat{f}(\xi)$$

and then by expanding the functions $h_k^\omega(\xi) \hat{f}(\xi)$ in Fourier series in suitable rectangles, and finally by taking the inverse Fourier transform. Note that any L^2 function can be represented as a superposition of curvelets φ_γ , but that the φ_γ are not orthogonal and the representation is not unique.

Curvelets and Wave Equations

Next we explain, in a purely formal way, how curvelets can be used to solve the Cauchy problem for the wave equation

$$\begin{aligned} (\partial_t^2 + A(x, D_x)) u(t, x) &= F(t, x) \quad \text{in } \mathbb{R} \times \mathbb{R}^n, \\ u(0, x) &= u_0(x), \\ \partial_t u(0, x) &= u_1(x). \end{aligned}$$

Further details and references are given in the next section. Here $A(x, D_x) = \sum_{j,k=1}^n g^{jk}(x) D_{x_j} D_{x_k}$ is a uniform elliptic operator, meaning that $g^{jk} = g^{kj}$ and $0 < \lambda \leq \sum_{j,k=1}^n g^{jk}(x) \xi_j \xi_k \leq \Lambda < \infty$ uniformly over $x \in \mathbb{R}^n$ and $\xi \in S^{n-1}$. We assume that g^{jk} are smooth and have uniformly bounded derivatives of all orders.

It is enough to construct an operator $S(t) : u_1 \mapsto u(t, \cdot)$ such that $u(t, x) = (S(t)u_1)(x)$ solves the above wave equation with $F \equiv 0$ and $u_0 \equiv 0$. Then, by Duhamel's principle, the general solution of the above equation will be

$$u(t, x) = \int_0^t S(t-s) F(s, x) ds + (\partial_t S(t) u_0)(x) + (S(t) u_1)(x).$$

To construct $S(t)$, we begin by factoring the wave operator $\partial_t^2 + A(x, D_x)$ into two first-order hyperbolic operators, known as *half-wave operators*. Let $P(x, D_x) = \sqrt{A(x, D_x)}$ be a formal square root of the elliptic operator $A(x, D_x)$. Then we have

$$\partial_t^2 + A(x, D_x) = (\partial_t - iP)(\partial_t + iP)$$

and the Cauchy problem for the wave equation with data $F \equiv 0, u_0 \equiv 0, u_1 = f$ is reduced to solving the two first-order equations

$$\begin{aligned} (\partial_t - iP)v &= 0, & v(0) &= f, \\ (\partial_t + iP)u &= v, & u(0) &= 0. \end{aligned}$$

If one can solve the first equation, then solvability of the second equation will follow from Duhamel's principle (the sign in front of P is immaterial).

Therefore, we only need to solve

$$\begin{aligned} (\partial_t - iP)v(t, x) &= 0, \\ v(0, x) &= f(x). \end{aligned}$$

For the moment, let us simplify even further and assume that $A(x, D_x)$ is the Laplacian $-\Delta$, so that P will be the operator given by

$$\widehat{Pf}(\xi) = |\xi| \hat{f}(\xi).$$

Taking the spatial Fourier transform of the equation for v and solving the resulting ordinary differential equation give the full solution

$$v(t, y) = (2\pi)^{-n} \int_{\mathbb{R}^n} e^{i(y \cdot \xi + t|\xi|)} \hat{f}(\xi) d\xi.$$

Thus, the solution is given by a Fourier integral operator acting on f :

$$v(t, y) = (2\pi)^{-n} \int_{\mathbb{R}^n} e^{i\Phi(t, y, \xi)} a(t, y, \xi) \hat{f}(\xi) d\xi.$$

In this particular case, the phase function is $\Phi(t, y, \xi) = y \cdot \xi + t|\xi|$, and the symbol is $a(t, y, \xi) \equiv 1$.

So far we have not used any special properties of f . Here comes the key point. *If f is a curvelet, then the phase function is well approximated on $\text{supp}(f)$ by its linearization in ξ :*

$$\Phi(t, y, \xi) \approx \nabla_\xi \Phi(t, y, \omega) \cdot \xi \quad \text{for } \xi \in \text{supp}(f).$$

(This statement may seem somewhat mysterious, but it really is one reason why curvelets are useful for wave imaging. A slightly more precise statement is as follows: if $\Psi(t, y, \xi)$ is smooth for $\xi \neq 0$, homogeneous of order 1 in ξ , and its derivatives are uniformly bounded over $t \in [-T, T]$ and $y \in \mathbb{R}^n$ and $\xi \in S^{n-1}$, then

$$|\Psi(t, y, \xi) - \nabla_\xi \Psi(t, y, \omega) \cdot \xi| \lesssim 1$$

whenever $\xi \cdot \omega \sim 2^k$ and $|\xi - (\xi \cdot \omega)\omega| \lesssim 2^{k/2}$. Also the derivatives of $\Psi(t, y, \xi) - \nabla_\xi \Psi(t, y, \omega) \cdot \xi$ satisfy suitable symbol bounds. Parabolic scaling is crucial here; we refer to [18, section “Travel Times and Scattering Relation”] for more on this point.) Thus, if $f = \varphi_\gamma$ then the solution v with this initial data is approximately given by

$$v(t, y) \approx (2\pi)^{-n} \int_{\mathbb{R}^n} e^{i(y+t\omega) \cdot \xi} \hat{\varphi}_\gamma(\xi) d\xi = \varphi_\gamma(y + t\omega).$$

Thus the half-wave equation for $P = \sqrt{-\Delta}$, whose initial data is a curvelet in direction ω , is approximately solved by translating the curvelet along a straight line in direction ω .

We now return to the general case, where $A(x, \xi)$ is a general elliptic symbol $\sum_{j,k=1}^n g^{jk}(x) \xi_j \xi_k$. We define

$$p(x, \xi) = \sqrt{A(x, \xi)}.$$

Then p is homogeneous of order 1 in ξ , and it generates a *Hamilton flow* $(x(t), \xi(t))$ in the phase space $T^*\mathbb{R}^n = \mathbb{R}^n \times \mathbb{R}^n$, determined by the ordinary differential equations

$$\begin{aligned} \dot{x}(t) &= \nabla_\xi p(x(t), \xi(t)), \\ \dot{\xi}(t) &= -\nabla_x p(x(t), \xi(t)). \end{aligned}$$

If $A(x, \xi)$ is smooth, then the curves $(x(t), \xi(t))$ starting at some point $(x(0), \xi(0)) = (x, \omega)$ are smooth and exist for all time. Note that if $p(x, \xi) = |\xi|$, then one has straight lines $(x(t), \xi(t)) = (x + t\omega, \omega)$.

Similarly as above, the half-wave equation

$$\begin{aligned} (\partial_t - iP)v(t, x) &= 0, \\ v(0, x) &= f(x) \end{aligned}$$

can be approximately solved as follows:

1. Write the initial data f in terms of curvelets as $f(y) = \sum_\gamma c_\gamma \varphi_\gamma(y)$.
2. For a curvelet $\varphi_\gamma(y)$ centered at x pointing in direction ω , let $\varphi_\gamma(t, y)$ be another curvelet centered at $x(t)$ pointing in direction $\xi(t)$. That is, translate each curvelet φ_γ for time t along the Hamilton flow for P .
3. Let $v(t, y) = \sum_\gamma c_\gamma \varphi_\gamma(t, y)$ be the approximate solution.

Thus, the wave equation can be approximately solved by decomposing the initial data into curvelets and then by translating each curvelet along the Hamilton flow.

Low-Regularity Wave Speeds and Volterra Iteration

Here we give some further details related to the formal discussion in the previous section, following the arguments in [67]. The precise assumption on the coefficients will be

$$g^{jk}(x) \in C^{1,1}(\mathbb{R}^n).$$

This means that $\partial^\alpha g^{jk} \in L^\infty(\mathbb{R}^n)$ for $|\alpha| \leq 2$, which is a minimal assumption which guarantees a well-defined Hamilton flow.

As discussed in section ‘‘Curvelets and Wave Equations,’’ by Duhamel’s formula, it is sufficient to consider the Cauchy problem

$$\begin{aligned} (\partial_t^2 + A(x, D_x)) u(t, x) &= 0 \quad \text{in } \mathbb{R} \times \mathbb{R}^n, \\ u(0, x) &= 0, \\ \partial_t u(0, x) &= f. \end{aligned}$$

Here, $A(x, D_x) = \sum_{j,k=1}^n g^{jk}(x) D_{x_j} D_{x_k}$ and $g^{jk} \in C^{1,1}(\mathbb{R}^n)$, $g^{jk} = g^{kj}$, and $0 < \lambda \leq \sum_{j,k=1}^n g^{jk}(x) \xi_j \xi_k \leq \Lambda < \infty$ uniformly over $x \in \mathbb{R}^n$ and $\xi \in S^{n-1}$.

To deal with the nonsmooth coefficients, we introduce the smooth approximations

$$A_k(x, \xi) = \sum_{i,j=1}^n g_k^{ij}(x) \xi_i \xi_j, \quad g_k^{ij} = \chi(2^{-k/2} D_x) g^{ij}$$

where $\chi \in C_c^\infty(\mathbb{R}^n)$ satisfies $0 \leq \chi \leq 1$, $\chi(\xi) = 1$ for $|\xi| \leq 1/2$, and $\chi(\xi) = 0$ for $|\xi| \geq 1$. We have written $(\chi(2^{-k/2} D_x) g) \hat{ }(\xi) = \chi(2^{-k/2} \xi) \hat{g}(\xi)$. Thus g_k^{ij} are smooth truncations of g^{ij} to frequencies $\leq 2^{k/2}$. We will use the smooth approximation A_k in the construction of the solution operator at frequency level 2^k , which is in keeping with paradifferential calculus.

Given a curvelet $\varphi_\gamma(y)$ where $\gamma = (k, \omega_\gamma, x_\gamma)$, we wish to consider a curvelet $\varphi_\gamma(t, y)$ which corresponds to a translation of φ_γ for time t along the Hamilton flow for $H_k(x, \xi) = \sqrt{A_k(x, \xi)}$. In fact, we shall define

$$\varphi_\gamma(t, y) = \varphi_\gamma \left(\Theta_\gamma(t) (y - x_\gamma(t)) + x_\gamma \right),$$

where $x_\gamma(t)$ and the $n \times n$ matrix $\Theta_\gamma(t)$ arise as the solution of the equations

$$\begin{aligned} \dot{x} &= \nabla_\xi H_k(x, \omega), \\ \dot{\omega} &= -\nabla_x H_k(x, \omega) + (\omega \cdot \nabla_x H_k(x, \omega)) \omega, \end{aligned}$$

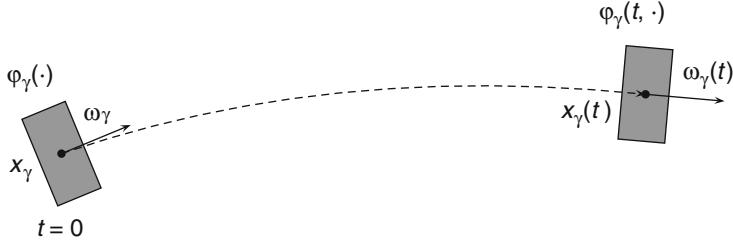

Fig. 4 The translation of a curvelet φ_γ for time t along the Hamilton flow

$$\dot{\Theta} = -\Theta (\omega \otimes \nabla_x H_k(x, \omega) - \nabla_x H_k(x, \omega) \otimes \omega)$$

with initial condition $(x_\gamma(0), \omega_\gamma(0), \Theta_\gamma(0)) = (x_\gamma, \omega_\gamma, I)$. Here $v \otimes w$ is the matrix with $(v \otimes w)x = (w \cdot x)v$. The idea is that $(x_\gamma(t), \omega_\gamma(t))$ is the Hamilton flow for H_k restricted to the unit cosphere bundle $S^*\mathbb{R}^n = \{(x, \xi) \in T^*\mathbb{R}^n; |\xi| = 1\}$, and $\Theta_\gamma(t)$ is a matrix which tracks the rotation of ω_γ along the flow and satisfies $\Theta_\gamma(t)\omega_\gamma(t) = \omega_\gamma$ for all t . See Fig. 4 for an illustration.

We define an approximate solution operator at frequency level 2^k by

$$E_k(t)f(y) = \sum_{\gamma': k' = k} (f, \varphi_{\gamma'})_{L^2(\mathbb{R}^n)} \varphi_{\gamma'}(t, y).$$

Summing over all frequencies, we consider the operator

$$E(t)f = \sum_{k=0}^{\infty} E_k(t)f.$$

This operator essentially takes a function f , decomposes it into curvelets, and then translates each curvelet at frequency level 2^k for time t along the Hamilton flow for H_k .

It is proved in [67, Theorem 3.2] that $E(t)$ is an operator of order 0, mapping $H^\alpha(\mathbb{R}^n)$ to $H^\alpha(\mathbb{R}^n)$ for any α . The fact that $E(t)$ is an approximate solution operator is encoded in the result that the wave operator applied to $E(t)$,

$$T(t) = (\partial_t^2 + A(x, D_x)) E(t),$$

which is a priori a second-order operator, is in fact an operator of order 1 and maps $H^{\alpha+1}(\mathbb{R}^n)$ to $H^\alpha(\mathbb{R}^n)$ for $-1 \leq \alpha \leq 2$. This is proved in [67, Theorem 4.5] and is due to the two facts. The first one is that when A is replaced by the smooth approximation A_k , the corresponding operator

$$\sum_k (\partial_t^2 + A_k(x, D_x)) E_k(t)$$

is of order 1 because the second-order terms cancel. Here, one uses that translation along the Hamilton flow approximately solves the wave equation. The second fact is that the part involving the nonsmooth coefficients

$$\sum_k (A_k(x, D_x) - A(x, D_x)) E_k(t)$$

is also of order 1 using that A_k is truncated to frequencies $\leq 2^{k/2}$ and using estimates for $A - A_k$ obtained from the $C^{1,1}$ regularity of the coefficients.

To obtain the full parametrix, one needs to consider the Hamilton flows both for $\sqrt{A_k}$ and $-\sqrt{A_k}$, corresponding to the two half-wave equations appearing in the factorization of the wave operator, and one also needs to introduce corrections to ensure that the initial values of the approximate solution are the given functions. For simplicity, we will not consider these details here and only refer to [67, Sect. 4]. The outcome of this argument is an operator $\mathbf{s}(t, s)$, which is strongly continuous in t and s as a bounded operator $H^\alpha(\mathbb{R}^n) \rightarrow H^{\alpha+1}(\mathbb{R}^n)$ satisfies $\mathbf{s}(t, s)f|_{t=s} = 0$ and $\partial_t \mathbf{s}(t, s)f|_{t=s} = f$, and further the operator

$$T(t, s) = (\partial_t^2 + A(x, D_x)) \mathbf{s}(t, s)$$

is bounded $H^\alpha(\mathbb{R}^n) \rightarrow H^\alpha(\mathbb{R}^n)$ for $-1 \leq \alpha \leq 2$.

We conclude this discussion by explaining the Volterra iteration scheme, which is used for converting the approximate solution operator to an exact one, as in [67, Theorem 4.6]. We look for a solution in the form

$$u(t) = \mathbf{s}(t, 0)f + \int_0^t \mathbf{s}(t, s)G(s) ds$$

for some $G \in L^1([-t_0, t_0]; H^\alpha(\mathbb{R}^n))$. From the properties of $\mathbf{s}(t, s)$, we see that u satisfies

$$(\partial_t^2 + A(x, D_x)) u = T(t, 0)f + G(t) + \int_0^t T(t, s)G(s) ds.$$

Thus, u is a solution if G is such that

$$G(t) + \int_0^t T(t, s)G(s) ds = -T(t, 0)f.$$

Since $T(t, s)$ is bounded on $H^\alpha(\mathbb{R}^n)$ for $-1 \leq \alpha \leq 2$, with norm bounded by a uniform constant when $|t|, |s| \leq t_0$, the last Volterra equation can be solved by iteration. This yields the required solution u .

4 Conclusion

In this chapter, inverse problems for the wave equation were considered with different types of data. All considered data correspond to measurements made on the boundary of a body in which the wave speed is unknown and possibly anisotropic. The case of the complete data, that is, with measurements of amplitudes and phases of waves corresponding to all possible sources on the boundary, was considered using the boundary control method. We showed that the wave speed can be reconstructed from the boundary measurements up to a diffeomorphism of the domain. This corresponds to the determination of the wave speed in the local travel time coordinates. Next, the inverse problem with less data, the scattering relation, was considered. The scattering relation consists of the travel times and the exit directions of the wave fronts produced by the point sources located on the boundary of the body. Such data can be considered to be obtained by measuring the waves up to smooth errors or measuring only the singularities of the waves. The scattering relation is a generalization of the travel time data, that is, the travel times of the waves through the body. Finally, we considered the use of wavelets and curvelets in the analysis of the waves. Using the curvelet representation of the waves, the singularities of the waves can be efficiently analyzed. In particular, the curvelets are suitable for the simulation of the scattering relation, even when the wave speed is nonsmooth. Summarizing, in this chapter, modern approaches to study inverse problems for wave equations based on the control theory, the geometry, and the microlocal analysis were presented.

Abstract

This paper deals with the inverse problem of the wave equation, which is of relevance in fields such as ultrasound tomography, seismic imaging, and nondestructive testing. We study the linearized problem by Fourier analysis, and we describe an iterative reconstruction method for the fully nonlinear problem in the time domain. We discuss practical problems such as the spectral incompleteness in reflection imaging and finding a good initial approximation. We demonstrate by numerical reconstructions from synthetic data what can be achieved.

1 Introduction

Imaging with ultrasound, or sonography, is a well-established technique in medicine and many other fields. It goes back to the middle of the last century [21]. The human body is scanned by a (usually handheld) transducer that emits the sound signals and records the reflected signals. The mathematical models used in present days are fairly simple. In particular they assume straight line propagation of the sound signals. More refined models take into account the bending of the rays. They go under the name of diffraction tomography [15, 32, 56].

In this article we deal with an even more refined method of ultrasound imaging which is based on the wave equation. This permits to take into account not only bent rays but also multiple reflections. These techniques are not yet part of current medical practice, but prototype scanners based on these principles have already been built and tested in a clinical environment [4, 20].

Speaking in mathematical terms, we deal with the ultrasound imaging problem as the inverse problem for the wave equation. We determine parameters such as the speed of sound and the attenuation from measurements of the field outside the object. Imaging with the wave equation plays an important role not only in medical radiology, but also in nondestructive testing and seismic exploration. Our goal is to deal with the fully nonlinear problem. We start with a survey on the results obtained by linearization. For the fully nonlinear problem, we describe in detail the Kaczmarz method in the time domain. It turns out that Kaczmarz method, whose linear version is widely used in X-ray tomography [25], can be viewed in a very intuitive way as consecutive time reversal. We show by numerical examples that Kaczmarz method easily solves the standard problems, such as transmission tomography and reflection imaging with broadband data. We also study the behavior of the method in nonstandard situations, such as caustics, trapped rays, and, in particular, missing low frequencies in the source pulse.

The literature on inverse problems for the wave equation is inexhaustible. So we restrict our discussion to the exact solution of the fully nonlinear coefficient inverse problem for general objects. We do not even mention the important work on obstacle scattering [12], where the object is homogeneous and only the shape of the object is sought for, nor do we deal with level set methods [18]. Neither do we discuss the many approximate methods, except for the Born approximation, because it gives so

much insight into the fully nonlinear problem. Other problems which we ignore are the linear inverse source problems [29] and phase contrast tomography [31].

2 The Model Problem

We consider the following initial value problem for the wave equation. Let Ω be a domain in $R^n, n = 2, 3$ and let $\Gamma = \partial\Omega$. Let $c(x)$ be the speed of sound in $x \in \Omega$. Let $T > 0$ be the observation time. Let u be a solution of the initial-boundary value problem

$$\frac{\partial^2 u}{\partial t^2}(x, t) = c^2(x)\Delta u(x, t), \quad x \in \Omega, \quad 0 < t < T, \quad (1)$$

$$\frac{\partial u}{\partial \nu} = q(t)\delta_{\Gamma,s}(x), \quad x \in \Gamma, \quad 0 < t < T, \quad (2)$$

$$u(x, t) = 0, \quad t < 0 \quad (3)$$

with ν the exterior normal on Γ . We consider the inverse problem of determining c from the values of $u(x, t)$ on $\Gamma \times (0, T)$, or on part of it. The function q represents the source pulse, and $\delta_{\Gamma,s}$ is the Dirac δ -function on Γ concentrated at the source $s \in \Gamma$. We always assume that $c^2(x) = c_0^2(x)/(1 + f(x))$ with the (known) background velocity c_0 and a function $f > -1$ which has to be determined.

We remark that everything we are doing in this paper can also be done for more general problems, such as problems with varying density [26], in moving media [61] and problems with attenuation [4, 20, 40].

3 The Born Approximation

Even though the underlying differential equation is linear, the inverse problem is nonlinear. Most of the literature on the problem makes use of some kind of linearization, mostly the Born approximation. Our goal is definitely to deal with the fully nonlinear problem. However linearization leads to valuable insights also for the nonlinear problem. Therefore we discuss the Born approximation in some detail.

An Explicit Formula for the Slab

We restrict ourselves to a very simple geometry: Ω is just the slab $0 < x_n < D$. Sources and receivers are sitting either on both boundaries (transmission mode) or on only one of them (reflection mode). It is more convenient to work with the inhomogeneous initial value problem

$$\frac{\partial^2 u}{\partial t^2}(x, t) = c^2(x) (\Delta u(x, t) + q(t)\delta(x - s)), \quad x \in R^n, 0 < t < T, \quad (4)$$

$$u(x, t) = 0, \quad t < 0 \quad (5)$$

with δ the Dirac function in R^n and s a source. We also assume $c(x) = c_0 > 0$ constant in this section. Equations (4), (5) is a simplified version of (1)–(3).

We also look at the problem in the frequency domain. For the Fourier transform in R^n , we use the notation

$$\hat{f}(\xi) = (2\pi)^{-n/2} \int_{R^n} e^{-ix \cdot \xi} f(x) dx$$

and we denote the inverse Fourier transform of f by \tilde{f} . Doing an inverse Fourier transform with respect to t in (4), we get

$$\Delta \tilde{u}(x, \omega) + k^2(1 + f)\tilde{u}(x, \omega) = -\tilde{q}(\omega)\delta(x - s) \quad (6)$$

where $k = \omega/c_0$ is the wave number. Because of (5) this equation has to be complemented by the Sommerfeld radiation condition for outgoing radiation, i.e.,

$$\frac{\partial \tilde{u}}{\partial |x|} - ik\tilde{u} \rightarrow 0, |x| \rightarrow \infty.$$

In this section we derive an explicit representation of the Born approximation by Fourier analysis. We follow [14, 42].

For $f = 0$, the solution of (6) is $\tilde{q}(\omega)G_k(x - s)$ with G_k the free space Green's function which we give in the plane wave decomposition

$$G_k(x) = i c_n \int_{R^{n-1}} e^{i(|x_n|k(\xi') - x' \cdot \xi')} \frac{d\xi'}{\kappa(\xi')} \quad (7)$$

where $c_2 = 1/(4\pi)$, $c_3 = 1/(8\pi^2)$, $\kappa(z) = \sqrt{k^2 - z^2}$. For $z > k$, $\kappa(z)$ is defined to be $i\sqrt{z^2 - k^2}$.

For arbitrary f , we put $\tilde{u}(x) = \tilde{q}(\omega)G_k(x - s) + v(x, s)$, obtaining for v

$$\Delta_x v(x, s) + k^2(1 + f(x))v(x, s) = -k^2\tilde{q}G_k(x - s)f(x).$$

Neglecting $f v$ leads to the Born approximation

$$\Delta_x v(x, s) + k^2 v(x, s) \approx -k^2\tilde{q}(\omega)G_k(x - s)f(x)$$

or

$$v(x, s) \approx k^2\tilde{q}(\omega) \int_{\Omega} G_k(x - y)G_k(y - s)f(y)dy.$$

With x' the first $n - 1$ coordinates of x and correspondingly for s, y we rewrite this as

$$v(x', x_n, s', s_n) \approx k^2 \tilde{q}(\omega) \int_0^D \int_{R^{n-1}} G_k(x' - y', x_n - y_n) f(y', y_n) \\ G_k(y' - s', y_n - s_n) dy' dy_n.$$

Inserting (7) we get

$$v(x', x_n, s', s_n) \approx -c_n^2 k^2 \tilde{q}(\omega) \int_0^D \int_{R^{n-1}} \int_{R^{n-1}} e^{i(|x_n - y_n| \kappa(\xi') - (x' - y') \cdot \xi')} \\ \int_{R^{n-1}} f(y', y_n) e^{i(|y_n - s_n| \kappa(\sigma') - (y' - s') \cdot \sigma')} \frac{d\xi' d\sigma'}{\kappa(\xi') \kappa(\sigma')} dy' dy_n.$$

The y' integral is just a $(n - 1)$ -dimensional Fourier transform, hence

$$v(x', x_n, s', s_n) \approx -(2\pi)^{n-1} k^2 c_n^2 \tilde{q}(\omega) \int_0^D \int_{R^{n-1}} \int_{R^{n-1}} e^{i(|x_n - y_n| \kappa(\xi') + |y_n - s_n| \kappa(\sigma') - x' \cdot \xi' + s' \cdot \sigma')} \\ \hat{f}(\sigma' - \xi', y_n) \frac{d\xi' d\sigma'}{\kappa(\xi') \kappa(\sigma')} dy_n. \quad (8)$$

where \hat{f} is the $(n - 1)$ -dimensional Fourier transform of f with respect to the first $n - 1$ variables. Fourier transforms of dimensions $n - 1$ with respect to x' and s' yield

$$\hat{v}(\xi', x_n, \sigma', s_n) \approx -k^2 c_n^2 \tilde{q}(\omega) \frac{(2\pi)^{2(n-1)}}{\kappa(\xi') \kappa(\sigma')} \int_0^D e^{i|x_n - y_n| \kappa(\xi') + i|y_n - s_n| \kappa(\sigma')} \\ \hat{f}(\xi' + \sigma', y_n) dy_n.$$

In particular we have

$$\hat{v}(\xi', 0, \sigma', 0) \approx A \hat{f}(\xi' + \sigma', -\kappa(\xi') - \kappa(\sigma')), \quad (9)$$

$$\hat{v}(\xi', D, \sigma', 0) \approx A e^{i D \kappa(\xi')} \hat{f}(\xi' + \sigma', \kappa(\xi') - \kappa(\sigma')) \quad (10)$$

where \hat{f} is now the n -dimensional Fourier transform of f and $A = -k^2 \tilde{q}(\omega) c_n^2 (2\pi)^{3n/2-1} / (\kappa(\xi') \kappa(\sigma'))$. Equations (9), (10) is the solution of the inverse problem of reflection and transmission imaging, resp., in the Born approximation. Note that the derivation of (9), (10) depends entirely on the plane wave decomposition of G_k which was used first in this context in [14].

Let's look at the transmission case, i.e., (10). For simplicity, we consider the 2D case. Consider the semicircle of radius k in the upper half plane around the origin. Attach to each point of this semicircle the semicircle of radius k around this point that opens downward. According to (10), \hat{f} is determined by the data along each

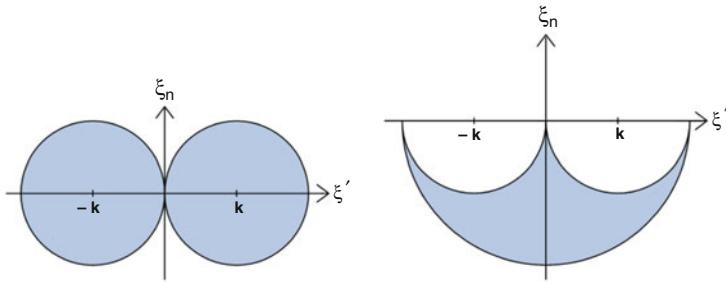

Fig. 1 *Left:* Fourier coverage for transmission imaging. *Right:* Fourier coverage for reflection imaging. k is the wave number. The figures are for $n = 2$. For $n = 3$, one has to rotate the figures around the vertical axis

of these semicircles. These semicircles fill the circles of radius k with midpoints $(\pm k, 0)$; see Fig. 1. In the reflection case (9) we proceed in the same way, except that we start out from the semicircle in the lower half plane. Now the attached semicircles fill the semicircle of radius $2k$ in the lower half plane, except for the circles of radius k around $(\pm k, 0)$.

Thus we see a fundamental difference between transmission and reflection imaging: In transmission imaging low frequency features f can be recovered irrespectively of the frequency content of the source pulse q , whereas in reflection imaging one needs low frequencies in the source pulse to recover low frequency features in f . This is one of the main difficulties in seismic imaging; see [9, 19, 22, 30, 60]. To the best of our knowledge, Fig. 1 appeared first in [35, 64]. The difficulties in reflection imaging without low frequencies will be discussed in section “Missing Low Frequencies”.

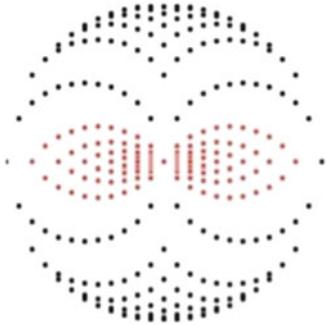

We also conclude from (9), (10) that combined transmission and reflection measurements determine \hat{f} within the ball of radius $2k$. In other words, since $\lambda = 2\pi/k$ is the wavelength of the irradiating sources, the spatial resolution according to Shannon’s sampling theorem is $2\pi/2k = \lambda/2$. This is a classical result already known to Born.

The numerical evaluation of (9), (10) is by no means trivial. In principle it can be done by Fourier transforms. However this requires a sophisticated software for non-equispaced fast Fourier transforms. Assuming uniform sampling of \hat{v} in ξ' and σ' leads to non-equispaced sampling of \hat{f} on a grid of the type shown in Fig. 2. An implementation similar to the filtered backprojection algorithm of X-ray computerized tomography has been given in [14].

An Error Estimate for the Born Approximation

We now assume that Ω is a ball of radius r , the background speed is constant as in the previous section, and that the illumination done is by plane waves. This leads to

Fig. 2 Non-equidistant grid at which \hat{f} is given by (9), (10) for $n = 2$

the problem

$$\Delta u + k^2(1 + f)u = 0, \quad (11)$$

$$u = u_i + u_s \quad (12)$$

where $u_i = \exp ikx \cdot \theta$ is the incoming wave with direction $\theta \in S^{n-1}$ and wave number k and u_s is the scattered wave satisfying the Sommerfeld radiation condition of exterior radiation. We assume f to be supported in Ω . θ runs through all of S^1 for $n = 2$ and through a great circle of S^2 for $n = 3$. The problem is to determine f from $g_\theta(z) = u_s(s\theta + z)$ for some s with $|s| > r$ and $z \in \theta^\perp$. The decisive tool for the error estimate is an estimate for the operator

$$\mathcal{G}_k u(x) = k^2 \int G_k(x - y)u(y)dy$$

in $L_2(|x| < r)$. In [41] it has been shown that

$$\|\mathcal{G}_k\|_{L_2(|x| < r)} = kr\gamma_n(kr)$$

where γ_n is a function with $\bar{\gamma}_n = \sup_{(0,\infty)} \gamma_n < \infty$. For instance, $\bar{\gamma}_2 \leq 0.8$. We have $u_s = k^2 \mathcal{G}_k(f(u_i + u_s))$, hence, with $q = kr\gamma_n(kr)$, $q\|f\|_{L_\infty(|x| < r)} < 1$

$$\|u_s\|_{L_2(|x| < r)} \leq \frac{q}{1 - q\|f\|_{L_\infty(|x| < r)}} \|f\|_{L_2(|x| < r)}. \quad (13)$$

We introduce the propagation operator

$$(U_\theta f)(z) = \int G_k(s\theta + z - y)f(y)u_i(y)dy;$$

see [14]. For the $(n - 1)$ -dimensional Fourier transform of U_θ in θ^\perp , we have

$$(U_\theta f)^\wedge(\zeta) = i \sqrt{\frac{\pi}{2}} e^{i|s|\kappa(\zeta)} \frac{1}{\kappa(\zeta)} \hat{f}((\epsilon\kappa(\zeta) - k)\theta + \zeta)$$

where $\kappa(\zeta) = \sqrt{k^2 - |\zeta|^2}$ and $\epsilon = \text{sgn}(s)$. This is essentially Theorem 3.1 of [50].

We have

$$k^{-2}g_\theta = U_\theta f + U_\theta \frac{u_s}{u_i} f$$

hence

$$k^{-2}\hat{g}_\theta(\zeta) = i \sqrt{\frac{\pi}{2}} e^{i|s|\kappa(\zeta)} \frac{1}{\kappa(\zeta)} \left(\hat{f}((\epsilon\kappa(\zeta) - k)\theta + \zeta) + (u_s f)^\wedge((\epsilon\kappa(\zeta)\theta + \zeta)) \right).$$

Now let $\xi \in R^n$ be in the ball $|\xi| < 2k$. We can find $\theta \in S^{n-1}$, $\zeta \in \theta^\perp$ with $\xi = (\epsilon\kappa(\zeta) - k)\theta + \zeta$. For any such choice of θ and ζ , the last formula yields

$$\hat{f}(\xi) = \hat{f}_B(\xi) - (u_s f)^\wedge(\xi + k\theta), \quad \hat{f}_B(\xi) = -i \sqrt{\frac{2}{\pi}} e^{-i|s|\kappa(\zeta)} \kappa(\zeta) k^{-2} \hat{g}_\theta(\zeta).$$

Since

$$|(u_s f)^\wedge| \leq (2\pi)^{-n/2} \|u_s\|_{L_2(|x| < r)} \|f\|_{L_2(|x| < r)}$$

we have for $|\xi| \leq 2k$

$$\left| \hat{f}(\xi) - \hat{f}_B(\xi) \right| \leq (2\pi)^{-n/2} \frac{q}{1 - q \|f\|_{L_\infty(|x| < r)}} \|f\|_{L_2(|x| < r)}^2. \quad (14)$$

Thus we obtained an approximation of second order in f for \hat{f} in the ball $|\xi| \leq 2k$. This is what we expect from the Born approximation. The restriction to the bandwidth $2k$ is also natural as this corresponds to the maximal spatial resolution of π/k .

We see from (14) that the decisive quantity for the Born approximation to be valid is $q \|f\|_{L_\infty(|x| < r)}$. In the engineering literature, see, e.g., [32], it is well known that this is a measure for the phase shift generated by the object f . Thus we arrive at the conclusion that the Born approximation works if the phase shift is sufficiently small. We also conclude from (14) that the reconstruction process, if restricted to the resolution π/k is fairly stable: there are no unstable operations in the computation of \hat{f}_B . It has been shown in [53] that this is also the case for the fully nonlinear problem, provided the geodesics behave reasonably. Thus the frequently discussed

instability of the inverse scattering problem is just a consequence of an inadequate choice of the frequency of the irradiating waves.

4 The Nonlinear Problem in the Time Domain

In this section we deal with the problem in the form (1)–(3). We suggest a very simple but practically useful iterative method and discuss some theoretical and practical aspects of it.

The Kaczmarz Method in the Time Domain

For a finite number of sources s_j , $j = 1, \dots, p$ we have to solve a system of the form

$$R_j(f) = g_j, \quad j = 1, \dots, p. \quad (15)$$

where R_j is an operator between a Hilbert space H of functions on $\Omega \times (0, T)$ and certain Hilbert spaces H_j of functions on $\Gamma \times (0, T)$. In our case the operator R_j is defined by $R_j(f) = u_j|_{\Gamma \times (0, T)}$, where u_j is the solution of (1)–(3) for the source $s = s_j$.

A natural method for solving (15) is the Kaczmarz method. This is an iterative method with the update

$$f_{j+1} = f_j + \alpha (R'_{j'}(f_j))^* C_{j'}^{-1} (g_{j'} - R_{j'}(f_j)), \quad j = 1, 2, \dots$$

where $j' = j \bmod p$. Here, R'_j is the Fréchet derivative of R_j , R'^*_j its adjoint, and C_j is a positive definite operator. Going through all the equations once is called a complete sweep of the Kaczmarz method.

In the linear case, i.e., if $R_j : H \rightarrow H_j$ is a linear bounded operator the convergence of the Kaczmarz method is well understood, in particular for the case of CT; see, e.g., [50], Theorem 5.1.

If $C_j - R_j R'^*_j$ is positive semidefinite, the sequence f_j converges for $0 < \alpha < 2$ to $Pf_1 + R^+g$, where P is the orthogonal projection on the nullspace of $R = (R_1, \dots, R_p)$ and R^+ is the Moore–Penrose generalized inverse of R . In the nonlinear case the situation is much less clear, see [6] for a theoretical discussion of the issue.

The Kaczmarz method is not to be confused with the Landweber iteration. In the Landweber method one does the update only after all the equations have been processed, while in Kaczmarz we do the update as soon as a single equation is processed. In practice Kaczmarz turns out to be much faster than Landweber. In the linear finite dimensional case Kaczmarz is identical to the SOR method, see Theorem 5.2 in [50]. Also, the speed of convergence depends on the ordering

of the sources. Sequential ordering does not yield the best results. Sophisticated arrangements, in particular random orderings, are much better. For the case of CT, see Section 5.3.1 of [50].

In order to compute $R'_j(f)$ for our imaging problem, we replace f by $f + h$ and u_j by $u_j + w$ with h, w small and ignore higher order terms. We get for w the differential equation

$$\frac{1}{c^2} \frac{\partial^2 w}{\partial t^2} = \Delta w - \frac{h}{c_0^2} \frac{\partial^2 u_j}{\partial t^2}, \quad x \in \Omega, 0 < t < T, \quad (16)$$

$$\frac{\partial w}{\partial \nu} = 0, \quad x \in \Gamma, 0 < t < T, \quad (17)$$

$$w = 0, \quad t < 0. \quad (18)$$

Hence we expect that

$$R'_j(f)h = w|_{\Gamma \times (0, T)}.$$

In fact it has been shown in [16] that with a suitable choice of Hilbert spaces H, H_j the operator R_j is Fréchet differentiable and the expression above is the derivative. A possible choice is $H = H^2(\Omega)$, restricted to functions $f > -1$, and $H_j = H^{1/2}(\Gamma \times (0, T))$.

Now we come to the problem of computing the adjoint of R'_j . For this we have to specify the spaces H, H_j . To make things easy, we put $H = L_2(\Omega), H_j = L_2(\Gamma \times (0, T))$, i.e., we consider R'_j as an unbounded operator between these spaces. Then the adjoint $R'_j{}^*$ satisfies

$$(R'_j(f)h, g)_{L_2(\Omega \times (0, T))} = (h, R'_j(f)^*g)_{L_2(\Gamma \times (0, T))}$$

for sufficiently smooth functions h, g . Determining the exact domain of definition of the adjoint is a more tricky question which is not considered here.

To find an explicit form of the adjoint, we follow [38]. We start out from the identity

$$\begin{aligned} & \int_{\Omega} \int_0^T \left(\frac{1}{c^2} \frac{\partial^2 w}{\partial t^2} - \Delta w \right) z dt dx - \int_{\Omega} \int_0^T \left(\frac{1}{c^2} \frac{\partial^2 z}{\partial t^2} - \Delta z \right) w dt dx \\ &= \int_{\Gamma} \int_0^T \left(\frac{\partial z}{\partial \nu} w - z \frac{\partial w}{\partial \nu} \right) dt dx + \left[\int_{\Omega} \frac{1}{c^2} \left(\frac{\partial w}{\partial t} z - w \frac{\partial z}{\partial t} \right) dx \right]_0^T. \end{aligned}$$

where ν is the exterior normal on Γ . This holds for any sufficiently smooth functions w, z on $\Omega \times (0, T)$. Choosing for w the solution of (16)–(18) with $u = u_j$ the solution of (1)–(3) for source j and for z the solution of the final value problem

$$\frac{\partial^2 z}{\partial t^2} = c^2 \Delta z \text{ in } \Omega \times (0, T), \quad (19)$$

$$\frac{\partial z}{\partial \nu} = g \text{ on } \Gamma \times (0, T), \quad (20)$$

$$z = 0 \text{ for } t > T \quad (21)$$

we obtain

$$-\int_{\Omega} \frac{h}{c_0^2} \int_0^T \frac{\partial^2 u_j}{\partial t^2} z dt dx = \int_{\Gamma} \int_0^T g(R'_j(f)h) dt dx,$$

or, using inner products,

$$-\left(h, \frac{1}{c_0^2} \int_0^T \frac{\partial^2 u_j}{\partial t^2} z dt \right)_{L_2(\Omega)} = (R'_j(f)h, g)_{L_2(\Gamma \times (0, T))}.$$

Hence

$$(R'_j(f))^* g = -\frac{1}{c_0^2} \int_0^T \frac{\partial^2 u_j}{\partial t^2} z dt \quad (22)$$

with z the solution of the final value problem (19)–(21). Note that z is nothing but the time reversed field. Thus the Kaczmarz method is just a consecutive form of time reversal, a technique that is used extensively for imaging problems [2, 3, 57].

Numerical Example (Transmission)

In this section we show what can be achieved for a mammography scanner patterned after [20] for the Salt Lake City breast phantom suggested in [4]. The reconstruction region is a circle of radius 8 cm. On the boundary we have 128 receivers and a modest number of sources, namely 8, see Fig. 3. The source pulse at the sources is $q(t) = \cos(\omega t) \exp(-(t/\tau)^2)$ with $\tau = \pi/\omega$. The frequency of the irradiating waves is 1 MHz, i.e., $\omega = 2\pi 10^6$ /s. With a background speed $c_0 = 1,500$ m/s this corresponds to a wavelength of 1.5 mm, hence to a spatial resolution of 0.75 mm. In Fig. 4 we display the rays, suggesting that a straight line assumption is useless. We show the reconstruction after 1 sweep and after 6 sweeps of the Kaczmarz method with relaxation parameter $\alpha = 2 \times 10^{12}$ and $C_j = 1$. Note that the number of sources as well as the number of sweeps is very small, leading to very reasonable reconstruction times. The spatial stepsize was chosen to be 0.33 mm, which corresponds to 1/6 of the wavelength.

For truly 3D examples, see [23, 39].

Fig. 4 Rays for breast phantom

Numerical Examples (Reflection)

In this example the reconstruction region is the slab $0 \leq x_n \leq D$, and we have sources and receivers on $x_n = 0$ only. This is the situation, e.g., in seismic imaging and in supine mammography [17, 26, 44]. In our example we adjust the Salt Lake City breast phantom of the previous section to the supine position of the patient, see Fig. 5. The five tumors have a diameter of 1.5 mm. To discover them, we need incoming waves of wavelength 3 mm, which, assuming a background speed of sound of 1,500 m/s, corresponds to a frequency of 500 kHz. From the section on the Born approximation we know that for reflection imaging we need low frequencies. So we are not surprised that the Kaczmarz method, as probably any other iterative

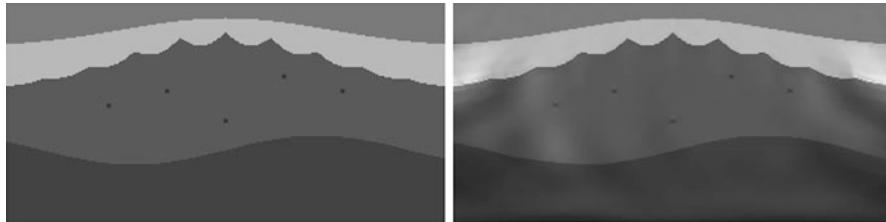

Fig. 5 *Left:* Breast phantom for patient in supine position. *Right:* Reconstruction

method, does not work for the comparatively high frequency of 500 kHz. What we do to circumvent this difficulty is to start the iteration with data for 30 kHz, use the result as an initial approximation for 1.2 MHz, and use the result again as an initial approximation for the final reconstruction with 500 kHz. This idea of starting with low frequencies is due to [8]. On each level we do only 6 sweeps, with relaxation parameters α chosen by trial and error. From Fig. 5 we see that the tumors are easily recovered, as we expect from the theory. Height of the pictures is 7.5 cm. The numerical work has been done on a 20 cm \times 10 cm rectangle with a step size of 0.5 mm. We remark that only 19 sources sitting on the top boundary of the reconstruction region were used, but the number of receivers (400) was much larger. In the computation we did not use these 19 sources consecutively. We rather chose the sources in a random order.

5 The Nonlinear Problem in the Frequency Domain

This problem was considered in the early nineties as the paradigm of a nonlinear ill-posed problem. It was treated by regularized versions of Newton's method. Numerical examples were restricted to objects of the size of the wavelength, see [24, 27, 33]. However in medical applications, e.g., in mammography, the object size is typically 100 wavelengths.

Initial Value Techniques for the Helmholtz Equation

In order to carry out the Kaczmarz method in the frequency domain, we have to solve the forward problem (6) and the corresponding adjoint problem repeatedly. In particular for high wave numbers k this is a numerical challenge [27]. Fortunately it is possible to use initial value techniques for the solution of elliptic equations such as (6). Such methods are notoriously unstable. However it is possible to stabilize them, simply by removing the evanescent waves, see [34, 48, 51]. These methods are effective only if the true speed of sound deviates from the background only a little, typically by not more than 10 %, as is the case in mammography. An improved version that is able to handle much greater variations of the velocity, as they occur, e.g., in seismics, can be found in [59].

The Kaczmarz Method in the Frequency Domain

Based on the initial value techniques of the previous section, an extremely efficient implementation of the Kaczmarz method in the frequency domain is possible [49]. We describe the method for Ω the ball of radius r and plane wave irradiation. f may now be a complex-valued function

$$f(x) = \frac{c_0^2}{c(x)^2} - 1 - \frac{i}{k} \frac{2\gamma(x)c_0}{c(x)}$$

with $\gamma(x)$ the (unknown) attenuation. Let Γ_j^\pm be the planes or straight lines perpendicular to θ_j touching Γ . We assume the functions $g_j^\pm = u_s$ on Γ_j^\pm to be known, i.e., Γ_j^\pm play the role of the detectors. The operator $R_j : L_2(\Omega) \rightarrow L_2(\Gamma_j^+)$, where u_s is the solution of the initial value problems for (11) with

$$u_s = g_j^-$$

$$\frac{\partial \tilde{u}_s}{\partial x_n}(x') = (2\pi)^{(1-n)/2} \int_{R^{(n-1)}} i \kappa(\xi') \hat{u}_s(\xi') e^{-ix' \cdot \xi'} d\xi'$$

on Γ_j^- , where x' , ξ' are the local variables on Γ_j^- , $\kappa(\xi') = \sqrt{k^2 - |\xi'|^2}$ and $\hat{\cdot}$ stands for the $(n-1)$ -dimensional Fourier transform with respect to x' . The last equation is a finite form of the Sommerfeld radiation condition, see, e.g., [11]. As in section (4.1), see also [38], we compute the adjoint of the derivative $(R'_j(f))^* : L_2(\Gamma_j^+) \rightarrow L_2(\Omega)$: $(R'_j(f)) * (r) = z$, where z is the solution of

$$\Delta z + k^2(1 + f)z = 0 \text{ between } \Gamma_j^- \text{ and } \Gamma_j^+, \quad (23)$$

$$z = 0, \quad \frac{\partial z}{\partial \theta_j} = \overline{ru_s} \text{ on } \Gamma_j^+. \quad (24)$$

We remark that (23), (24) is just the frequency domain form of time reversal.

6 Initial Approximations

The biggest problem with Kaczmarz method is to find an initial approximation for which the process converges. In this section we derive a heuristic criterion that works surprisingly well in practice, at least for transmission imaging. The condition reads

$$\left| \int (f - f_0) ds \right| \leq \lambda \quad (25)$$

where λ is the largest wavelength contained in the spectrum of the pulse q and the integral is taken along the geodesics belonging to the initial guess c_0 for c .

We give two derivations of (25). Both of them are heuristic but fortunately they agree, and they perform well in practice. The first derivation uses the frequency domain formulation (6) of the problem. The forward operator R_j is defined by $R_j(f) = \tilde{u}|_\Gamma$ with \tilde{u} the solution of (6) with $s = s_j$. With $w = \tilde{u} - \tilde{u}_0$, \tilde{u}_0 the solution of (6) with $f = f_0$, $s = s_j$ we have

$$R_j(f) - R_j(f_0) = w|_\Gamma, \quad (26)$$

$$-\Delta w - k^2(1 + f_0)w = k^2(f - f_0)\tilde{u}. \quad (27)$$

For simplicity, we assume that we do the Kaczmarz method with $C_j = R'_j(f_j)(R'_j(f_j))^*$. Then the first approximation f_1 of the Kaczmarz method satisfies

$$R'_j(f_0)(f_1 - f_0) = \alpha(R_j(f) - R_j(f_0)).$$

Let w_1 be the solution of

$$-\Delta w_1 - k^2(1 + f_0)w_1 = k^2(f_1 - f_0)\tilde{u}_0/\alpha. \quad (28)$$

Then

$$w_1|_\Gamma = R'_j(f_0)(f_1 - f_0)/\alpha = R_j(f) - R_j(f_0).$$

Thus the solutions w , w_1 of (27), (28) coincide on Γ . Comparing (27) and (28), we see that f_1 can be similar to f only if \tilde{u} , \tilde{u}_0 have similar phase,

$$|\text{phase}(\tilde{u}) - \text{phase}(\tilde{u}_0)| < \pi, \quad (29)$$

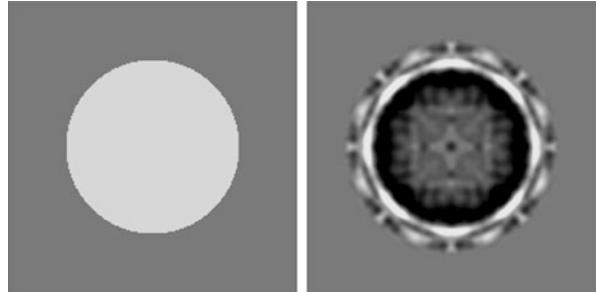

say. If this condition is not satisfied, then even the first iterate f_1 goes astray. Thus we consider (25) as a highly necessary condition for the convergence of the Kaczmarz method with starting element f_0 . According to the WKB-approximation of \tilde{u} , we have

$$\tilde{u} \approx A \exp(i k \Phi)$$

where the phase Φ satisfies the eikonal equation $|\nabla \Phi|^2 = 1 + f$ and A is the real-valued amplitude. The same holds for \tilde{u}_0 with an amplitude A_0 and a phase Φ_0 . For f close to f_0 , we have

$$\Phi \approx \Phi_0 + \frac{1}{2} \int (f - f_0) ds$$

Fig. 6 Example for non-convergence if (25) is not satisfied. *Left:* True object. *Right:* Object to which the method converges

where the integral is along the geodesics of the background; see [53]. Combining the last three equations leads to (25).

The second derivation of (25) takes place in the time domain. We look at the traces $u(x', 0, t)$ and $u_0(x', 0, t)$. Qualitatively they look similar: They resemble time delayed and scaled versions of the pulse q . The delays are roughly the integrals of $1/c$, $1/c_0$, resp., along the geodesics. Thus the difference of the delays is approximately

$$\int \frac{ds}{c} - \int \frac{ds}{c_0} = \int \left(\sqrt{1+f} - \sqrt{1+f_0} \right) \frac{ds}{c_0} = \int \frac{f-f_0}{2} \frac{ds}{c_0}.$$

The width w of the pulse q is determined by the lowest frequency ω in the pulse. We have approximately $w = \pi/\omega$. Minimization of the norm of the difference of the traces has an effect only if the traces overlap, i.e., if the difference of the delays is smaller than the width of the pulse. This means that

$$\left| \int \frac{f-f_0}{2} \frac{ds}{c_0} \right| < \pi/\omega$$

Since $\lambda = 2\pi c_0/\omega$, this is equivalent to (25).

We remark that (25) has been derived in [54] as the condition for the validity of the ray method for the inverse problem.

In order to confirm (25) numerically we created a simple test phantom which is 0.125 in the circle of radius 6 cm, the ambient speed of sound c_0 being 1,500 m/s. It was illuminated by 8 sources sitting on the circle of radius 8 cm. The sources had a constant signature from 350 down to 120 and 80 kHz, respectively. In this case the left hand side of (25) is 1.5 cm for $f_0 = 0$, while the largest wavelength is 1.25 and 1.875 cm, respectively. Thus (25) is satisfied for the lowest frequency 80 kHz, and in fact we observed convergence to the true object. For the lowest frequency 120 kHz (25) is not satisfied. The method became stationary at an object that is quite different from the true object; see Fig. 6. We remark the highest frequency (350 kHz) is of no relevance here. If we double it, the convergence behavior is the same.

7 Peculiarities

Missing Low Frequencies

Often the source pulse q contains only high frequencies, i.e., \tilde{q} (the signature in the jargon of seismic imaging) vanishes near 0. As we have seen previously this is not much of a problem in transmission imaging; it only forces us to use a good initial approximation. But it is one of the main difficulties in reflection imaging. We mentioned this in the framework of the Born approximation in Sect. 3. Again we restrict ourselves to the two-dimensional case. Assuming that the source pulse q has wave numbers in $[k_{\min}, k_{\max}]$, we conclude from (9) that \hat{f} is determined by the reflection data inside the circle of radius $2k_{\max}$, except for the circles with radius k_{\min} around $(\pm k_{\min}, 0)$; see Fig. 7. This means that the reconstruction is essentially a high pass filtered version of the true object.

For special media, we can do better [47]. For instance, if the medium in the slab $0 < x_n < D$ is layered, i.e., f depends on x_n only, then the n -dimensional Fourier transform of f becomes $\hat{f}(\xi', \xi_n) = (2\pi)^{(n-1)/2} \delta(\xi') \hat{f}(\xi_n)$, where δ is the Dirac δ function in R^{n-1} and \hat{f} on the right hand side is the one-dimensional Fourier transform. In the reflection case we have $x_n = s_n = 0$ in (8), and since the problem is invariant with respect to translation in R^{n-1} we can restrict s' to 0. Hence (8) assumes the form

$$v(x', 0, 0, 0) \approx -c_n^2 k^2 (2\pi)^{n-1/2} \tilde{q}(\omega) \int_{R^{n-1}} e^{-ix' \cdot \xi'} \hat{f}(-2\kappa(\xi')) \frac{d\xi'}{k^2 - |\xi'|^2}$$

or

$$(\Delta_{x'} + k^2)v(x', 0, 0, 0) \approx c_n^2 k^2 (2\pi)^{n-1/2} \tilde{q}(\omega) \int_{R^{n-1}} e^{-ix' \cdot \xi'} \hat{f}(-2\kappa(\xi')) d\xi'. \quad (30)$$

If x' runs through all of R^{n-1} , we can recover \hat{f} from this relation in the interval $[0, 2k]$. However in practice x' is restricted to a finite aperture $|x'| \leq R$. This makes

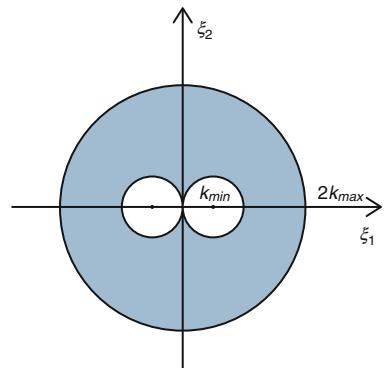

Fig. 7 Fourier coverage for reflection data with smallest wavenumber k_{\min} and largest wavenumber k_{\max}

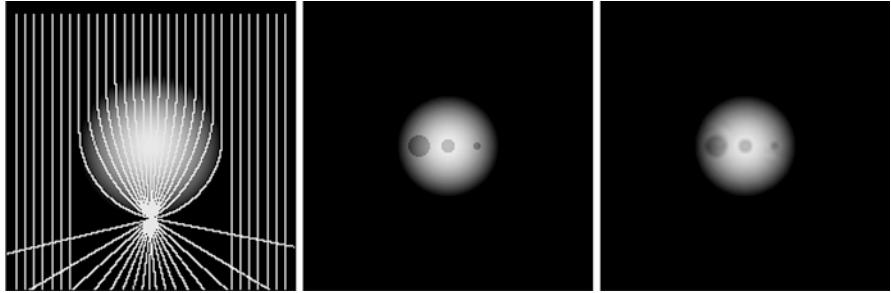

Fig. 8 *Left:* Luneburg lens with rays focussing on a focal point on the rim. *Middle:* Luneburg lens with a few tumors. *Right:* Reconstruction with 6 sweeps of the Kaczmarz method

it difficult to determine \hat{f} in all of $[0, 2k]$. For instance, let f represent a point object in depth z , i.e., $f(x_n) = \delta(x_n - z)$. Then, $\hat{f}(-2\kappa(\xi')) = (2\pi)^{-1/2} e^{2ik(\xi')}$ is a smooth function away from $|\xi'| = k$, but oscillates rapidly near this manifold, in particular for large z . In the vicinity of a point ξ' , $|\xi'| < k$ it looks like a function of bandwidth

$$-2z|\nabla_{\xi'}\kappa(\xi')| = 2z|\xi'|/\kappa(\xi').$$

Thus, by the sampling theorem, $\hat{f}(\xi')$ can be recovered from (30) only if $R > 2z|\xi'|/\kappa(\xi')$, i.e., for $|\xi'| < k/\sqrt{1 + 4z^2/R^2}$. Summing up we arrive at the following conclusion:

We can determine $\hat{f}(\xi')$ for objects up to depth z from reflection data with aperture R and wave number k only for

$$k/\sqrt{1 + 4z^2/R^2} \leq |\xi'| \leq 2k. \quad (31)$$

The derivation for (31) given here is entirely heuristic, but it has been corroborated in many numerical experiments. For an alternative derivation, see [62]. Making use of analytic continuation one can go beyond this result and determine the remaining part of \hat{f} provided that k, R, z satisfy a certain condition, see [47].

Another case in which we can do something without low frequencies is the case of media with a small dip angle, see [46].

Caustics and Trapped Rays

It seems that the Kaczmarz method is very robust with respect to peculiarities, such as caustics and trapped rays. As an example in which caustics occur we treat the famous Luneburg lens [36], which generates a focal spot on the rim of the lens, see Fig. 8. We see that the Kaczmarz method does not have the slightest problem with the reconstruction.

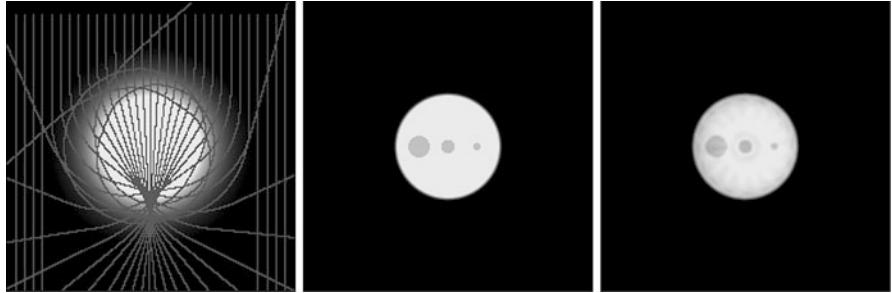

Fig. 9 *Top left:* Medium with trapped rays. *Middle:* Trapped rays medium with tumors. *Right:* Reconstruction with 6 sweeps of the Kaczmarz method

With trapped rays we have the same situation. In Fig. 9 we display the ray pattern for a medium with trapped rays [28]. We add some tumors and do the reconstruction. As in the previous example the Kaczmarz method does the reconstruction without any trouble.

The Role of Reflectors

It belongs to the lore of seismic imaging that reflectors greatly improve the reconstructed images; see [10, 13, 63]. In this section we study this phenomenon within the Born approximation and we demonstrate its practical relevance by numerical simulations; see also [45].

We again assume Ω to be the strip $0 < x_n < D$. We use the form (4), (5) of the inverse problem. We put the sources on $x_n = D$ and model the reflector at $x_n = 0$ by stipulating the Neumann boundary condition $\partial u / \partial x_n = 0$ on $x_n = 0$. Proceeding exactly as in section “An Explicit Formula for the Slab” we get for the Born approximation

$$v(x', x_n, s', s_n) \approx k^2 \tilde{q}(\omega) \int_{\Omega} G_k^0(x' - y', x_n, y_n) G_k^0(y' - s', y_n, s_n) f(y) dy.$$

where

$$G_k^0(x' - y', x_n, y_n) = G_k(x' - y', x_n - y_n) + G_k(x' - y', x_n + y_n)$$

is Green’s function for the Neumann boundary condition at $x_n = 0$. We first do $(n - 1)$ -dimensional Fourier transforms with respect to x' and s' , obtaining

$$\hat{v}(\xi', x_n, \sigma', s_n) \approx k^2 \tilde{q}(\omega) \int_0^D \int_{R^{n-1}} \hat{G}_k^0(\xi', x_n, y_n) \hat{G}_k^0(\sigma', y_n, s_n) e^{-i(\xi' + \sigma') \cdot y'} dy' dy_n \quad (32)$$

where the hat stands for the $(n - 1)$ -dimensional Fourier transform. From (7) we see that

$$\hat{G}_k(\xi', x_n) = i(2\pi)^{(n-1)/2} c_n \frac{e^{i|x_n|a(\xi')}}{\kappa(\xi')}.$$

Thus,

$$\hat{G}_k^0(\xi', x_n, y_n) = i(2\pi)^{(n-1)/2} c_n \frac{e^{i|x_n-y_n|\kappa(\xi')} + e^{i|x_n+y_n|\kappa(\xi')}}{\kappa(\xi')}.$$

It follows that for $x_n = s_n = D$, $0 \leq y_n \leq D$

$$\hat{G}_0(\xi', x_n, y_n) = 2i(2\pi)^{(n-1)/2} c_n \frac{e^{ir_n\kappa(\xi')}}{\kappa(\xi')} \cos(y_n\kappa(\xi'))$$

$$\hat{G}_0(\sigma', y_n, s_n) = 2i(2\pi)^{(n-1)/2} c_n \frac{e^{is_n\kappa(\sigma')}}{\kappa(\sigma')} \cos(y_n\kappa(\sigma'))$$

Inserting this into (32) leads to

$$\begin{aligned} \hat{v}(\xi', D, \sigma', D) &\approx A \int_0^D \int_{R_{n-1}} e^{-i(\xi'+\sigma') \cdot y'} \cos(\kappa(\xi')y_n) \cos(\kappa(\sigma')y_n) f(y', y_n) \\ &\quad dy' dy_n, \\ A &= -4c_n^2 (2\pi)^{n-1} k^2 \tilde{q}(\omega) \frac{e^{i(D\kappa(\xi')+D\kappa(\sigma'))}}{\kappa(\xi')\kappa(\sigma')}. \end{aligned}$$

The y' integral is a $(n-1)$ -dimensional Fourier transform. Hence

$$\hat{v}(\xi', D, \sigma', D) \approx (2\pi)^{(n-1)/2} A \int_0^D \cos(\kappa(\xi')y_n) \cos(\kappa(\sigma')y_n) \hat{f}(\xi' + \sigma', y_n) dy_n. \quad (33)$$

Here \hat{f} is the $(n-1)$ -dimensional Fourier transform of f with respect to x' . Since

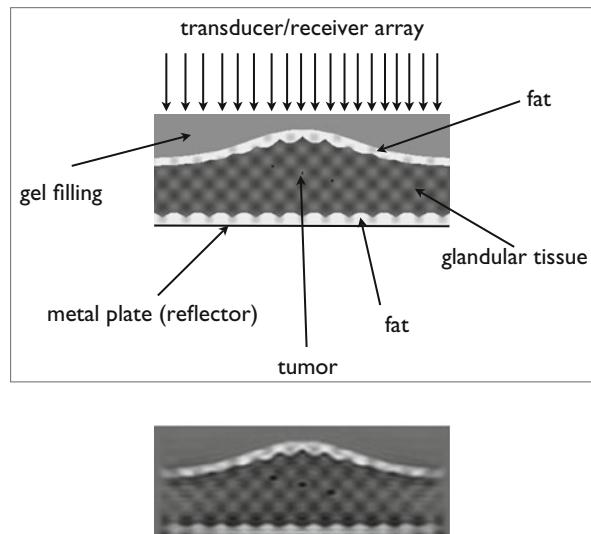

$$\begin{aligned} \cos(\kappa(\xi')y_n) \cos((\kappa(\sigma')y_n)) &= \frac{1}{2} \{ \cos((\kappa(\xi') + \kappa(\sigma'))y_n) + \\ &\quad \cos((\kappa(\xi') - \kappa(\sigma'))y_n) \} \end{aligned}$$

we have

$$\begin{aligned} \hat{v}(\rho', D, \sigma', D) &\approx (2\pi)^{(n-1)/2} \frac{A}{2} \{ (C \hat{f}(\xi' + \sigma', \cdot))(\kappa(\xi') + \kappa(\sigma')) + \\ &\quad (C \hat{f}(\xi' + \sigma', \cdot))(\kappa(\xi) - \kappa(\sigma')) \} \end{aligned} \quad (34)$$

where C denotes the cosine transform:

Fig. 10 Top: Principle of CARI. Bottom: Reconstruction from CARI-data with 20 Kaczmarz sweeps

$$(Cf)(\xi) = \int_0^D \cos(\xi x) f(x) dx.$$

Equation (34) is the solution in the Born approximation of the inverse scattering problem with a reflector. The essential difference to the solution without a reflector, as given in (9), is that the argument $\kappa(\rho') - \kappa(\sigma')$ shows up, indicating that small frequencies are involved.

In [43] it is shown that (34) in fact permits the determination of the Fourier transform of f for frequencies down to 0. In [45] it is shown what can be achieved by a combination of reflectors with the Kaczmarz method in mammography [5, 58] see Fig. 10. Again we use 19 sources at the top boundary. The relaxation parameter α is 3×10^7 . We work with a source pulse whose signature is uniform from 50 to 500 kHz. Without the mirror the results would be completely unsatisfactory.

8 Direct Methods

In this section we mention some non-iterative methods which provide exact solutions to the nonlinear problem.

Boundary Control

The boundary control method for inverse problems of hyperbolic differential equation has been developed in [1]. We follow [55] and start out from the formulation

(1)–(3) of the inverse problem. Let u_h be the solution of (1) with $\partial u / \partial v = h$ on $\Gamma \times (0, T)$ and $a^+(t) = (a(t) + a(2T - t))/2$ for any function a . Let for functions h, g on $\Gamma \times (0, T)$

$$[h, g] = \int_{\Omega} c^{-2}(x) u_{h_t}(x, T) u_{g_t}(x, T) dx,$$

$$[h, g]_1 = \int_{\Omega} \nabla u_h(x, T) \cdot \nabla u_g(x, T) dx.$$

The key to the boundary control method are the relations

$$[h, g] = \int_{\Gamma} \int_0^T (u_g^+ h - g^+ u_h) dx dt, \quad (35)$$

$$[h, g]_1 = \int_{\Gamma} \int_0^T (u_{g_t}^+ h + g^+ u_{h_t}) dx dt. \quad (36)$$

Note that the right hand sides of (35), (36) can be evaluated without knowing c . All we need to know is u_h, u_g on $\Gamma \times (0, 2T)$ for the functions h, g , and this is just the data for the inverse problem.

Now let φ be any harmonic function in Ω . We determine a function h^φ on $\Gamma \times (0, T)$ such that $u_{h^\varphi} = \varphi$. Let $h_s(x, t) = q(t)\delta(x - s)$ for each source s on Γ . We try the Ansatz

$$h^\varphi = \sum_s a_s h_s$$

with certain coefficients a_s , i.e.,

$$\varphi(x) = \sum_s a_s u_{h_s}(x, T).$$

The coefficients a_s may be determined from the equations

$$\int_{\Omega} \nabla \varphi(x) \cdot \nabla u_{h_w}(x, T) dx = \sum_s a_s \int_{\Omega} \nabla u_{h_s}(x, T) \cdot \nabla u_{h_w}(x, T) dx$$

which, by the Gauss integral theorem can be written as

$$\int_{\Gamma} \frac{\partial \varphi}{\partial v}(x) u_{h_w}(x, T) dx = \sum_s a_s [h_w, h_s]_1 \quad (37)$$

The left hand side and the coefficients on the right hand side are determined by the data. Solving (37) for a_s we get the function h^φ . We do this for many harmonic functions φ, ψ . By (35) we then can compute the numbers

$$\int_{\Omega} c^{-2} \varphi \psi dx = [h^\varphi, h^\psi].$$

Since the products of harmonic functions are complete in $L_2(\Omega)$, this determines c .

Inverse Scattering

The inverse problem of ultrasound tomography is a typical case of inverse scattering. Uniqueness questions have been dealt with in [37, 52]. Since the methods in these papers are, in principle, constructive, numerical methods can be based on these methods, see [7].

9 Conclusion

The mathematics of sonic imaging is well understood, at least for the linearized problem with constant background. Reasonably efficient iterative methods for the fully nonlinear problems are available for transmission imaging. Time domain as well as frequency domain methods are being used. In reflection imaging the main problem is the lack of low frequencies in the source pulse. It is not clear at present if this problem ever finds a satisfactory solution.

Abstract

We give a self-contained presentation of coherent array imaging in random media, which are mathematical models of media with uncertain small-scale features (inhomogeneities). We describe the challenges of imaging in random media and discuss the coherent interferometric (CINT) imaging approach. It is designed to image with partially coherent waves, so it works at distances that do not exceed a transport mean-free path. The waves are incoherent when they travel longer distances, due to strong cumulative scattering by the inhomogeneities, and coherent imaging becomes impossible. In this article we base the presentation of coherent imaging on a simple geometrical optics model of wave propagation with randomly perturbed travel time. The model captures the canonical form of the second statistical moments of the wave field, which describe the loss of coherence and decorrelation of the waves due to scattering in random media. We use it to give an explicit resolution analysis of CINT which includes the assessment of statistical stability of the images.

1 Introduction

Sensor array imaging is an important technology in a variety of applications such as medical ultrasound, nondestructive evaluation of materials, underwater acoustics, geophysical prospecting, radar, and elsewhere. In general terms, it seeks to estimate wave sources or reflecting structures in a medium using measurements at the sensors, which are devices that transform one form of energy into another. In radar the sensors are antennas that convert electromagnetic waves to/from electrical signals. In underwater acoustics they are hydrophones that convert changes in water pressure to electrical signals, and so on.

The array consists of many sensors which are placed close together on a measurement surface, so that they behave like a collective entity. It occupies a bounded set, the *array aperture*, which we denote by \mathcal{A} . In problems like synthetic aperture radar [16], there isn't an actual array. Instead, one or more sensors mounted on a moving platform span a long path, the synthetic aperture. To fix ideas we assume throughout an actual array, but most of the results presented here extend to problems with synthetic apertures.

When the sensors are just receivers, we say that the array is *passive*. The sources of waves are typically far away from the passive array, and the problem is to determine them from the measurements at the receivers. *Active* arrays consist of sensors that are sources and receivers. They probe the medium with waves emitted by one or many sources and receive the echoes from the unknown reflecting structures.

The recordings at the receivers are called the *array data*. We are concerned with *coherent imaging* systems, meaning that the data are time-resolved measurements of the waves. Equivalently, in the Fourier domain, the data are measurements of the amplitude and the phase of the Fourier components of the waves, for all

the frequencies in the bandwidth. Incoherent imaging systems like in infrared or optical tomography measure the net intensity of the waves, which are typically single frequency or narrow-band. They image at distances that are larger than a transport mean-free path, a length scale which marks the onset of diffusion in random media [29, 35]. They involve very different data processing and give worse image resolution than the coherent ones.

Imaging is a simplified inverse problem for the wave equation. One example of an inverse problem is to determine the coefficients in the wave equation, like the wave speed, from measurements of the solution at the sensor locations. This is a nonlinear and ill-posed problem that is difficult to solve [30, 33, 34]. Imaging seeks less information about the medium, such as the loci of jumps of the wave velocity, which model the location of reflecting structures. It is an easier problem as long as we know the source of waves and how the waves propagate.

An imaging system is useful only if it is robust to uncertainties in the problem. We may think of uncertainties as “noise,” but not all noise is the same. Some is easier to deal with, like additive measurement noise considered in most of the applied imaging literature. However, uncertainties in the model of wave propagation are much harder to mitigate. We study the effect of such uncertainties arising in imaging in complex media with numerous small inhomogeneities, i.e., with microstructure. This is unknown in practice and cannot be estimated from the necessarily band-limited data as part of the imaging process. The microstructure may not even be interesting in applications. However, it cannot be ignored because although one inhomogeneity by itself is negligible, there are many of them and their cumulative wave scattering effect builds up as the waves travel in the medium.

We deal with the unknown microstructure by modeling it with random processes, and thus study *imaging in random media*. We describe first the forward problem, that is the mapping from the random microstructure to the solution of the wave equation at the location of the sensors. This solution is a random field. The data are one realization of this field, corresponding to one realization of the random medium. The challenge is to find imaging methods that are robust, i.e., that produce images which do not change significantly with the realization of the random medium. The robustness is called *statistical stability*.

To analyze imaging in random media, we study the statistics of the wave field at the sensors. Specifically, we calculate the mean field, which we call the *coherent field*, and its random fluctuations, the *incoherent field*. When the fluctuations are small, the *data is coherent* and imaging is easier. When the fluctuations dominate the mean field, the *data is incoherent*. This is a typical regime in applications like diffusion tomography. We look at a regime between these two, where the *data is partially coherent*. The cumulative scattering effects are important in this regime, and mathematics allows us to understand them under simplifying assumptions like: the inhomogeneities are weak scatterers; there is separation of scales; the microstructure decorrelates rapidly with distance. Recent results [22, 25] have relaxed the latter assumption to media with long range correlation, and the case of strong inhomogeneities can be handled in some media [21].

The analysis of wave propagation in random media is quite involved, and it is specific to the scaling regime. There is no universal treatment of the problem, no one fits all regime. The detailed quantification of cumulative scattering effects and the calculation of important scales such as the scattering mean-free path and the transport mean-free path depend on the assumptions on the microstructure and the frequency range [35]. However, there are canonical effects such as the loss of coherence and decorrelation of the waves that can be given a generic description, via the second statistical moments of the random wave field. We describe them with the simplest model of wave propagation in random media, which accounts only for random wavefront distortions. It is a geometrical optics approximation of the solution of the wave equation, with randomly perturbed travel time. We use this model for the purpose of a self-contained analysis of coherent imaging in random media. The results extend to more general wave scattering regimes, as described in [3, 7–9, 18, 27].

2 Main Text

The presentation is organized as follows: We begin in Sect. 3 with the basics of imaging. We formulate the data model and the reverse time migration imaging function as an approximate least squares solution of the inverse problem. Migration is the basic imaging method in many applications. We describe in Sect. 4 the challenges of imaging in complex media. The analysis of imaging in such media is in Sects. 7 and 8. It uses the random travel time model described in Sect. 5 and the setup given in Sect. 6. We show with detailed calculations in Sect. 7 how migration imaging fails in complex media with significant cumulative wave scattering by the microstructure. Then we analyze in Sect. 8 the coherent interferometric (CINT) approach, which is designed to image with partially coherent waves. We give a detailed resolution analysis of this method, including the assessment of its statistical stability and illustrate the results with numerical simulations.

3 Basic Imaging

In this section we present a mathematical formulation of imaging with sensor arrays. We begin in section “The Forward Model” with the description of the model of the data recorded by passive and active arrays. We call it the *forward model* because it maps the source distribution or the reflectivity, the unknowns in the imaging problem, to the wave field measured by the sensors. In general there is no explicit inverse mapping from the array data to the unknown source density or reflectivity. We show in section “Least Squares Inversion” how we can state the imaging problem in variational, *least squares data fit* form. The mathematical model of the *time reversal* process can be viewed as an approximation of the solution of the least squares problem, as described in section “The Normal Operator and the Time Reversal Process”. It can be computed and used for imaging only when we

know the medium through which the waves propagate. We discuss its refocusing in smooth media and robustness to additive noise in section ‘‘Imaging in Smooth and Known Media.’’

The Forward Model

We base the forward model of the array data on the scalar wave equation for the acoustic pressure $p(t, \vec{\mathbf{x}})$

$$\frac{1}{c^2(\vec{\mathbf{x}})} \frac{\partial^2 p(t, \vec{\mathbf{x}})}{\partial t^2} - \Delta p(t, \vec{\mathbf{x}}) = F(t, \vec{\mathbf{x}}), \quad \vec{\mathbf{x}} \in \mathbb{R}^3, \quad t > 0, \quad (1)$$

where $c(\vec{\mathbf{x}})$ is the wave speed and $F(t, \vec{\mathbf{x}})$ the source density. We call $p(t, \vec{\mathbf{x}})$ the wave field and relate it to the source using Duhamel’s principle

$$p(t, \vec{\mathbf{x}}) = \int_0^t ds \int_{\mathbb{R}^n} d\vec{\mathbf{y}} F(s, \vec{\mathbf{y}}) G(t-s, \vec{\mathbf{y}}, \vec{\mathbf{x}}) = \int_{\mathbb{R}^n} d\vec{\mathbf{y}} F(t, \vec{\mathbf{y}}) \star_t G(t, \vec{\mathbf{y}}, \vec{\mathbf{x}}). \quad (2)$$

Here $G(t, \vec{\mathbf{x}}, \vec{\mathbf{y}})$ is the causal Green’s function, the solution in the sense of distributions of

$$\frac{1}{c^2(\vec{\mathbf{x}})} \frac{\partial^2 G(t, \vec{\mathbf{x}}, \vec{\mathbf{y}})}{\partial t^2} - \Delta_{\vec{\mathbf{x}}} G(t, \vec{\mathbf{x}}, \vec{\mathbf{y}}) = \delta(\vec{\mathbf{x}} - \vec{\mathbf{y}})\delta(t), \quad \vec{\mathbf{x}}, \vec{\mathbf{y}} \in \mathbb{R}^n, \quad t > 0, \quad (3)$$

$$G(t, \vec{\mathbf{x}}, \vec{\mathbf{y}}) = 0, \quad t < 0, \quad (4)$$

where $\Delta_{\vec{\mathbf{x}}}$ is the Laplace operator in the $\vec{\mathbf{x}}$ variable, and δ is the Dirac distribution. The second equality in (2) is because both the source and Green’s function are causal (supported at time $t > 0$), and we can write

$$\int_0^t ds F(s, \vec{\mathbf{y}}) G(t-s, \vec{\mathbf{x}}, \vec{\mathbf{y}}) = \int_{-\infty}^{\infty} ds F(s, \vec{\mathbf{y}}) G(t-s, \vec{\mathbf{y}}, \vec{\mathbf{x}}) = F(t, \vec{\mathbf{y}}) \star_t G(t, \vec{\mathbf{x}}, \vec{\mathbf{y}}).$$

Convolutions are not convenient for the analysis, so we often work in the Fourier (frequency) domain. The Fourier transform of the wave field is defined as

$$\hat{p}(\omega, \vec{\mathbf{x}}) = \int_{-\infty}^{\infty} dt p(t, \vec{\mathbf{x}}) e^{i\omega t}, \quad (5)$$

and the inverse transform is

$$p(t, \vec{\mathbf{x}}) = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \hat{p}(\omega, \vec{\mathbf{x}}) e^{-i\omega t}. \quad (6)$$

The dual variable to time t in these transformations, denoted by ω , is the angular frequency (measured in radians per second). It is related to the frequency (measured in Hz) by a factor of 2π . We also relate ω to the *wavenumber* k and the *wavelength* λ using a reference wave speed scale c_o ,

$$k = \frac{\omega}{c_o} = \frac{2\pi}{\lambda}. \quad (7)$$

The advantage of working in the Fourier domain is that the convolution in (2) becomes a product

$$\hat{p}(\omega, \vec{x}) = \int_{\mathbb{R}^n} d\vec{y} \hat{F}(\omega, \vec{y}) \hat{G}(\omega, \vec{y}, \vec{x}), \quad (8)$$

with $\hat{G}(\omega, \vec{y}, \vec{x})$ the Fourier transform of the causal Green's function. This is the same as the outgoing Green's function of the Helmholtz equation.

Passive Array Data Model

When imaging with passive arrays, $F(t, \vec{x})$ is unknown. We assume for simplicity that it has the separable form

$$F(t, \vec{x}) = f(t)\rho(\vec{x}), \quad (9)$$

where the same signal $f(t)$ is emitted from all the points in the support of the source density $\rho(\vec{x})$. In some applications like synthetic aperture radar, $f(t)$ is a complex valued and long (chirped) signal. But in other applications $f(t)$ is a function of small temporal support, a pulse. We assume henceforth such a pulse and model $f(t)$ as a base-band pulse $f_B(t)$ modulated by an harmonic signal at carrier (central) frequency $\omega_o/(2\pi)$,

$$f(t) = e^{i\omega_o t} f_B(t). \quad (10)$$

The terminology becomes clear in the frequency domain, where

$$\hat{f}(\omega) = \int_{-\infty}^{\infty} d\omega f(t) e^{i\omega t} = \hat{f}_B(\omega - \omega_o). \quad (11)$$

The signal $f_B(t)$ is called base-band pulse because its Fourier transform $\hat{f}_B(\omega)$ is supported at $\omega \in [-\pi B, \pi B]$. Then, the frequencies $\omega/2\pi$ in the support of $\hat{f}(\omega)$ lie in the interval centered at $\omega_o/(2\pi)$ of bandwidth B .

The N_r receivers located at \vec{x}_r in the aperture \mathcal{A} of the array measure the data

$$D(t) = \{d(t, \vec{x}_r)\}, \quad t \in (0, T], \quad \vec{x}_r \in \mathcal{A}, \quad r = 1, \dots, N_r, \quad (12)$$

over the time duration T . Equivalently, in the Fourier domain we have

$$\hat{D}(\omega) = \left\{ \hat{d}(\omega, \vec{\mathbf{x}}_r) \right\}, \quad |\omega - \omega_o| \leq \pi B, \quad \vec{\mathbf{x}}_r \in \mathcal{A}, \quad r = 1, \dots, N_r. \quad (13)$$

The goal of imaging is to estimate from these data the support of ρ , which is contained in a compact set $I_w \subset \mathbb{R}^n$ called the *imaging window*.

We use a terminology borrowed from the seismic imaging literature, and refer to $d(t, \vec{\mathbf{x}}_r)$ as *time traces*, to emphasize that they are time recordings. Their model comes from (2),

$$d(t, \vec{\mathbf{x}}_r) = 1_{(0,T]}(t) \left[\int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \int_{I_w} d\vec{\mathbf{y}} \hat{F}(\omega, \vec{\mathbf{y}}) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) e^{-i\omega t} + \mathcal{N}_r(t) \right], \quad (14)$$

where we added the noise $\mathcal{N}_r(t)$ indexed by the receiver. We assume as is typical that $\mathcal{N}_r(t)$ is white noise, i.e., a real-valued stationary Gaussian generalized process with zero expectation, covariance equal to the delta distribution, and independent over the receivers

$$\mathbb{E}[\mathcal{N}_r(t)] = 0, \quad \mathbb{E}[\mathcal{N}_r(t)\mathcal{N}_{r'}(t')] = \sigma_{\mathcal{N}}^2 \delta(t - t')\delta_{r,r'}. \quad (15)$$

Here \mathbb{E} denotes statistical expectation; $\delta_{r,r'}$ is the Kronecker delta symbol; the parameter $\sigma_{\mathcal{N}}$ scales the noise level and the time window $1_{(0,T]}(t)$ is equal to one when $t \in (0, T]$ and zero otherwise. The waves are transient and thus can be captured for large enough T . We assume such a T so we can ignore the window $1_{(0,T]}(t)$ in the first term of (14), and obtain the following relation in the Fourier domain,

$$\hat{d}(\omega, \vec{\mathbf{x}}_r) \approx \int_{I_w} d\vec{\mathbf{y}} \hat{F}(\omega, \vec{\mathbf{y}}) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) + \hat{\mathcal{N}}_r^T(\omega), \quad \hat{\mathcal{N}}_r^T(\omega) = \int_0^T dt \mathcal{N}_r(t) e^{i\omega t}. \quad (16)$$

The forward map \mathcal{M} takes the unknown source density ρ to the data space \mathbb{D} . We show in the next section how to formulate the inverse problem as an optimization that computes an “approximate inverse” of \mathcal{M} in some sense. This is not an actual inverse which may not even exist. For optimization, it is convenient to work in function spaces with inner products. Thus we assume that $\rho(\vec{\mathbf{y}})$ lies in $L^2(I_w)$, the Hilbert space of real valued and square integrable functions supported in I_w , with inner product

$$(\rho, \eta) = \int_{I_w} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \eta(\vec{\mathbf{y}}), \quad \forall \rho, \eta \in L^2(I_w), \quad (17)$$

and norm $\|\rho\|_2 = \sqrt{(\rho, \rho)}$. The data lies in the vector space of functions of finite energy

$$\mathbb{D} = \left\{ \hat{d}(\omega, \vec{\mathbf{x}}_r) \in \mathbb{C}, \text{ s.t. } \sum_{r=1}^{N_r} \int_{|\omega-\omega_o| \leq \pi B} d\omega \left| \hat{d}(\omega, \vec{\mathbf{x}}_r) \right|^2 < \infty \right\}, \quad (18)$$

endowed with the complex inner product

$$\langle \hat{d}, \hat{g} \rangle = \int_{|\omega-\omega_o| \leq \pi B} d\omega \sum_{r=1}^{N_r} \overline{\hat{d}(\omega, \vec{\mathbf{x}}_r)} \hat{g}(\omega, \vec{\mathbf{x}}_r), \quad \forall \hat{d}, \hat{g} \in \mathbb{D}, \quad (19)$$

and the norm $\|\hat{d}\|_{\mathbb{D}} = \sqrt{\langle \hat{d}, \hat{d} \rangle}$.

The forward map $\mathcal{M} : L^2(I_w) \rightarrow \mathbb{D}$ is the linear operator defined by

$$[\mathcal{M}\rho](\omega, \vec{\mathbf{x}}_r) = \hat{f}(\omega) \int_{I_w} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}). \quad (20)$$

It assumes that we know the pulse and the wave speed $c(\vec{\mathbf{x}})$, i.e., the Green's function. The latter assumption turns out to be critical, and it is not satisfied in complex media with microstructure.

Active Array Data Model

To state the model for active arrays, we redefine the coefficient in the wave equation as

$$\frac{1}{c^2(\vec{\mathbf{x}})} \rightsquigarrow \frac{1}{c^2(\vec{\mathbf{x}})} + \frac{\rho(\vec{\mathbf{x}})}{c_o^2}, \quad (21)$$

where $c(\vec{\mathbf{x}})$ is the *assumed known* wave speed in the medium which hosts the perturbation (reflectivity) $\rho(\vec{\mathbf{x}})$ that we wish to estimate. It is supported in a compact set $I_w \subset \mathbb{R}^n$ that defines the imaging region. The name *reflectivity* suggests that we expect it to cause reflected waves (echoes) that can be measured at the array. This is relevant for most imaging setups where the array lies on one side of the medium. For example, in exploration geophysics, the receivers lie on the surface of the earth and do not see waves that interact with the subsurface unless ρ reflects them.

Suppose that the excitation comes from a source in the array, idealized as a point at $\vec{\mathbf{x}}_s \in \mathcal{A}$,

$$F(t, \vec{\mathbf{x}}) = f(t) \delta(\vec{\mathbf{x}} - \vec{\mathbf{x}}_s). \quad (22)$$

The array has $N_s \geq 1$ sources which may emit simultaneously, but we assume here that the excitation is with one source at a time, and we emphasize with the notation $p(t, \vec{\mathbf{x}}, \vec{\mathbf{x}}_s)$ the dependence of the wave field on the source location. It satisfies

$$\frac{1}{c^2(\vec{\mathbf{x}})} \frac{\partial^2 p(t, \vec{\mathbf{x}}, \vec{\mathbf{x}}_s)}{\partial t^2} - \Delta_{\vec{\mathbf{x}}} p(t, \vec{\mathbf{x}}, \vec{\mathbf{x}}_s) = -\frac{\rho(\vec{\mathbf{x}})}{c_o^2} \frac{\partial^2 p(t, \vec{\mathbf{x}}, \vec{\mathbf{x}}_s)}{\partial t^2} + f(t) \delta(\vec{\mathbf{x}} - \vec{\mathbf{x}}_s), t > 0, \quad (23)$$

with initial condition

$$p(0, \vec{\mathbf{x}}, \vec{\mathbf{x}}_s) = \frac{\partial}{\partial t} p(0, \vec{\mathbf{x}}, \vec{\mathbf{x}}_s) = 0, \quad (24)$$

and we can write it in terms of the causal Green's function using Duhamel's principle

$$p(t, \vec{\mathbf{x}}, \vec{\mathbf{x}}_s) = f(t) \star_t G(t, \vec{\mathbf{x}}, \vec{\mathbf{x}}_s) - \int_{I_W} d\vec{\mathbf{y}} \frac{\rho(\vec{\mathbf{y}})}{c_o^2} \frac{\partial^2 p(t, \vec{\mathbf{y}}, \vec{\mathbf{x}}_s)}{\partial t^2} \star_t G(t, \vec{\mathbf{x}}, \vec{\mathbf{y}}). \quad (25)$$

In the forward model we evaluate (25) at the receiver locations $\vec{\mathbf{x}} = \vec{\mathbf{x}}_r \in \mathcal{A}$, for $r = 1, \dots, N_r$. (The sources and receivers may be collocated). The first term $f(t) \star_t G(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)$ is the direct wave that does not interact with the reflectivity. We can remove it by time windowing, assuming that it arrives much earlier than the echoes from the medium. Thus, we redefine the origin of time of the measurements after the direct arrival of the wave from $\vec{\mathbf{x}}_s$, and let henceforth $p(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)$ model the echoes from the medium for $t \in (0, T]$. The second term in (25) depends nonlinearly on ρ . We use its linearization, known as the *Born approximation*, as is typical in imaging. The approximation holds when ρ has small amplitude and/or small support, although numerical experiments suggest that it may have a wider range of validity. We refer to [32] for its analysis in media with general bounded background wave speed $c(\vec{\mathbf{x}})$.

The Born data model is

$$d(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s) \approx \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} k^2 \hat{f}(\omega) \int_{I_W} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \hat{G}(\omega, \vec{\mathbf{y}}, \vec{\mathbf{x}}_s) e^{-i\omega t} + 1_{(0,T]}(t) \mathcal{N}_{rs}(t), \quad (26)$$

where $\mathcal{N}_{rs}(t)$ is the additive noise indexed by the receivers and the sources. The latter index reminds us that the noise varies from one illumination to another. We suppose as before that $\mathcal{N}_{rs}(t)$ is white noise, independent over the array sensors

$$\mathbb{E}[\mathcal{N}_{rs}(t)] = 0, \quad \mathbb{E}[\mathcal{N}_{rs}(t) \mathcal{N}_{r's'}(t')] = \sigma_{\mathcal{N}}^2 \delta(t - t') \delta_{r,r'} \delta_{s,s'}. \quad (27)$$

We also choose a large enough T , so that we can neglect the effect of the window in the first term of the right-hand side of (26).

The forward map $\mathcal{M} : L^2(I_W) \rightarrow \mathbb{D}$ takes square integrable reflectivity functions ρ to functions in the data space

$$\mathbb{D} = \left\{ \hat{d}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s) \in \mathbb{C}, \quad \sum_{r=1}^{N_r} \sum_{s=1}^{N_s} \int_{|\omega-\omega_0| \leq \pi B} d\omega \left| \hat{d}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s) \right|^2 < \infty \right\}, \quad (28)$$

with complex inner product

$$\langle \hat{d}, \hat{g} \rangle = \int_{|\omega-\omega_0| \leq \pi B} d\omega \sum_{r=1}^{N_r} \sum_{s=1}^{N_s} \overline{\hat{d}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)} \hat{g}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s), \quad \forall \hat{d}, \hat{g} \in \mathbb{D}, \quad (29)$$

and induced norm $\|\hat{d}\|_{\mathbb{D}} = \sqrt{\langle \hat{d}, \hat{d} \rangle}$. It is given by

$$[\mathcal{M}\rho](\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s) = k^2 \hat{f}(\omega) \int_{I_W} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \hat{G}(\omega, \vec{\mathbf{y}}, \vec{\mathbf{x}}_s), \quad (30)$$

and it assumes that we know both the pulse $\hat{f}(\omega)$ and the Green's function, i.e., $c(\vec{\mathbf{x}})$.

Least Squares Inversion

The imaging problem is to estimate from the array measurements the location of the unknown remote sources and/or reflectors in the medium. We show here how it relates to the problem of least squares minimization of the misfit between the measured data and the model prediction. Because the data space depends on the type of the array, we treat separately passive and active arrays. In both cases the unknown lies in the Hilbert space $L^2(I_W)$ with inner product (17).

Connection to Bayesian Inversion

The least squares minimization of the misfit between the measured data and the model prediction is widely used in the literature. It arises in Bayesian inversion, where the least squares minimizer is known as the *maximum likelihood* estimator.

Denote by $\pi(d|\rho)$ the density of the *likelihood function*, which is the probability that we observe the data d given ρ . Bayes' rule says that the *posterior probability* density $\pi(\rho|d)$ of ρ , given the data, is

$$\pi(\rho|d) = \frac{\pi(d|\rho)\pi(\rho)}{\pi(d)},$$

where $\pi(\rho)$ is the prior probability density of ρ and $\pi(d)$ is the marginal likelihood density of the data. Assuming no information about ρ prior to the measurements, we take a uniform density $\pi(\rho)$ over the imaging region. The marginal likelihood $\pi(d)$ tells us if the data can be achieved by measurements. We suppose that this is so, which means that $\pi(d)$ is just a constant which plays no role in the estimation.

Under all these assumptions, we obtain that maximizing the posterior $\pi(\rho|d)$ is the same as maximizing the likelihood function $\pi(d|\rho)$. This is given by

$$\pi(d|\rho) \sim \exp \left[-\frac{\|d - \mathcal{M}\rho\|_{\mathbb{D}}^2}{2\sigma_T^2} \right], \quad (31)$$

and its maximizer, the maximum likelihood estimate, is the same as the least squares solution described in the next sections. The symbol \sim in Eq. (31) means equal up to a normalization constant. We have a normal probability density because we assume white noise which is Gaussian and independent over the receivers. The variance $\sigma_T^2 = T\sigma_{\mathcal{N}}^2$ is the noise power at a sensor, calculated over the duration T of the measurements. The noise is essentially uncorrelated over the frequencies when the bandwidth is sampled at intervals $\Delta\omega \gg 2\pi/T$, as follows by a straightforward calculation.

Imaging with Passive Arrays

The variational formulation of the inverse problem is: Find $\rho \in L^2(I_w)$, a minimizer of the data misfit

$$\mathcal{O}(\rho) = \|\hat{d} - \mathcal{M}\rho\|_{\mathbb{D}}^2 = \int_{|\omega - \omega_0| \leq \pi B} d\omega \sum_{r=1}^{N_r} \left| \hat{d}(\omega, \vec{x}_r) - [\mathcal{M}\rho](\omega, \vec{x}_r) \right|^2. \quad (32)$$

We may add a penalty term in (32), such as a multiple of $\|\rho\|_2^2$ to regularize the problem. We do not do so because it does not play a role in the basic imaging methods derived below. However, regularization is important and one can use other penalties, such as total variation and sparsity promoting norms, to improve the quality of images [15, 26].

The first-order optimality condition satisfied by the minimizer of (32) is

$$[\mathcal{M}^* \mathcal{M}\rho](\vec{y}^s) = [\mathcal{M}^* \hat{d}](\vec{y}^s), \quad \forall \vec{y}^s \in I_w, \quad (33)$$

where the operator $\mathcal{M}^* : \mathbb{D} \rightarrow L^2(I_w)$ is the adjoint of \mathcal{M} , defined formally by the relation

$$\langle \hat{d}, \mathcal{M}\rho \rangle = (\mathcal{M}^* \hat{d}, \rho), \quad \forall \rho \in L^2(I_w), \quad \hat{d} \in \mathbb{D}. \quad (34)$$

It is given explicitly by

$$[\mathcal{M}^* \hat{d}](\vec{y}^s) = \int_{|\omega - \omega_0| \leq \pi B} d\omega \hat{f}(\omega) \sum_{r=1}^{N_r} \overline{\hat{d}(\omega, \vec{x}_r)} \hat{G}(\omega, \vec{y}^s, \vec{x}_r), \quad (35)$$

where $\vec{\mathbf{y}}^s$ are the *search points* that sweep the imaging region I_w , and the bar denotes the complex conjugate.

Equation (33) are the normal equations and $\mathcal{M}^* \mathcal{M} : L^2(I_w) \rightarrow L^2(I_w)$ is the *normal operator*

$$[\mathcal{M}^* \mathcal{M} \rho](\vec{\mathbf{y}}^s) = \int_{I_w} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \mathcal{K}_{\text{pas}}(\vec{\mathbf{y}}, \vec{\mathbf{y}}^s), \quad (36)$$

with kernel

$$\mathcal{K}_{\text{pas}}(\vec{\mathbf{y}}, \vec{\mathbf{y}}^s) = \int_{|\omega - \omega_0| \leq \pi B} d\omega \left| \hat{f}(\omega) \right|^2 \sum_{r=1}^{N_r} \overline{\hat{G}(\omega, \vec{\mathbf{y}}, \vec{\mathbf{x}}_r)} \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r). \quad (37)$$

It is usually not invertible, so one way of solving (33) is to compute the pseudo-inverse of $\mathcal{M}^* \mathcal{M}$, which is typically very expensive. However, the kernel $\mathcal{K}_{\text{pas}}(\vec{\mathbf{y}}, \vec{\mathbf{y}}^s)$ has the important property that is large for points $\vec{\mathbf{y}}$ in the vicinity of $\vec{\mathbf{y}}^s$ and small otherwise, as we explain in more detail in section “The Normal Operator and the Time Reversal Process.” Thus, from the point of view of approximating the support of ρ , we may replace the normal operator in (33) by the identity, and obtain that

$$\rho(\vec{\mathbf{y}}^s) \sim [\mathcal{M}^* \hat{d}] (\vec{\mathbf{y}}^s) = \int_{|\omega - \omega_0| \leq \pi B} d\omega \hat{f}(\omega) \sum_{r=1}^{N_r} \overline{\hat{d}(\omega, \vec{\mathbf{x}}_r)} \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r). \quad (38)$$

The factor $\hat{f}(\omega)$ is not essential in imaging with pulses, although it is important when the source emits a long chirped signal or a stationary noise signal. In that case the factor $\hat{f}(\omega)$ arises in a data pre-processing step known as pulse compression. Since we assume that the source emits a pulse, we may neglect $\hat{f}(\omega)$ in (38) to obtain

$$\rho(\vec{\mathbf{y}}^s) \sim \mathcal{J}(\vec{\mathbf{y}}^s) = \int_{|\omega - \omega_0| \leq \pi B} \frac{d\omega}{2\pi} \sum_{r=1}^{N_r} \overline{\hat{d}(\omega, \vec{\mathbf{x}}_r)} \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r). \quad (39)$$

This is useful for applications where $f(t)$ may not be known. The normalization constant $1/(2\pi)$ is convenient for inverting the Fourier transform.

The meaning of the symbol \sim in (38) and (39) is that large values of the right-hand sides correspond to points in the vicinity of the support of ρ . Thus, $[\mathcal{M}^* \hat{d}] (\vec{\mathbf{y}}^s)$ or its simplification $\mathcal{J}(\vec{\mathbf{y}}^s)$ are imaging functions.

Imaging with Active Arrays

The case of active arrays is similar to the above, except that the data space is given by (28), and the complex inner product is (29). The unknown reflectivity ρ is estimated by a minimizer of

$$\mathcal{O}(\rho) = \|\hat{d} - \mathcal{M}\rho\|_{\mathbb{D}}^2 = \int_{|\omega-\omega_0| \leq \pi B} d\omega \sum_{r=1}^{N_r} \sum_{s=1}^{N_s} \left| \hat{d}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s) - [\mathcal{M}\rho](\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s) \right|^2, \quad (40)$$

and satisfies the normal equations

$$[\mathcal{M}^* \mathcal{M}\rho](\vec{\mathbf{y}}^s) = \left[\mathcal{M}^* \hat{d} \right](\vec{\mathbf{y}}^s), \quad \forall \vec{\mathbf{y}}^s \in I_w. \quad (41)$$

The adjoint operator $\mathcal{M}^* : \mathbb{D} \rightarrow L^2(I_w)$ defined formally by

$$\langle \hat{d}, \mathcal{M}\rho \rangle = (\mathcal{M}^* \hat{d}, \rho), \quad \forall \rho \in L^2(I_w), \quad \hat{d} \in \mathbb{D}, \quad (42)$$

has the explicit expression

$$\begin{aligned} \left[\mathcal{M}^* \hat{d} \right](\vec{\mathbf{y}}^s) &= \int_{|\omega-\omega_0| \leq \pi B} d\omega k^2 \hat{f}(\omega) \sum_{r=1}^{N_r} \sum_{s=1}^{N_s} \overline{\hat{d}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)} \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r) \\ &\quad \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_s), \end{aligned} \quad (43)$$

and the normal operator $\mathcal{M}^* \mathcal{M} : L^2(I_w) \rightarrow L^2(I_w)$,

$$[\mathcal{M}^* \mathcal{M}\rho](\vec{\mathbf{y}}^s) = \int_{I_w} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \mathcal{K}_{\text{act}}(\vec{\mathbf{y}}, \vec{\mathbf{y}}^s), \quad (44)$$

has the kernel

$$\begin{aligned} \mathcal{K}_{\text{act}}(\vec{\mathbf{y}}, \vec{\mathbf{y}}^s) &= \int_{|\omega-\omega_0| \leq \pi B} d\omega k^4 \left| \hat{f}(\omega) \right|^2 \sum_{r=1}^{N_r} \overline{\hat{G}(\omega, \vec{\mathbf{y}}, \vec{\mathbf{x}}_r)} \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r) \\ &\quad \sum_{s=1}^{N_s} \overline{\hat{G}(\omega, \vec{\mathbf{y}}, \vec{\mathbf{x}}_s)} \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_s). \end{aligned} \quad (45)$$

We discuss this kernel in some detail in section ‘‘The Normal Operator and the Time Reversal Process,’’ and we relate it to the kernel (37) arising in imaging with passive arrays. Again, we expect that \mathcal{K}_{act} peaks near its diagonal, so we can estimate the support of the reflectivity by replacing $\mathcal{M}^* \mathcal{M}$ with the identity in the normal equations. We obtain

$$\begin{aligned} \rho(\vec{\mathbf{y}}^s) &\sim \left[\mathcal{M}^* \hat{d} \right](\vec{\mathbf{y}}^s) = \int_{|\omega-\omega_0| \leq \pi B} d\omega k^2 \hat{f}(\omega) \sum_{r=1}^{N_r} \sum_{s=1}^{N_s} \overline{\hat{d}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)} \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r) \\ &\quad \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_s), \end{aligned} \quad (46)$$

with symbol \sim having the same meaning as in (39).

The factor $\omega^2 \hat{f}(\omega)$ in (46) amounts to convolving the second derivative $f''(t)$ of the emitted signal with the time reversed data. But in the Born approximation (26) the time reversed data is determined by $f''(-t)$ convolved with the Green's functions. Thus, we have $f''(t) \star_t f''(-t)$ in (46). Such convolutions are important only when the emitted signals are long, like chirps, or noise signals. Because our $f(t)$ is a pulse, we can estimate the support of the reflectivity using the imaging function

$$\rho(\vec{\mathbf{y}}^s) \sim \mathcal{J}(\vec{\mathbf{y}}^s) = \int_{|\omega - \omega_0| \leq \pi B} \frac{d\omega}{2\pi} \sum_{r=1}^{N_r} \sum_{s=1}^{N_s} \overline{\hat{d}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)} \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r) \quad (47)$$

$$\hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_s).$$

The Normal Operator and the Time Reversal Process

We draw here an analogy between the normal operator and the time reversal process, to give a physical meaning of its replacement by the identity in Eqs. (38) and (46). The time reversal process is described in section “The Time Reversal Process.” The connection to the normal operator is in section “The Normal Operator.”

The Time Reversal Process

The time reversal process is a physical experiment that uses an array of N sensors which act as both receivers and sources. It is a two-step process. In the first step the sensors are receivers which record over a time window $\chi_T(t)$ of duration T , the waves generated by a remote point-like source at $\vec{\mathbf{y}}$ that emits a pulse $\varphi(t)$. This may be the same as $f(t)$, but it is convenient for the discussion to take an arbitrary function $\varphi(t)$, with the same bandwidth as $f(t)$. We can model the density of the point-like source by letting ρ be supported in a ball $B_R(\vec{\mathbf{y}})$ centered at $\vec{\mathbf{y}}$ of radius $R \ll \lambda_o$. This allows us to approximate the Green's function in the model of the data by its value at $\vec{\mathbf{y}}$, and obtain a net source amplitude equal to the integral of ρ over $B_R(\vec{\mathbf{y}})$. The wave equation and the imaging function are linear in ρ , so we normalize the net source amplitude to one.

In the second step of the experiment, the array time reverses the recordings and re-emits them simultaneously from all the sensors, which act as sources. The resulting wave propagates in the medium, and it refocuses near the original source, due to the time reversibility of the wave equation. The quality of the refocusing depends on how large the array is, the length of time of the recordings, and the medium.

The recordings at the receivers are denoted by

$$d_\chi(t, \vec{\mathbf{x}}_r) = \chi_T(t)\varphi(t) \star_t G(t, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}), \quad (48)$$

and their time reversed version $d_{TR}(t, \vec{\mathbf{x}}_r) = d_\chi(T-t, \vec{\mathbf{x}}_r)$ has the Fourier transform

$$\hat{d}_{TR}(\omega, \vec{\mathbf{x}}_r) = e^{i\omega T} \overline{\hat{d}_\chi(\omega, \vec{\mathbf{x}}_r)}, \quad (49)$$

for $r = 1, \dots, N$. This is the ideal model, without additive noise. We obtain from (48) that

$$\hat{d}_\chi(\omega, \vec{\mathbf{x}}_r) = \int \frac{d\omega'}{2\pi} \hat{\chi}(\omega' T) \hat{\phi}(\omega - \omega') \hat{G}(\omega - \omega', \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \approx \hat{\phi}(\omega) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}), \quad (50)$$

where we let

$$\chi_T(t) = \frac{1}{T} \chi\left(\frac{t}{T}\right),$$

for a function χ of dimensionless argument and support of order one. The approximation in (50) is for large recording times T satisfying $\omega_o T \gg 1$, and for the window normalization $\chi_T(0) = 1$.

The array emits the time reversed field d_{TR} from all the sensors at once, and the wave observed at the search points $\vec{\mathbf{y}}^s$ is modeled by

$$\begin{aligned} p_{TR}(T+t, \vec{\mathbf{y}}^s, \vec{\mathbf{y}}) &= \sum_{r=1}^N \int \frac{d\omega}{2\pi} \hat{d}_{TR}(\omega, \vec{\mathbf{x}}_r) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) e^{-i\omega(T+t)} \\ &= \sum_{r=1}^N \int \frac{d\omega}{2\pi} \overline{\hat{d}_\chi(\omega, \vec{\mathbf{x}}_r)} \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) e^{-i\omega t} \\ &\approx \sum_{r=1}^N \int \frac{d\omega}{2\pi} \overline{\hat{\phi}(\omega)} \overline{\hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}})} \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) e^{-i\omega t}, \end{aligned} \quad (51)$$

where we used the approximation (50). Because of the time reversibility of the wave equation, it refocuses at the original source, at offset time $t = 0$. The *time reversal point spread function*

$$\mathcal{K}_{TR}(\vec{\mathbf{y}}^s, \vec{\mathbf{y}}) = p_{TR}(T, \vec{\mathbf{y}}^s, \vec{\mathbf{y}}) \approx \sum_{r=1}^N \int \frac{d\omega}{2\pi} \overline{\hat{\phi}(\omega)} \overline{\hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}})} \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) \quad (52)$$

models the refocused wave field. We describe it briefly in section ‘‘Imaging in Smooth and Known Media’’ in the case of smooth media. The cross-range resolution of the refocusing depends on the wavelength, the distance from the source to the array and the array aperture. The range resolution is determined by the bandwidth. In complex media the focusing may be improved. This is known as *super-resolution*.

By improved we mean that with a limited aperture we may get better cross-range resolution than we would if the medium were smooth. We refer to [6, 19, 27] for the analysis and illustration of super-resolution.

The Normal Operator

In the case of passive arrays, the normal operator is given by (36). It is a linear integral operator with kernel $\mathcal{K}_{\text{pass}}(\vec{\mathbf{y}}, \vec{\mathbf{y}}^s)$ written explicitly in (37). We see that it is the same as the time reversal point spread function (52) for $\varphi(\omega) = |\hat{f}(\omega)|^2$. That is to say, the kernel of the normal operator is mathematically equivalent to the time reversal function for a source at $\vec{\mathbf{y}}$, emitting the pulse with Fourier transform equal to $|\hat{f}(\omega)|^2$. The tighter the refocusing of the wave at $\vec{\mathbf{y}}$ in the time reversal process, the more the kernel is peaked at $\vec{\mathbf{y}} = \vec{\mathbf{y}}^s$, and the closer the behavior of the normal operator to an approximate identity in Eq. (38).

The normal operator for the case of active arrays is given by (44), and its kernel is (45). Let us write it assuming that each sensor in the array acts as a source and receiver, so that $N_r = N_s = N$. We have

$$\mathcal{K}_{\text{act}}(\vec{\mathbf{y}}, \vec{\mathbf{y}}^s) = \int_{|\omega - \omega_0| \leq \pi B} d\omega k^4 |\hat{f}(\omega)|^2 \left[\sum_{r=1}^N \overline{\hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}})} \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r) \right]^2, \quad (53)$$

which can be related to the time reversal process using the time-dependent field

$$p_{TR}^{(N)}(T + t, \vec{\mathbf{y}}, \vec{\mathbf{y}}^s) = \int_{|\omega - \omega_0| \leq \pi B} d\omega k^2 |\hat{f}(\omega)| \sum_{r=1}^N \overline{\hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}})} \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r) e^{-i\omega t}. \quad (54)$$

This is the wave observed at location $\vec{\mathbf{y}}^s$ and time $T + t$ in the time reversal process, in the case of a source at $\vec{\mathbf{y}}$, emitting a pulse with Fourier coefficient $k^2 |\hat{f}(\omega)|$. The focusing in (54) is expected at $t = 0$, and the time reversal point spread function is equal to $p_{TR}^{(N)}(T, \vec{\mathbf{y}}, \vec{\mathbf{y}}^s)$. The kernel (53) is, up to a constant, the time convolution of $p_{TR}^{(N)}$ with itself, evaluated at $t = 0$,

$$\mathcal{K}_{\text{act}}(\vec{\mathbf{y}}, \vec{\mathbf{y}}^s) = 2\pi p_{TR}^{(N)}(T + t, \vec{\mathbf{y}}, \vec{\mathbf{y}}^s) \star_t p_{TR}^{(N)}(T + t, \vec{\mathbf{y}}, \vec{\mathbf{y}}^s)|_{t=0}. \quad (55)$$

If the wave field $p_{TR}^{(N)}(T + t, \vec{\mathbf{y}}, \vec{\mathbf{y}}^s)$ focuses at $\vec{\mathbf{y}}^s = \vec{\mathbf{y}}$ around $t = 0$, so will the kernel. Thus, the normal operator behaves as an approximate identity if the time reversal process focuses with sharp resolution.

The generalization of (55) to arrays with N_r receivers and N_s sources is

$$\mathcal{K}_{\text{act}}(\vec{\mathbf{y}}, \vec{\mathbf{y}}^s) = 2\pi p_{TR}^{(N_r)}(T + t, \vec{\mathbf{y}}, \vec{\mathbf{y}}^s) \star_t p_{TR}^{(N_s)}(T + t, \vec{\mathbf{y}}, \vec{\mathbf{y}}^s)|_{t=0}. \quad (56)$$

In particular, for a single source $N_s = 1$, and there is no refocusing of $p_{TR}^{(N_s)}(T + t, \vec{\mathbf{y}}, \vec{\mathbf{y}}^s)$ at $\vec{\mathbf{y}}^s = \vec{\mathbf{y}}$. The behavior of the kernel is determined by the refocusing of the wave $p_{TR}^{(N_r)}(T + t, \vec{\mathbf{y}}, \vec{\mathbf{y}}^s)$.

Imaging in Smooth and Known Media

In known media the imaging function (39) is the mathematical analogue of the time reversal point spread function. We describe it in this section for the case of smooth media. In unknown media we cannot compute (39). We use instead the *reverse time migration* imaging function that propagates the waves from the array to the imaging region in a surrogate medium. It is the method of choice in many imaging applications. The *Kirchhoff migration* imaging function is a high frequency approximation of the reverse time migration function, where the propagation is replaced by a synchronization of the waves using travel times.

Once we have defined the imaging functions, the question is how well do they work? To answer it, we identify two properties that make an imaging method useful:

1. The image should focus at ρ , i.e., $|\mathcal{J}(\vec{\mathbf{y}}^s)|$ should be large near the support of ρ and small elsewhere.
2. The focusing should be robust.

We study in section “Robustness to Additive Noise.” We postpone the more involved discussion of *robustness to uncertainties in complex media* until Sects. 7 and 8. The characterization of the focusing of the image is known as *resolution analysis*. We state the resolution limits for a setup with small arrays.

Passive Arrays

When we know the medium, and therefore the Green’s function \hat{G} , we can process the data as in (39) to form an image. The data processing has the physical interpretation of taking the traces received at the array, time reversing them, and then back-propagating them to the imaging point via the Green’s function. Because the Green’s function models the actual wave propagation in the known medium, the back-propagation in $\mathcal{J}(\vec{\mathbf{y}}^s)$ is equivalent to solving the wave equation with source term

$$F(t, \vec{\mathbf{x}}) = \sum_{r=1}^{N_r} d(-t, \vec{\mathbf{x}}_r) \delta(\vec{\mathbf{x}} - \vec{\mathbf{x}}_r),$$

and evaluating the pressure field at $\vec{\mathbf{y}}^s \in I_w$, at the expected time of refocus. The imaging process is mathematically equivalent to the time reversal process described in section “The Normal Operator and the Time Reversal Process” because we know precisely the medium!

To study the imaging function (39), let us recall the model (16) of the data and write

$$\mathcal{J}(\vec{\mathbf{y}}^s) = \int_{|\omega - \omega_o| \leq \pi B} d\omega \sum_{r=1}^{N_r} \overline{\hat{d}(\omega, \vec{\mathbf{x}}_r)} \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r) = \langle \mathcal{J}(\vec{\mathbf{y}}^s) \rangle + \delta \mathcal{J}(\vec{\mathbf{y}}^s). \quad (57)$$

The first term is the model of the image in the absence of noise

$$\langle \mathcal{J}(\vec{\mathbf{y}}^s) \rangle = \int_{I_W} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \int_{|\omega - \omega_o| \leq \pi B} d\omega \overline{\hat{f}(\omega)} \sum_{r=1}^{N_r} \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r), \quad (58)$$

and the second term models the effect of the noise

$$\delta \mathcal{J}(\vec{\mathbf{y}}^s) = \int_{|\omega - \omega_o| \leq \pi B} d\omega \sum_{r=1}^{N_r} \overline{\hat{\mathcal{N}}_r^T(\omega)} \hat{G}(\omega, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r). \quad (59)$$

We study $\delta \mathcal{J}(\vec{\mathbf{y}}^s)$ in section ‘‘Robustness to Additive Noise,’’ so we concentrate here on $\langle \mathcal{J}(\vec{\mathbf{y}}^s) \rangle$, which we rewrite as

$$\langle \mathcal{J}(\vec{\mathbf{y}}^s) \rangle \approx \int_{I_W} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \int_{|\omega - \omega_o| \leq \pi B} \frac{d\omega}{2\pi} \overline{\hat{f}(\omega)} \sum_{r=1}^{N_r} \overline{\alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})} \alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) e^{i\omega[\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) - \tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})]} \quad (60)$$

$$= \int_{I_W} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \sum_{r=1}^{N_r} \overline{\alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})} \alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) f(\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) - \tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s)). \quad (61)$$

Here we used the geometrical optics approximation of the Green’s function in the assumed smooth medium

$$\hat{G}(\omega, \vec{\mathbf{x}}, \vec{\mathbf{y}}) \approx \alpha(\vec{\mathbf{x}}, \vec{\mathbf{y}}) e^{i\omega\tau(\vec{\mathbf{x}}, \vec{\mathbf{y}})}, \quad (62)$$

with amplitude α and travel time τ . They are calculated along rays (geodesics) connecting $\vec{\mathbf{x}}$ to $\vec{\mathbf{y}}$ by solving with the method of characteristics a transport equation and an eikonal equation [5, 24]. In the case of homogeneous media with wave speed c_o , they have the explicit expression

$$\alpha(\vec{\mathbf{x}}, \vec{\mathbf{y}}) = \alpha_o(\vec{\mathbf{x}}, \vec{\mathbf{y}}) := \frac{1}{4\pi |\vec{\mathbf{x}} - \vec{\mathbf{y}}|} \quad \text{and} \quad \tau(\vec{\mathbf{x}}, \vec{\mathbf{y}}) = \tau_o(\vec{\mathbf{x}}, \vec{\mathbf{y}}) := \frac{|\vec{\mathbf{x}} - \vec{\mathbf{y}}|}{c_o}. \quad (63)$$

We can understand what to expect from (61) by referring to the example in Fig. 1, with a source of small support around point $\vec{\mathbf{y}}$. Because data $d(t, \vec{\mathbf{x}}_r)$ are essentially the emitted pulse delayed by the travel time $\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})$, we get a contribution to the

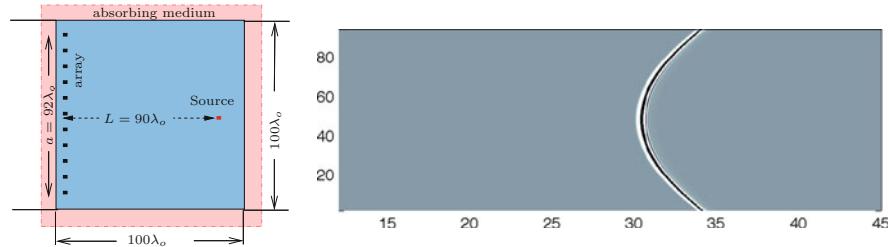

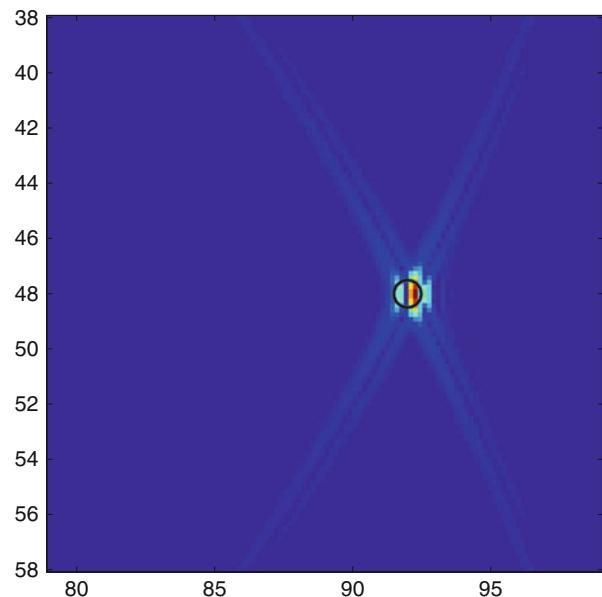

Fig. 1 Plot of the passive array data traces for a point source in a homogeneous medium. They solve the wave equation in a homogeneous medium with wave speed $c_o = 1.5$ km/s, for a source emitting a pulse with wide frequency band [1.5–4.5] MHz. We plot $d(t, \vec{x}_r)$ in grey scale, as a function of time in the abscissa and receiver location in the ordinate. All the lengths are scaled by the central wavelength $\lambda_o = 0.5$ mm. The simulation setup is shown on the left

Fig. 2 Kirchhoff migration image for one point source in a homogeneous medium. This is the image obtained using (64) for the passive array data traces shown in Fig. 1. We plot the absolute value of the imaging function. The abscissa is range in λ_o and the ordinate is cross-range in λ_o

sum in (61) if \vec{y}^s lies near the isochrone with travel time equal to $\tau(\vec{x}_r, \vec{y})$, at least for one receiver. For example, in homogeneous media this means that \vec{y}^s is near the sphere of center \vec{x}_r and radius $|\vec{x}_r - \vec{y}|$, at least for one receiver. With this reasoning, we expect that $\langle |\mathcal{J}(\vec{y}^s)| \rangle$ is large near the intersection of all these isochrones, for all receivers in the array. Such points are close to \vec{y} , as we illustrate in Fig. 2. The imaging function for point-like sources is called the *point spread function* and its essential support around \vec{y} defines the resolution limits.

We assume in this article a typical imaging regime with an array of linear size a that is much smaller than the distance to the source, and with bandwidth $B < \omega_o$. The direction from the source to the array is called *range*, and the distance along it

is of the order of the range scale L . The directions orthogonal to the range are called *cross-range*. The support of the point spread function in cross-range, the *cross-range resolution*, is of the order $\lambda_o L/a$. It improves as we increase the frequency and the array aperture. The range resolution depends on the temporal support of the pulse, which defines the precision of the arrival time estimation of the waves, and thus of the distance to the source. Because the pulse $f(t)$ has the temporal support $O(1/B)$, it is of the order c_o/B . These resolution limits are widely known and can be deduced from the calculations in Sect. 7.

A common imaging approach in the applied literature is a further simplification of $\mathcal{J}^M(\vec{\mathbf{y}}^s)$, known as *Kirchhoff migration* [4],

$$\mathcal{J}^{\text{KM}}(\vec{\mathbf{y}}^s) = \sum_{r=1}^{N_r} d(\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s), \vec{\mathbf{x}}_r). \quad (64)$$

It is similar to reverse time migration except that it neglects the geometrical spreading factor $\alpha(\vec{\mathbf{y}}^s, \vec{\mathbf{x}}_r)$ in the Green's function, as if it were a constant across the array. This approximation is justified in our setup because the array aperture is much smaller than the distance between the array and the imaging region.

Active Arrays

The *reverse time migration* function for active arrays is

$$\begin{aligned} \mathcal{J}^M(\vec{\mathbf{y}}^s) &= \int_{|\omega - \omega_o| \leq \pi B} \frac{d\omega}{2\pi} \sum_{r=1}^{N_r} \sum_{s=1}^{N_s} \overline{\hat{d}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)} \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) \hat{G}(\omega, \vec{\mathbf{x}}_s, \vec{\mathbf{y}}^s) \\ &\approx \int_{|\omega - \omega_o| \leq \pi B} \frac{d\omega}{2\pi} \sum_{r=1}^{N_r} \sum_{s=1}^{N_s} \overline{\hat{d}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)} \alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) \alpha(\vec{\mathbf{x}}_s, \vec{\mathbf{y}}^s) e^{i\omega[\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) + \tau(\vec{\mathbf{x}}_s, \vec{\mathbf{y}}^s)]} \\ &= \sum_{r=1}^{N_r} \sum_{s=1}^{N_s} d(\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) + \tau(\vec{\mathbf{x}}_s, \vec{\mathbf{y}}^s), \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s) \alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) \alpha(\vec{\mathbf{x}}_s, \vec{\mathbf{y}}^s). \end{aligned} \quad (65)$$

The *Kirchhoff migration* function neglects the geometrical spreading factors $\alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s)$ of the Green's function, and forms an image by simply summing the traces “synchronized” by the expected round trip travel time,

$$\mathcal{J}^{\text{KM}}(\vec{\mathbf{y}}^s) = \sum_{r=1}^{N_r} \sum_{s=1}^{N_s} d(\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) + \tau(\vec{\mathbf{x}}_s, \vec{\mathbf{y}}^s), \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s). \quad (66)$$

We show in Fig. 5 the Kirchhoff migration images obtained with the data traces in Figs. 3 and 4. In each case we indicate the location of the scatterers with a black circle (Fig. 5).

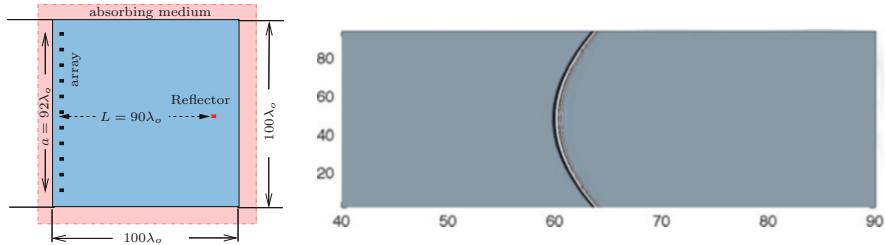

Fig. 3 Plot of the active array data traces for a point reflector in a homogeneous medium, and an illumination from the center element in \mathcal{A} . The abscissa is time in μs and the ordinate is the receiver location in λ_o . The simulation setup is shown on the *left*. It is the same as in Fig. 1 with the source being replaced by a soft acoustic reflector, i.e., a disk of diameter λ_o with homogeneous Dirichlet conditions on its boundary

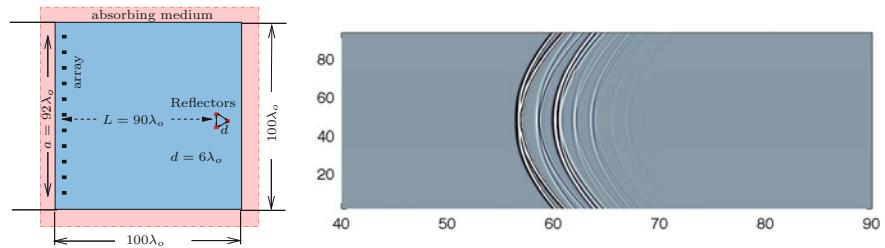

Fig. 4 Plot of the active array data traces for three reflectors in a homogeneous medium, and an illumination from the center element in the array. The abscissa is time in μs and the ordinate is the receiver location in λ_o . The simulation setup is shown on the *left*. The Born approximation used in the derivation of the imaging function captures only the primary echoes shown by the strong hyperbolae in the figure. The later arrivals are multiply scattered waves between the reflectors

We leave the interpretation of the imaging functions to the reader. They are straightforward extensions of the results for passive arrays.

Robustness to Additive Noise

To quantify the effect of the noise, we view the imaging problem in a stochastic framework, where $\mathcal{J}(\vec{y}^s)$ is a random process due to the noise. The expectation of $\mathcal{J}(\vec{y}^s)$ is its *coherent part* $\mathbb{E}[\mathcal{J}(\vec{y}^s)] = \langle \mathcal{J}(\vec{y}^s) \rangle$, and the random fluctuations are $\delta \mathcal{J}(\vec{y}^s) = \mathcal{J}(\vec{y}^s) - \mathbb{E}[\mathcal{J}(\vec{y}^s)]$. Intuitively, robustness of the imaging method means that the coherent part $\langle \mathcal{J} \rangle$ dominates the fluctuations $\delta \mathcal{J}$ in the vicinity of its peaks, so we can determine with high fidelity the support of the unknown ρ . That is to say, the images do not change in essential ways with the realization of noise. In an imaging experiment we can compute only *one realization of the random process* $\mathcal{J}(\vec{y}^s)$, which is what we call *an image*. It corresponds to the one realization of the noise in the data gathered by the receivers in the array. If we could compare such

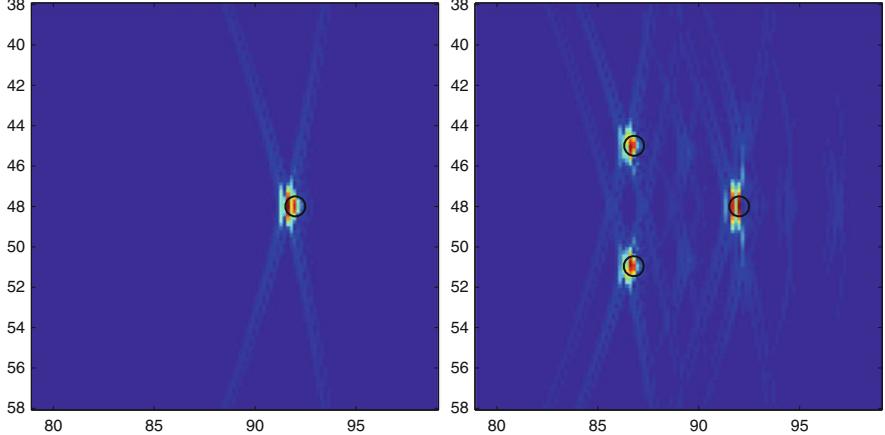

Fig. 5 Imaging results in homogeneous media using the traces plotted in Figs. 3 and 4. The images are computed with Eq. (66). The absolute value of the image for one reflector is shown on the *left* and for three reflectors on the *right*. The abscissa is range in λ_o and the ordinate is cross-range in λ_o . The imaging function is based on the Born approximation, and the image has some faint artifacts due to the multiply reflected waves seen in the right plot of Fig. 4

an image with $\langle \mathcal{J}(\vec{\mathbf{y}}^s) \rangle$, the ideal image with noiseless data, we would see many spurious peaks distributed throughout the search domain I_w , i.e., one realization of $\delta \mathcal{J}(\vec{\mathbf{y}}^s)$. If $|\delta \mathcal{J}|$ is smaller than $|\langle \mathcal{J} \rangle|$ for points in the support of ρ , with high probability, then the estimates of the support of ρ are essentially independent of the realization of the noise and the method is robust.

We assess below the robustness of images with passive arrays. The case of active arrays is similar. Recall Eqs. (57)–(59) and the assumptions (15) on $\mathcal{N}_r(t)$. Assume also a point-like source at $\vec{\mathbf{y}}$ in order to simplify the calculations. The coherent part of the image evaluated at $\vec{\mathbf{y}}$ is

$$\langle \mathcal{J}(\vec{\mathbf{y}}) \rangle \approx \int_{|\omega - \omega_o| \leq \pi B} d\omega \overline{\hat{f}(\omega)} \sum_{r=1}^{N_r} \left| \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \right|^2 \approx f(0) \sum_{r=1}^{N_r} |\alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})|^2, \quad (67)$$

and we wish that its magnitude be larger than $|\delta \mathcal{J}(\vec{\mathbf{y}})|$ with high probability. We can estimate this probability using Chebyshev's inequality

$$\begin{aligned} P[|\mathcal{J}(\vec{\mathbf{y}})| > |\langle \mathcal{J}(\vec{\mathbf{y}}) \rangle|] &= 1 - P[|\delta \mathcal{J}(\vec{\mathbf{y}})| \geq |\langle \mathcal{J}(\vec{\mathbf{y}}) \rangle|] \geq 1 - \frac{\mathbb{E}[|\delta \mathcal{J}(\vec{\mathbf{y}})|^2]}{|\langle \mathcal{J}(\vec{\mathbf{y}}) \rangle|^2} \\ &= 1 - \left(\frac{1}{\text{SNR}(\vec{\mathbf{y}})} \right)^2, \end{aligned} \quad (68)$$

where SNR stands for the signal to noise ratio

$$\text{SNR}(\vec{\mathbf{y}}) = \frac{|\langle \mathcal{J}(\vec{\mathbf{y}}) \rangle|}{\sqrt{\text{Var}[\mathcal{J}(\vec{\mathbf{y}})]}}, \quad \text{Var}[\mathcal{J}(\vec{\mathbf{y}})] = \sqrt{\mathbb{E}[|\delta \mathcal{J}(\vec{\mathbf{y}})|^2]}. \quad (69)$$

The “signal” is the coherent part (67) of the random process $\mathcal{J}(\vec{\mathbf{y}})$ and the “noise” is $\delta \mathcal{J}(\vec{\mathbf{y}})$. Its model follows from (59) and the geometrical optics approximation of the Green’s function

$$\delta \mathcal{J}(\vec{\mathbf{y}}) \approx \sum_{r=1}^{N_r} \alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) \int_{|\omega - \omega_o| \leq \pi B} d\omega \overline{\hat{\mathcal{N}}_r^T(\omega)} e^{i\omega \tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s)}. \quad (70)$$

It is a linear superposition of independent Gaussian noise terms, so it is Gaussian, with mean $\mathbb{E}[\delta \mathcal{J}(\vec{\mathbf{y}}^s)] = 0$ and variance

$$\begin{aligned} \text{Var}[\mathcal{J}(\vec{\mathbf{y}}^s)] &\approx \sigma_{\mathcal{N}}^2 \sum_{r=1}^{N_r} |\alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s)|^2 \iint_{|\omega - \omega_o| \leq \pi B} d\omega d\omega' e^{i(\omega - \omega')\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s)} \\ &\quad \int_0^T dt e^{-i(\omega - \omega')t} \\ &\approx 4\pi^2 B \sigma_{\mathcal{N}}^2 \sum_{r=1}^{N_r} |\alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s)|^2. \end{aligned} \quad (71)$$

The last approximation is for very large T and for $B\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) \gg 1$, as is the case under our assumption that the temporal width $O(1/B)$ of the pulse is much smaller than the travel times from the source to the array.

The SNR follows from (67) and (71)

$$\text{SNR}[\mathcal{J}(\vec{\mathbf{y}})] \approx \frac{|f(0)|}{2\pi\sigma_{\mathcal{N}}\sqrt{B}} \sqrt{\sum_{r=1}^N |\alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})|^2} \leq \frac{\|f\|}{2\pi\sigma_{\mathcal{N}}} \sqrt{\sum_{r=1}^N |\alpha(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})|^2}, \quad (72)$$

where

$$\|f\|^2 = \int dt |f(t)|^2 = \frac{1}{2\pi} \int_{|\omega - \omega_o| \leq \pi B} d\omega |\hat{f}(\omega)|^2.$$

It increases linearly with the norm of the emitted signal and decreases with the “noise level” $\sigma_{\mathcal{N}}$. Having more sensors is beneficial because the sum over r increases. The amplitudes α decrease with the distance from the source to the array, so the noise level should be much lower than the norm of the emitted pulse in order to have high fidelity images of remote sources.

We neglect henceforth additive noise, for simplicity. Noise is of course part of any imaging experiment. It can be added easily in the analysis that follows and its effects can be studied as described above.

4 Challenges of Imaging in Complex Media

In the previous section we considered media that were largely known and smooth, with the exception of a compactly supported embedded reflector. In many imaging applications with active arrays the medium is complex, with wave speed $c(\vec{x})$ that is not smooth and unknown. A natural idea is to estimate the function $c(\vec{x})$ by the minimizer of the least squares functional $\|\mathcal{F}(c) - \hat{d}\|_{\mathbb{D}}^2$, where \mathcal{F} is the *nonlinear forward mapping* that takes the wave speed c to the data space \mathbb{D} . Given the large number of unknowns, corresponding to a discretization of $c(\vec{x})$ on a grid, the optimization would have to use a gradient-based optimization method like Gauss–Newton [23], which linearizes locally $\mathcal{F}(c)$. It turns out that it is easier to linearize $\mathcal{F}(c)$ with respect to localized perturbations of $c(\vec{x})$ than with respect to distributed (smooth) ones. For example, the smooth part of $c(\vec{x})$ determines the travel times τ of the waves, and in high frequency regimes small perturbations of τ give large changes of the wave field that oscillates like $e^{i\omega\tau}$. This indicates that it should be easier to estimate a sparse set of large discontinuities of $c(\vec{x})$, which is the goal in imaging, than the rest of the function.

There is computational experience on the least squares minimization over $c(\vec{x})$ in piecewise smooth media, and some convergence studies exist [30, 31, 34, 37]. The problem is difficult because the least squares functional is not convex, and the optimization gets stuck easily in local minima that have nothing to do with the true $c(\vec{x})$. Thus, success can be expected only when the initial guess of $c(\vec{x})$ is very good. What this means exactly is complicated and poorly understood at the moment.

The most powerful idea that has emerged in inversion in complex media is that of *separation of scales*. We already introduced it in Eq. (22), where we distinguished between the background speed $c(\vec{x})$ (assumed smooth there) and the reflectivity ρ . We extend it in the next section to media with microscale. Reverse time migration is designed to estimate ρ , and as we explained in the previous section, it is based on the linearization \mathcal{M} of the forward mapping \mathcal{F} . This linearization works well in many cases, but when there are strong reflecting interfaces like air-solid boundaries, the data contain strong multiply scattered echoes which cause image artifacts. See for example [36] for data processing algorithms intended to suppress such multiple reflections. In any case, migration imaging can work well only when we know the background velocity, which determines the wave propagation between the reflection events. When we have it wrong, the migration images are not well focused and the reflectivity is mapped to wrong places. The estimation of the background speed is called *velocity analysis* or *inversion*. We do not discuss it here, but we note that it is strongly connected to migration imaging [4]. On one hand, the quality of the migration images depends on knowing the background speed, and on the other hand this speed can be estimated by comparing migration images formed with various data subsets [14]. This idea is behind the iterative migration-velocity analysis inversion methods that are popular in fields like reflection seismology [4].

Cluttered Media

Imaging becomes complicated in media with rapidly fluctuating wave speed $c(\vec{\mathbf{x}})$ due to numerous small inhomogeneities. Because the array data is necessarily band limited, it is not possible to recover all these fluctuations in detail as part of the inversion. This motivates us to separate the wave speed in two parts: the “macrostructure” which can in principle be recovered in inversion, and the “microstructure” or “clutter” which is the uncertain part of $c(\vec{\mathbf{x}})$. What we call macrostructure is the smooth part $\bar{c}(\vec{\mathbf{x}})$ of the wave speed assumed known, and a sparse set of its large discontinuities modeled by the reflectivity $\rho(\vec{\mathbf{x}})$. Strictly speaking the reflectivity is a fine scale feature of $c(\vec{\mathbf{x}})$, but it can be estimated from the data so we think of it as part of the macrostructure. The assumption that \bar{c} is known is because we do not consider velocity estimation. We refer to [17] for an example of robust velocity estimation in complex media with microstructure.

The separation of scales is now

$$\frac{1}{c^2(\vec{\mathbf{x}})} = \frac{1}{\bar{c}^2(\vec{\mathbf{x}})} \left[1 + \sigma \mu \left(\frac{\vec{\mathbf{x}}}{\ell} \right) \right] + \frac{\rho(\vec{\mathbf{x}})}{c_o^2}, \quad (73)$$

with $\mu(\vec{\mathbf{x}})$ representing the uncertain microstructure or clutter, the rapid fluctuations of $c(\vec{\mathbf{x}})$ on scales ℓ comparable to the wavelength or less than that. The amplitude σ of $\mu(\vec{\mathbf{x}})$ is typically small, meaning that an inhomogeneity by itself is a weak scatterer with respect to ρ . It is the cumulative effect of the inhomogeneities that becomes significant as the waves travel deeper in cluttered media. See for example the illustration in Fig. 6, where we have the same setup as in Fig. 4, but the wave speed has rapid fluctuations, as shown on the left. The amplitude of these fluctuations is small in comparison with the reflectivity of the three point-like scatterers modeled in the simulations as “sound soft,” with the acoustic pressure vanishing at their boundary. These three scatterers cause strong echoes that are somewhat visible in the noisy traces, with arrivals lying on curves that are perturbations of the hyperbole in Fig. 4. But there are many other echoes recorded before and after these arrivals, due to multiple scattering by the inhomogeneities. They are more significant than the waves scattered between the reflectors in Fig. 4, so we will make a big mistake if we neglect the clutter. Much worse than using the Born approximation (linearization) with respect to ρ .

The Random Model

The clutter (microstructure) is uncertain, so we model it mathematically as a *random process* $\mu(\vec{\mathbf{x}})$, a collection of random variables parametrized by $\vec{\mathbf{x}} \in \mathbb{R}^n$. The macrostructure modeled with \bar{c} and ρ in (73) is the *deterministic part* of $c(\vec{\mathbf{x}})$ because it is feasible to recover it from the array data. The wave field $p(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)$ at the array is a random process parameterized by time, the receiver

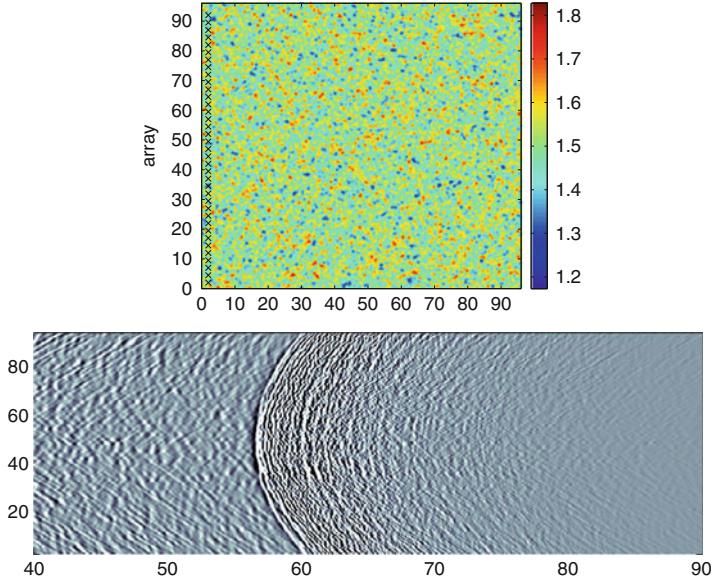

Fig. 6 Plot of the active array data traces for three reflectors in a heterogeneous medium. The abscissa is time in μs and the ordinate is receiver location in λ_o . The setup of the simulation is shown on the left where the units in the color bar are Km/s

and source locations. The data $\{d(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)\}$ are *one realization of this process*. If we had measurements in many media we could superpose them to approximate the statistical average (expectation) $\mathbb{E}[p(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)]$ which we call the *coherent part* of the data. This is useful in imaging because we can relate it in a robust way to the unknown reflectivity. But in reality there is only one medium, with one microstructure given by one realization of the random $\mu(\vec{\mathbf{x}})$. Thus, we do not have direct access to the coherent part of the data and must deal with its uncertain, *incoherent part* $d(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s) - \mathbb{E}[p(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)]$. This impedes imaging and causes uncertainty in the reconstructions.

The reflectivity ρ is deterministic, but the wave field $p(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)$ is random so we may view the reconstructions of ρ in a probabilistic setting. A reconstruction is a mathematical model of an imaging function which involves the random field $p(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)$, so it is a random processes. We can compute only one realization of this process because we have only one realization of the random wave field, the data $\{d(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)\}$. This realization is what we call *an image*.

We study the focusing of imaging functions in random media by looking first at $\mathbb{E}[\mathcal{J}(\vec{\mathbf{y}}^s)]$ and then at its SNR at the peaks. In the case of imaging functions like reverse time migration, which are linear in $\{p(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)\}$, the expectation of the image is determined by the coherent part of the data $\mathbb{E}[p(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)]$. This is not the same as what we would measure in a medium without clutter. Multiple scattering leads to *loss of coherence of the waves*, which mani-

fests as an *exponential decay* of $\mathbb{E}[p(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)]$ with the distance of propagation. The length scale of exponential decay is called *the scattering mean-free path* and it depends on many factors like the wavelength, the range of propagation, and the statistics of $\mu(\vec{\mathbf{x}})$. Energy is conserved, so the incoherent part of the field, the random fluctuations, gain strength. We see in Fig. 6 a realization of such fluctuations, the many echoes recorded before and after the coherent arrivals.

Time Reversal Is Not Imaging

We already saw that, superficially, there is a connection between imaging and the time reversal process. This is why they are often studied side by side. But the *two are not the same at all in cluttered media*.

Time reversal works better in clutter [6, 19, 27] because scattering by the inhomogeneities spreads out the time reversed wave field captured and then re-emitted at the array, as if it came from an array of *effective aperture* $a_e > a$. The more scattering is, the larger the effective aperture, meaning that good focusing in cross-range, with resolution of the order $\lambda_o L/a_e$, can be achieved with very small arrays [19, 20]. Moreover, the refocusing is *statistically stable* under generic assumptions [27]. This is due to the time reversability of the wave equation and the fact that the time reversed field propagates to the source in the *same medium* it came from.

In migration imaging the back-propagation is done analytically or numerically in a surrogate medium with wave speed \bar{c} because we do not know the microscale of the real medium. Migration works well only when the clutter effects are weak, as shown explicitly in Sect. 7. More precisely, when the array is closer than a *scattering mean-free path* from the imaging region. Otherwise the coherent part of the data, the “signal,” is exponentially damped due to scattering in clutter and the incoherent fluctuations, and the “clutter noise” is significant. The images are difficult to interpret and change unpredictably with the realization of clutter. The sole mechanism of dealing with the “clutter noise” in migration is the summation over the sensors. If we had only additive and uncorrelated noise like in section “Robustness to Additive Noise,” it would average out approximately for arrays with many sensors like in the law of large numbers. But clutter noise has persistent correlations over the sensors and over frequencies, and it cannot be averaged out by summation. More involved data processing is needed to mitigate it.

A natural question arises: Could we improve the migration results if we knew the statistics of clutter? Could we just create a realization of the clutter with the given statistics and then back-propagate the data in it instead of the medium with speed \bar{c} ? The answer is no. In fact we would do much worse than back-propagating in the smooth medium because we would essentially double the distance traveled by the waves in clutter. *The clutter effects are undone only when the waves go back through the same medium* as is the case in the time reversal process.

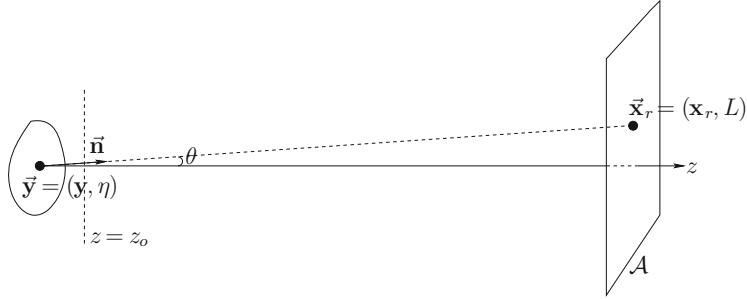

Fig. 7 System of coordinates and setup for imaging with passive arrays in random media

5 The Random Travel Time Model of Wave Propagation

In this section we describe a geometrical optics model of wave propagation in random media. It allows an explicit and self-contained analysis of resolution and statistical stability of images, and yet it captures canonical scattering effects on the wavefront. That is to say, the first two statistical moments of the wave field, which describe the loss of coherence and decorrelation of the waves due to scattering in the random medium, look the same as those derived from more sophisticated models. This makes the random travel time model a good testbed for studying imaging with partially coherent waves in random media.

Consider the setup illustrated in Fig. 7, with a passive array at range L from the source and the range axis z orthogonal to the aperture $\mathcal{A} = [-\frac{a}{2}, \frac{a}{2}] \times [-\frac{a}{2}, \frac{a}{2}]$. We use henceforth the notation $\vec{x}_r = (\mathbf{x}_r, L)$ for the points in the array with cross-range components $\mathbf{x}_r \in \mathcal{A}$, and $\vec{y} = (\mathbf{y}, \eta)$ for the points in the support of the source, with range η and cross-range vector \mathbf{y} .

We are interested in the outgoing Green's function $\hat{G}(\omega, \vec{x}_r, \vec{y})$ of the Helmholtz equation in an medium with random wave speed $c(\vec{x})$ of the form (73) with fluctuations around the constant value $\bar{c} = c_o$. The fluctuations are modeled by the random process μ assumed stationary and twice differentiable with bounded derivatives, almost surely. It has mean zero

$$\mathbb{E}[\mu(\vec{\mathbf{u}})] = 0, \quad (74)$$

and an integrable covariance

$$\mathcal{R}(\vec{\mathbf{u}}) = \mathbb{E} [\mu(\vec{\mathbf{u}} + \vec{\mathbf{u}}') \mu(\vec{\mathbf{u}}')], \quad (75)$$

normalized by

$$\mathcal{R}(0) = 1, \quad \int_{\mathbb{R}^3} d\vec{\mathbf{u}} \mathcal{R}(\vec{\mathbf{u}}) = O(1). \quad (76)$$

The length scale ℓ in (73) is the correlation length, the typical size of the inhomogeneities, and $\sigma \ll 1$ models the amplitude of the weak fluctuations of $c(\vec{x})$. The fluctuations are isotropic, so the correlation length is the same in all directions, and the covariance depends on the Euclidian norm of its argument $\mathcal{R}(\vec{u}) = \mathcal{R}(|\vec{u}|)$. Any covariance will do, but to simplify the calculation of the statistical moments of the Green's function we take the Gaussian covariance

$$\mathcal{R}(|\vec{u}|) = e^{-\frac{|\vec{u}|^2}{2}}. \quad (77)$$

In the random travel time model the Green's function is approximated by

$$\hat{G}(\omega, \vec{x}_r, \vec{y}) \approx \frac{e^{i\omega[\tau_o(\vec{x}_r, \vec{y}) + v_\tau(\vec{x}_r, \vec{y})]}}{4\pi |\vec{x}_r - \vec{y}|}, \quad (78)$$

with reference travel time τ_o given by (63) perturbed by the random process $v_\tau(\vec{x}_r, \vec{y})$ obtained by integrating μ along the straight ray from \vec{y} to \vec{x}_r ,

$$v_\tau(\vec{x}_r, \vec{y}) = \frac{\sigma |\vec{x}_r - \vec{y}|}{2c_o} \int_0^1 dt \mu \left(\frac{(1-t)\vec{y}}{\ell} + \frac{t\vec{x}_r}{\ell} \right). \quad (79)$$

We refer to [28] for the derivation of the model, which holds in the asymptotic regime with separation of scales defined by

$$\lambda \ll \ell \lesssim L, \quad (80)$$

and

$$\sigma \ll \min \left\{ \frac{\sqrt{\ell\lambda}}{L}, \left(\frac{\ell}{L} \right)^{\frac{3}{2}} \right\}. \quad (81)$$

The high frequency assumption (80) is natural for the geometrical optics approximation. Assumption (81) guarantees that ray bending is negligible from the source to the array, and the geometrical spreading factor (the amplitude of the Green's function) is approximately the same as in the homogeneous medium. It also gives that the travel time $\tau(\vec{x}_r, \vec{y})$, the solution of the eikonal equation in the random medium, is given by

$$\tau(\vec{x}_r, \vec{y}) = \tau_o(\vec{x}_r, \vec{y}) + v_\tau(\vec{x}_r, \vec{y}) + \delta\tau, \quad (82)$$

with negligible remainder $\delta\tau$ satisfying $|\omega \delta\tau| \ll 1$.

Remark 1. Referring to the traces displayed in Fig. 6, the random travel time model coupled with the Born approximation describes the echoes from the reflectors, but not the many arrivals that occur before and after them. These arrivals are incoherent

waves that do not contribute to the resolution analysis of coherent imaging methods, as long as they do not dominate the coherent arrivals. Imaging does not work when the incoherent echoes dominate unless we filter them out as explained for example in [1, 2, 10, 13].

Long Range Scaling and Gaussian Statistics

We rewrite (79) as

$$\nu_\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) = \frac{(2\pi)^{1/4}\sigma\sqrt{\mathcal{L}\ell}}{2c_o} \nu(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}), \quad (83)$$

in terms of the random process

$$\nu(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) = \frac{1}{(2\pi)^{1/4}\sqrt{\ell/\mathcal{L}}} \int_0^1 dt \mu \left(\frac{\vec{\mathbf{y}}}{\ell} + \frac{t\vec{\mathbf{n}}}{\ell/\mathcal{L}} \right), \quad (84)$$

where $\mathcal{L} = |\vec{\mathbf{x}}_r - \vec{\mathbf{y}}|$ and $\vec{\mathbf{n}} = \frac{\vec{\mathbf{x}}_r - \vec{\mathbf{y}}}{\mathcal{L}}$ is the unit vector from the point $\vec{\mathbf{y}}$ in the source to the receiver at $\vec{\mathbf{x}}_r$. The normalization by $(2\pi)^{1/4}$ is convenient in the calculation of the statistical moments of the Green's function, for the choice (77) of the covariance of the fluctuations.

We are interested in a long range regime where the waves interact with many inhomogeneities as they travel from the source to the array

$$\ell \ll \mathcal{L} = O(L), \quad (85)$$

and the random phase in (78) is large. We know from the central limit theorem that as $\mathcal{L}/\ell \rightarrow \infty$, the right-hand side in (84) converges in distribution to a Gaussian process. Thus, the long range assumption (85) allows us to approximate $\nu(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})$ by a Gaussian process, with mean zero and covariance calculated in Appendix 1,

$$\mathbb{E}[\nu(\vec{\mathbf{x}}, \vec{\mathbf{y}})\nu(\vec{\mathbf{x}}', \vec{\mathbf{y}}')] \approx \int_{-\infty}^{\infty} \frac{d\tilde{t}}{\sqrt{2\pi}} \int_0^1 dt \mathcal{R} \left[\tilde{t} \vec{\mathbf{n}} + \frac{(1-t)(\vec{\mathbf{y}}' - \vec{\mathbf{y}}) + t(\vec{\mathbf{x}}' - \vec{\mathbf{x}})}{\ell} \right]. \quad (86)$$

Moreover, we can estimate the magnitude of the random phase in (78) by

$$\omega\nu_\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) = O\left(\frac{\sigma\sqrt{L\ell}}{\lambda}\right), \quad (87)$$

and ask that it be large

$$\frac{\sigma\sqrt{L\ell}}{\lambda} \gg 1, \quad (88)$$

so that the random medium has a significant effect on the wavefront, and imaging becomes difficult.

When we compare the two assumptions (81) and (88) on σ , we see that they are consistent if $\ell \gg \sqrt{\mathcal{L}\lambda}$ because then we have

$$\frac{\lambda}{\sqrt{L\ell}} \ll \min \left\{ \frac{\sqrt{\lambda\ell}}{L}, \left(\frac{\ell}{L} \right)^{\frac{3}{2}} \right\} = \frac{\sqrt{\lambda\ell}}{L}.$$

Therefore, our regime is defined by the length scale separation

$$\sqrt{\lambda L} \ll \ell \ll L, \quad (89)$$

and the amplitude σ of the fluctuations satisfying

$$\frac{\lambda}{\sqrt{L\ell}} \ll \sigma \ll \frac{\sqrt{\lambda\ell}}{L}. \quad (90)$$

Statistical Moments

Since v_τ is approximately Gaussian, we can estimate the moments of the Green's function in terms of the covariance (86). The calculations simplify for the Gaussian covariance (77), where (86) becomes

$$\mathbb{E} [v(\vec{x}, \vec{y}) v(\vec{x}', \vec{y}')] \approx \int_0^1 dt e^{-\frac{|t(\mathbf{x}' - \mathbf{x})_\perp + (1-t)(\mathbf{y}' - \mathbf{y})_\perp|^2}{2\ell^2}} \approx \int_0^1 dt e^{-\frac{|t(\mathbf{x}' - \mathbf{x}) + (1-t)(\mathbf{y}' - \mathbf{y})|^2}{2\ell^2}}. \quad (91)$$

This follows by direct integration over \tilde{t} in (86), where $(\mathbf{x}' - \mathbf{x})_\perp$ and $(\mathbf{y}' - \mathbf{y})_\perp$ are the projection of the vectors $\vec{x} - \vec{x}'$ and $\vec{y}' - \vec{y}$ on the plane orthogonal to the ray direction \vec{n} . The second approximation in (91) replaces these projections by the cross-range components of $\vec{x} - \vec{x}'$ and $\vec{y}' - \vec{y}$, and holds under the following scaling assumptions on the array aperture and support of the source

$$\frac{|(\vec{x}' - \vec{x}) \cdot \vec{n}|}{\ell} = \frac{|\mathbf{x}' - \mathbf{x}|}{\ell} \sin \theta = O\left(\frac{a^2}{\ell L}\right) \ll 1, \quad (92)$$

$$\frac{|\mathbf{y}' - \mathbf{y}|}{\ell} \sin \theta \approx \frac{|\mathbf{y}' - \mathbf{y}|}{\ell} \frac{a}{L} \ll 1, \quad \frac{|\eta - \eta'|}{\ell} \cos \theta \approx \frac{|\eta' - \eta|}{\ell} \ll 1. \quad (93)$$

Loss of Coherence

Using (91) in the formula

$$\mathbb{E} \left[e^{i\omega v_\tau(\vec{x}, \vec{y})} \right] \approx e^{-\frac{\omega^2}{2} \mathbb{E}[v_\tau^2(\vec{x}, \vec{y})]}, \quad (94)$$

which is approximate because ν_τ is only approximately Gaussian, we obtain that

$$\mathbb{E} \left[\hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \right] \approx \hat{G}_o(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) e^{-\frac{\mathcal{L}}{\mathcal{S}(\omega)}}, \quad (95)$$

where $\hat{G}_o(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) = \frac{e^{ik\mathcal{L}}}{4\pi\mathcal{L}}$ is the Green's function in the homogeneous medium and

$$\mathcal{S}(\omega) = \frac{4}{\sqrt{2\pi} k^2 \sigma^2 \ell}, \quad k = \frac{\omega}{c_o}. \quad (96)$$

This result shows that the coherent part of \hat{G} , its expectation, is smaller than \hat{G}_o . In fact, it is much smaller under our scaling assumption (90), which gives

$$\frac{\mathcal{L}}{\mathcal{S}(\omega)} = O \left(\frac{\sigma^2 \ell L}{\lambda^2} \right) \gg 1. \quad (97)$$

Since

$$\mathbb{E} \left[|\hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}})|^2 \right] = |\hat{G}_o(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}})|^2 = \frac{1}{(4\pi\mathcal{L})^2}, \quad (98)$$

we see that the standard deviation of the field dominates its mean

$$\sqrt{\mathbb{E} \left[|\hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}})|^2 \right] - \left| \mathbb{E} \left[\hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \right] \right|^2} \approx \left| \hat{G}_o(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \right| \gg \left| \mathbb{E} \left[\hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \right] \right|. \quad (99)$$

That is to say, the random phase causes large random fluctuations of \hat{G} .

The wave emitted from $\vec{\mathbf{y}}$ and recorded at $\vec{\mathbf{x}}_r$ is given by the Fourier synthesis

$$p(t, \vec{\mathbf{x}}_r; \vec{\mathbf{y}}) = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \hat{f}(\omega) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) e^{-i\omega t} \approx \frac{f \left[t - \tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) - \nu_\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \right]}{4\pi L}. \quad (100)$$

It is similar to the wave recorded in the homogeneous medium, but the arrival time of the pulse f fluctuates as described by the process ν_τ . When we take the expectation of (100) we calculate the envelope of the pulses in (100), and obtain a deformed and damped signal centered at time $\tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})$. Indeed, Eqs. (95) and (100) give that

$$\mathbb{E} \left[p(t, \vec{\mathbf{x}}_r; \vec{\mathbf{y}}) \right] \approx \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \frac{\hat{f}(\omega)}{4\pi\mathcal{L}} e^{-\frac{\omega^2}{2\Omega^2} - i\omega [t - \tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})]} = \frac{f_\Omega \left[t - \tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \right]}{4\pi\mathcal{L}}, \quad (101)$$

where we defined the deformed and damped pulse

$$f_\Omega(t) = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \hat{f}(\omega) e^{-\frac{\omega^2}{2\Omega^2} - i\omega t} = \sqrt{2\pi} f(t) \star_t e^{-\frac{\Omega^2 t^2}{2}}, \quad (102)$$

and let

$$\Omega^2 = \frac{4c_o^2}{\sqrt{2\pi}\sigma^2\ell L} \approx \frac{\omega^2\mathcal{S}(\omega)}{\mathcal{L}} \ll \omega^2. \quad (103)$$

For example, when the emitted pulse is the Gaussian

$$f(t) = e^{-i\omega_o t} e^{-\frac{B^2 t^2}{2}}, \quad \hat{f}(\omega) = \frac{\sqrt{2\pi}}{B} e^{-\frac{(\omega-\omega_o)^2}{2B^2}}, \quad (104)$$

the pulse f_Ω takes the form

$$f_\Omega(t) = \frac{\Omega}{\sqrt{\Omega^2 + B^2}} \exp\left[-i\left(\frac{\Omega^2}{B^2 + \Omega^2}\right)\omega_o t - \frac{B^2\Omega^2 t^2}{2(\Omega^2 + B^2)} - \frac{\omega_o^2}{2(\Omega^2 + B^2)}\right]. \quad (105)$$

Its central frequency is shifted to the lower value

$$\left(\frac{\Omega^2}{B^2 + \Omega^2}\right)\omega_o < \omega_o,$$

its essential support is wider by a factor of $\sqrt{1 + B^2/\Omega^2}$ than that of $f(t)$, and the amplitude of the peak is smaller

$$f_\Omega(0) = \frac{\Omega}{\sqrt{\Omega^2 + B^2}} e^{-\frac{\omega_o^2}{2(\Omega^2 + B^2)}} \ll f(0) = 1.$$

Remark 2. Formula (95) and the subsequent discussion on pulse deformation capture the loss of coherence effects derived from more sophisticated models. The loss of coherence manifests as an exponential decay of the mean wave field with the distance \mathcal{L} of propagation. The length scale $\mathcal{S}(\omega)$ of decay is the scattering mean-free path and it depends on the frequency and the second-order statistics (the covariance) of the fluctuations μ . The latter appears in the expression (96) of \mathcal{S} as the product $\sigma^2\ell$ in the denominator.

Statistical Decorrelation of the Waves

The second moments of the Green's function are given by

$$\mathbb{E}\left[\hat{G}(\omega, \vec{x}, \vec{y})\overline{\hat{G}}(\omega', \vec{x}', \vec{y}')\right] \approx \hat{G}_o(\omega, \vec{x}, \vec{y})\overline{\hat{G}_o}(\omega', \vec{x}', \vec{y}')e^{-\frac{1}{2}\mathbb{E}\left[(\omega v_\tau(\vec{x}, \vec{y}) - \omega' v_\tau(\vec{x}', \vec{y}'))^2\right]}, \quad (106)$$

where we used again that v_τ is approximately Gaussian. The expectation in the exponent follows from definition (83) and the expression (91) of the covariance of v ,

$$e^{-\frac{1}{2}\mathbb{E}[(\omega v_\tau(\vec{x}, \vec{y}) - \omega' v_\tau(\vec{x}', \vec{y}'))^2]} \approx e^{-\frac{(\omega - \omega')^2}{2\Omega^2} - \frac{\omega\omega'}{\Omega^2} \left[1 - \int_0^1 dt e^{-\frac{|t(\mathbf{x}-\mathbf{x}') + (1-t)(\mathbf{y}-\mathbf{y}')|^2}{2\ell^2}} \right]}. \quad (107)$$

The term in the square parenthesis is non-negative, and recalling the scaling relation (103), we note that the moments are essentially zero when $|\mathbf{x} - \mathbf{x}'|$ and/or $|\mathbf{y} - \mathbf{y}'|$ are larger or equal to ℓ . Indeed, the parenthesis in the exponent in the right-hand side of (107) is order one in this case and

$$e^{-\frac{1}{2}\mathbb{E}[(\omega v_\tau(\vec{x}, \vec{y}) - \omega' v_\tau(\vec{x}', \vec{y}'))^2]} = O\left(e^{-\frac{\omega_0^2}{\Omega^2}}\right) \ll 1.$$

When the cross-range offsets are smaller than the correlation length ℓ , we can simplify the expression (107) using the series expansion of the exponential in the square bracket, and obtain that

$$\mathbb{E}\left[\hat{G}(\omega, \vec{x}, \vec{y})\overline{\hat{G}}(\omega', \vec{x}', \vec{y}')\right] \approx \hat{G}_o(\omega, \vec{x}, \vec{y})\overline{\hat{G}_o}(\omega', \vec{x}', \vec{y}') \quad (108)$$

$$e^{-\frac{(\omega - \omega')^2}{2\Omega^2} - \frac{|\mathbf{x}-\mathbf{x}'|^2 + (\mathbf{x}-\mathbf{x}') \cdot (\mathbf{y}-\mathbf{y}') + |\mathbf{y}-\mathbf{y}'|^2}{2X^2(\bar{\omega})}}.$$

Here $\bar{\omega} = (\omega + \omega')/2$ is the central frequency and

$$X(\bar{\omega}) = \frac{\sqrt{3}\Omega}{\bar{\omega}}\ell. \quad (109)$$

In the derivation of (109) we used that $\Omega \ll \bar{\omega}$, as stated by the scaling relation (103). The result says that the moments decay exponentially with the cross-range offsets, on the scale $X(\bar{\omega}) \ll \ell$, which is consistent with the assumption $|\mathbf{x} - \mathbf{x}'|, |\mathbf{y} - \mathbf{y}'| \ll \ell$ used in the derivation. For larger cross-range offsets, the moments are exponentially small, as noted above. This is precisely what (109) gives, so we can use the result for all cross-range offsets, with negligible errors in the analysis of imaging in the following sections.

It is clear that the maximum of (109) occurs at the same frequency $\omega' = \omega$ and the same points in the cross-range plane $\mathbf{x}' = \mathbf{x}$ and $\mathbf{y}' = \mathbf{y}$. The decay of the moments with the frequency and cross-range offsets describes the statistical decorrelation of the waves. Indeed, the correlation coefficient is defined by

$$\text{Corr}\left[\hat{G}(\omega, \vec{x}, \vec{y}), \hat{G}(\omega', \vec{x}', \vec{y}')\right] =$$

$$\frac{\mathbb{E}\left[\hat{G}(\omega, \vec{x}, \vec{y})\overline{\hat{G}}(\omega', \vec{x}', \vec{y}')\right] - \mathbb{E}\left[\hat{G}(\omega, \vec{x}, \vec{y})\right]\mathbb{E}\left[\overline{\hat{G}}(\omega', \vec{x}', \vec{y}')\right]}{\sqrt{\text{Var}\left[\hat{G}(\omega, \vec{x}, \vec{y})\right]\text{Var}\left[\overline{\hat{G}}(\omega', \vec{x}', \vec{y}')\right]}},$$

with variance estimated in (99). Recalling from (95) that the mean field is exponentially small, we estimate the correlation as

$$\left| \text{Corr} \left[\hat{G}(\omega, \vec{\mathbf{x}}, \vec{\mathbf{y}}), \hat{G}(\omega', \vec{\mathbf{x}}', \vec{\mathbf{y}}') \right] \right| \approx e^{-\frac{(\omega-\omega')^2}{2\Omega^2} - \frac{|\mathbf{x}-\mathbf{x}'|^2 + (\mathbf{x}-\mathbf{x}') \cdot (\mathbf{y}-\mathbf{y}') + |\mathbf{y}-\mathbf{y}'|^2}{2X^2(\bar{\omega})}}. \quad (110)$$

It decays with the frequency offset on the scale Ω , called the *decoherence frequency*, and with the cross-range offsets on the length scale X , called the *decorrelation length*. This scale is proportional to the wavelength, as stated in (109).

Remark 3. The expression of the moments in (109) is the same as that derived from more sophisticated models of cumulative scattering effects in random media. The detailed expressions of the decoherence frequency and decorrelation length change with the model, but Eq. (109) captures the canonical form of the second moments, and thus of the statistical decorrelation of the waves.

6 Setup for Imaging

We consider the setup for imaging with passive arrays illustrated in Fig. 7, with the range axis originating from the center of the source and the array of aperture \mathcal{A} orthogonal to it. For active arrays, the excitation comes from a source in \mathcal{A} and ρ is the reflectivity that we wish to estimate. In either case the array is assumed planar and square, with side length a satisfying the scaling relation (92). We let a be larger or similar to the correlation length, so that the Fresnel number Φ_a satisfies

$$\Phi_a = \frac{a^2}{\lambda L} \gtrsim \frac{\ell^2}{\lambda L} \gg 1. \quad (111)$$

The waves are approximately planar in regimes with smaller Fresnel number and we cannot estimate the cross-range location of the support of ρ .

We restrict the analysis to a paraxial regime, where we can write

$$\omega \tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) = k \sqrt{(L-\eta)^2 + |\mathbf{x}_r - \mathbf{y}|^2} \approx k \left[L - \eta + \frac{|\mathbf{x}_r|^2}{2L} - \frac{\mathbf{x}_r \cdot \mathbf{y}}{L} \right]. \quad (112)$$

This holds for apertures satisfying $\frac{a^4}{\lambda L^3} \ll 1$, and supports of ρ of radius R in cross-range and R_η in range, satisfying $\frac{R^2}{\lambda L} \ll 1$ and $R_\eta \ll \frac{L^2 \lambda}{a^2}$. Merging all our assumptions on a , we obtain that

$$\sqrt{\lambda L} \ll a \ll \min \left\{ \sqrt{\ell L}, (\lambda L^3)^{1/4} \right\} = (\lambda L^3)^{1/4}, \quad (113)$$

where the last equality holds in our regime defined by (89) because

$$\frac{\sqrt{\ell L}}{(\lambda L^3)^{1/4}} = \left(\frac{\ell}{\sqrt{\lambda L}} \right)^{1/2} \gg 1.$$

The summary of the assumptions on the cross-range support of ρ is

$$R \ll \min \left\{ \sqrt{\lambda L}, \frac{\ell L}{a} \right\} = \sqrt{\lambda L}, \quad (114)$$

where we recalled (93) and used that

$$\frac{\ell L}{a \sqrt{\lambda L}} = \frac{\ell}{\sqrt{\lambda L}} \frac{L}{a} \gg 1.$$

The range support of ρ satisfies

$$R_\eta \ll \min \left\{ \ell, \frac{L^2 \lambda}{a^2} \right\}. \quad (115)$$

We take the complex-valued Gaussian pulse (104) for the sake of explicit calculations. Its bandwidth B satisfies

$$\frac{c_o}{L} \ll B \ll \omega_o. \quad (116)$$

The first inequality ensures that $f(t)$ is a pulse of small temporal support, so we can determine the travel times $\tau_o(\vec{x}_r, \vec{y}) = O(L/c_o)$ from the measurements of the acoustic pressure $p(t, \vec{x}_r)$ at the array. The second inequality means that all the frequencies in the bandwidth are of the order ω_o and therefore the wavelengths satisfy $\lambda \approx \lambda_o$. The decoherence frequency and decorrelation length defined in Sect. 5 obey the scaling relations

$$\Omega \ll \omega_o, \quad X(\omega) \approx X(\omega_o) \ll \ell \lesssim a. \quad (117)$$

To simplify the analysis of the CINT imaging function in Sect. 8, we assume in addition that the decorrelation length satisfies

$$X(\omega_o) \ll \sqrt{\lambda_o L}. \quad (118)$$

Using the definition (109) of $X(\omega_o)$, we see that this is equivalent to asking that

$$\Omega \ll \omega_o \frac{\sqrt{\lambda_o L}}{\ell} \ll \omega_o, \quad (119)$$

where the second inequality is implied by (89).

We analyze in Sects. 7 and 8 the imaging function $\mathcal{J}(\vec{\mathbf{y}}^s)$ of two methods: Kirchhoff migration and coherent interferometry. We use the same symbol for the imaging functions to simplify the notation, and define $\mathcal{J}(\vec{\mathbf{y}}^s)$ at points $\vec{\mathbf{y}}^s$ in a search domain that contains the support of the source. The size of this domain is chosen, so that we can use the paraxial approximation (112) for the travel time $\tau_o(\vec{\mathbf{x}}, \vec{\mathbf{y}}^s)$. We use for convenience the continuum aperture approximation, which is based on the assumption that the sensors in the array are close together. The approximation amounts to replacing sums over the sensors by scaled integrals over the aperture \mathcal{A} . The scaling factor is $N/|\mathcal{A}|$, with N the number of sensors and $|\mathcal{A}| = a^2$ the area of the aperture.

The resolution analysis of the imaging function $\mathcal{J}(\vec{\mathbf{y}}^s)$ involves two steps: In the first step we study the focusing of its expectation. Since the imaging process occurs in one medium, corresponding to one realization of the random process μ , we do not have access to $\mathbb{E}[\mathcal{J}(\vec{\mathbf{y}}^s)]$. But if the imaging were robust, the result would look almost the same independent of the realization, so $\mathcal{J}(\vec{\mathbf{y}}^s)$ would be close to its expectation, which is why we study it. The second step of the resolution analysis is the assessment of the statistical stability of $\mathcal{J}(\vec{\mathbf{y}}^s)$. It amounts to calculating the SNR of the image at its peaks.

Most of our discussion is about imaging with passive arrays. The extension to active arrays is straightforward for our random travel time model combined with the Born approximation.

7 Migration Imaging

In this section we analyze migration imaging with passive arrays. We consider only the Kirchhoff migration imaging function because it is essentially the same as reverse time migration in the paraxial regime described in Sect. 6. It is given by

$$\mathcal{J}(\vec{\mathbf{y}}^s) = \sum_{r=1}^N p(\tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s), \vec{\mathbf{x}}_r) \approx \frac{N}{|\mathcal{A}|} \int_{\mathcal{A}} d\mathbf{x} p(\tau_o(\vec{\mathbf{x}}, \vec{\mathbf{y}}^s), \vec{\mathbf{x}}), \quad \vec{\mathbf{x}} = (\mathbf{x}, L), \quad (120)$$

where $p(t, \vec{\mathbf{x}})$ is the pressure field modeled by

$$p(t, \vec{\mathbf{x}}) = \int_{\mathbb{R}^3} d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) p(t, \vec{\mathbf{x}}; \vec{\mathbf{y}}), \quad (121)$$

in terms of the spatial source density $\rho(\vec{\mathbf{y}})$ and the field $p(t, \vec{\mathbf{x}}; \vec{\mathbf{y}})$ due to a point source at $\vec{\mathbf{y}}$. The latter is defined in (100), and we rewrite it here using the simplification of the Green's function

$$\hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \approx \frac{e^{i\omega[\tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) + v_t(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})]}}{4\pi L} \approx \frac{1}{4\pi L} e^{ik(L - \eta + \frac{|\mathbf{x}_r|^2}{2L} - \frac{\mathbf{x}_r \cdot \mathbf{x}}{L}) + i\omega v_t(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})}, \quad (122)$$

that holds under the scaling assumptions (113) and (114). The wave field due to the point source is given by

$$\begin{aligned} p(t, \vec{x}; \vec{y}) &\approx \int_{-\infty}^{\infty} d\omega \frac{\hat{f}(\omega)}{8\pi^2 L} e^{i\omega[\tau_o(\vec{x}, \vec{y}) - t] + i\omega v_t(\vec{x}, \vec{y})} \approx \\ &\int_{-\infty}^{\infty} d\omega \frac{\hat{f}(\omega)}{8\pi^2 L} e^{ik(L - \eta + \frac{|\mathbf{x}_t|^2}{2L} - \frac{\mathbf{x}_t \cdot \mathbf{y}}{L}) + i\omega v_t(\vec{x}, \vec{y}) - i\omega t}. \end{aligned} \quad (123)$$

The Expectation

Taking the expectation in (120) and using (121), we obtain that

$$\mathbb{E} [\mathcal{J}(\vec{y}^s)] = \int_{\mathbb{R}^3} d\vec{y} \rho(\vec{y}) \mathbb{E} [\mathcal{J}(\vec{y}^s; \vec{y})], \quad (124)$$

with mean point spread function

$$\mathbb{E} [\mathcal{J}(\vec{y}^s; \vec{y})] \approx \frac{N}{|\mathcal{A}|} \int_{\mathcal{A}} d\mathbf{x} \mathbb{E} [p(\tau_o(\vec{x}, \vec{y}^s), \vec{x}, \vec{y})]. \quad (125)$$

The expectation of p is given by (101), and using the approximation (112) of the travel time we write

$$\tau_o(\vec{x}, \vec{y}^s) - \tau_o(\vec{x}, \vec{y}) \approx \frac{1}{c_o} \left[\eta^s - \eta + \frac{(\mathbf{y}^s - \mathbf{y}) \cdot \mathbf{x}}{L} \right], \quad (126)$$

for $\vec{y}^s = (\mathbf{y}^s, \eta^s)$. Equation (125) becomes

$$\begin{aligned} \mathbb{E} [\mathcal{J}(\vec{y}^s; \vec{y})] &\approx \frac{N e^{-\frac{\omega_o^2}{2(B^2 + \Omega^2)}}}{4\pi L \sqrt{B^2/\Omega^2 + 1}} \\ &\int_{\mathcal{A}} \frac{d\mathbf{x}}{|\mathcal{A}|} e^{-\frac{i[k_o(\eta^s - \eta) + \frac{k_o(\mathbf{y}^s - \mathbf{y}) \cdot \mathbf{x}}{L}]}{(B^2/\Omega^2 + 1)} - \frac{B^2[(\eta^s - \eta) + \frac{(\mathbf{y}^s - \mathbf{y}) \cdot \mathbf{x}}{L}]^2}{2c_o^2(B^2/\Omega^2 + 1)}}, \end{aligned} \quad (127)$$

where $k_o = \omega_o/c_o$ is the central wave number, and it is not difficult to see that the mean point spread function peaks at $\vec{y} = (\mathbf{y}, \eta)$, as it should.

To determine the range resolution, we evaluate (127) at $\mathbf{y}^s = \mathbf{y}$

$$\mathbb{E} [\mathcal{J}(\vec{y}^s = (\mathbf{y}, \eta^s); \vec{y})] \approx \frac{N e^{-\frac{\omega_o^2}{2(B^2 + \Omega^2)}}}{4\pi L \sqrt{B^2/\Omega^2 + 1}} e^{-\frac{ik_o(\eta^s - \eta)}{(B^2/\Omega^2 + 1)} - \frac{B^2(\eta^s - \eta)^2}{2c_o^2(B^2/\Omega^2 + 1)}}, \quad (128)$$

and estimate the range resolution in terms of the standard deviation of the Gaussian

$$|\eta^s - \eta| \lesssim \frac{c_o}{B} \sqrt{B^2/\Omega^2 + 1}. \quad (129)$$

The result in the homogeneous medium corresponds to letting $\Omega \rightarrow \infty$ in this equation, in which case the range resolution would be c_o/B , as stated in section “Imaging in Smooth and Known Media.” In our regime the resolution is worse due to the broadening of the pulse f_Ω noted in section “Statistical Moments.”

The cross-range resolution is estimated from

$$\begin{aligned} \mathbb{E} [\mathcal{J}(\vec{\mathbf{y}}^s = (\mathbf{y}^s, \eta); \vec{\mathbf{y}})] &\approx \frac{N e^{-\frac{\omega_o^2}{2(B^2/\Omega^2+1)}}}{4\pi L \sqrt{B^2/\Omega^2 + 1}} \int_{\mathcal{A}} \frac{d\mathbf{x}}{|\mathcal{A}|} e^{-\frac{i k_o (\mathbf{y}^s - \mathbf{y}) \cdot \mathbf{x}/L}{(B^2/\Omega^2+1)} - \frac{B^2 [k_o (\mathbf{y}^s - \mathbf{y}) \cdot \mathbf{x}/L]^2}{2\omega_o^2 (B^2/\Omega^2+1)}} \\ &\approx \frac{N e^{-\frac{\omega_o^2}{2(B^2+\Omega^2)}}}{4\pi L \sqrt{B^2/\Omega^2 + 1}} \int_{\mathcal{A}} \frac{d\mathbf{x}}{|\mathcal{A}|} e^{-\frac{i k_o (\mathbf{y}^s - \mathbf{y}) \cdot \mathbf{x}/L}{(B^2/\Omega^2+1)}} \\ &= \frac{N e^{-\frac{\omega_o^2}{2(B^2+\Omega^2)}}}{4\pi L \sqrt{B^2/\Omega^2 + 1}} \prod_{j=1}^2 \text{sinc} \left[\frac{k_o a (\mathbf{y}^s - \mathbf{y}) \cdot \mathbf{e}_j}{2L(B^2/\Omega^2 + 1)} \right]. \end{aligned} \quad (130)$$

The first approximation holds because B and Ω are much smaller than ω_o , and the third line follows by integration over the square aperture \mathcal{A} . We estimate the cross-range resolution by the support of the main peak of the sinc function

$$|(\mathbf{y}^s - \mathbf{y}) \cdot \mathbf{e}_j| \lesssim \frac{\lambda_o L}{a} \left(\frac{B^2}{\Omega^2} + 1 \right). \quad (131)$$

It is worse than that in the homogeneous medium of $\lambda_o L/a$ because of the shift of the central frequency of the deformed pulse $f_\Omega(t)$ to a lower value, as noted in section “Statistical Moments.”

The value of the mean point spread function at the peak is given by

$$\mathbb{E} [\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})] \approx \frac{N e^{-\frac{\omega_o^2}{2(B^2+\Omega^2)}}}{4\pi L \sqrt{B^2/\Omega^2 + 1}} \ll \mathcal{J}_o(\vec{\mathbf{y}}; \vec{\mathbf{y}}) = \frac{N}{4\pi L}. \quad (132)$$

It is much smaller than $\mathcal{J}_o(\vec{\mathbf{y}}; \vec{\mathbf{y}})$, the peak of the point spread function in the homogeneous medium. Finally, the mean imaging function (124) equals the unknown density ρ integrated against the blurring kernel (127).

The SNR

To simplify the calculations, we consider only the SNR of the point spread function $\mathcal{J}(\vec{\mathbf{y}}^s; \vec{\mathbf{y}})$ evaluated at the peak $\vec{\mathbf{y}}^s = \vec{\mathbf{y}}$. We have

$$\begin{aligned} \mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}}) &\approx N \int_{\mathcal{A}} \frac{d\mathbf{x}}{|\mathcal{A}|} p(\tau_o(\vec{\mathbf{x}}, \vec{\mathbf{y}}), \vec{\mathbf{x}}; \vec{\mathbf{y}}) \approx \frac{N \sqrt{2\pi}}{8\pi^2 L B |\mathcal{A}|} \int_{\mathcal{A}} d\mathbf{x} \\ &\quad \int_{-\infty}^{\infty} d\omega e^{-\frac{(\omega-\omega_o)^2}{2B^2} + i\omega v_\tau(\vec{\mathbf{x}}, \vec{\mathbf{y}})}, \end{aligned} \quad (133)$$

where we used Eqs. (100) and (122) and the Gaussian pulse (104). The mean square follows from (109)

$$\begin{aligned} \mathbb{E}[|\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})|^2] &\approx \frac{N^2}{32\pi^3 L^2 B^2 |\mathcal{A}|^2} \iint_{\mathcal{A}} d\mathbf{x} d\mathbf{x}' \\ &\quad \iint_{-\infty}^{\infty} d\omega d\omega' e^{-\frac{(\omega-\omega_o)^2}{2B^2} - \frac{(\omega'-\omega_o)^2}{2B^2} - \frac{(\omega-\omega')^2}{2\Omega^2} - \frac{|\mathbf{x}'-\mathbf{x}|^2}{2X^2(\omega_o)}}, \end{aligned}$$

and changing variables to

$$\bar{\omega} = \frac{\omega + \omega'}{2}, \quad \tilde{\omega} = \omega - \omega' \quad \text{and} \quad \tilde{\mathbf{x}} = \frac{\mathbf{x} + \mathbf{x}'}{2}, \quad \tilde{\mathbf{x}} = \mathbf{x} - \mathbf{x}',$$

we obtain

$$\begin{aligned} \mathbb{E}[|\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})|^2] &\approx \frac{N^2}{32\pi^3 L^2 B |\mathcal{A}|} \int_{R^2} d\tilde{\mathbf{x}} e^{-\frac{|\tilde{\mathbf{x}}|^2}{2X^2(\omega_o)}} \int_{-\infty}^{\infty} \frac{d\bar{\omega}}{B} e^{-\frac{(\bar{\omega}-\omega_o)^2}{B^2}} \\ &\quad \int_{-\infty}^{\infty} d\tilde{\omega} e^{-\frac{\tilde{\omega}^2}{2} \left(\frac{1}{\Omega^2} + \frac{1}{2B^2} \right)} = \frac{N^2 X^2}{8\pi L^2 |\mathcal{A}| \sqrt{2B^2/\Omega^2 + 1}}. \end{aligned} \quad (134)$$

In the first line of this equation we integrated over $\tilde{\mathbf{x}}$ and used the scaling assumption (117) on the decorrelation length X to extend the integral over $\tilde{\mathbf{x}}$ to the whole plane. The second line follows by integrating the Gaussians in $\tilde{\mathbf{x}}$, $\bar{\omega}$ and $\tilde{\omega}$.

The variance of the point spread function at the peak is derived from (132) and (134)

$$\text{Var}[\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})] = \mathbb{E}[|\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})|^2] - |\mathbb{E}[\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})]|^2 \approx \frac{N^2 X^2}{8\pi L^2 |\mathcal{A}| \sqrt{2B^2/\Omega^2 + 1}}, \quad (135)$$

and the SNR is given by

$$\text{SNR} [\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})] = \frac{|\mathbb{E}[\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})]|}{\sqrt{\text{Var}[\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})]}} \approx \frac{1}{\sqrt{2\pi}} \frac{a}{X} \frac{(2B^2/\Omega^2 + 1)^{1/4}}{(B^2/\Omega^2 + 1)^{1/2}} e^{-\frac{\omega_o^2}{2(B^2 + \Omega^2)}}, \quad (136)$$

where we used that $|\mathcal{A}| = a^2$. Thus, we see that the SNR improves when we increase the aperture and the bandwidth. We restricted the bandwidth by $B \ll \omega_o$, so the exponentially small factor plays an important role in the SNR. The definition (109) of the decorrelation length gives that

$$\frac{a}{X} = O\left(\frac{a \omega_o}{\Omega \ell}\right)$$

and to achieve a large SNR we need

$$\frac{a}{\ell} \gg \frac{\Omega}{\omega_o} \exp\left[\frac{\omega_o^2}{2(B^2 + \Omega^2)}\right].$$

The first factor is small, but the exponential is huge and such large apertures cannot be realized in practice. Therefore, the SNR of the Kirchhoff migration function is small and that the imaging function is not robust.

8 CINT Imaging

The statistical instability of migration imaging is due to the large random phase $\omega v_\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})$ in the Green's function, so a natural idea for improving the imaging is to cancel the random phase by data processing. We could cancel the phase exactly by working with the intensities $|\hat{p}(\omega, \vec{\mathbf{x}}_r)|^2$ of the measurements, but this is not a good idea. To see why consider a point source at $\vec{\mathbf{y}}$, so that

$$\hat{p}(\omega, \vec{\mathbf{x}}_r) = \hat{p}(\omega, \vec{\mathbf{x}}_r; \vec{\mathbf{y}}) = \hat{f}(\omega) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}). \quad (137)$$

The intensity is

$$|\hat{p}(\omega, \vec{\mathbf{x}}_r; \vec{\mathbf{y}})|^2 = |\hat{f}(\omega)|^2 |\hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}})|^2 \approx \frac{|\hat{f}(\omega)|^2}{(4\pi|\vec{\mathbf{x}}_r - \vec{\mathbf{y}}|)^2} \approx \frac{|\hat{f}(\omega)|^2}{(4\pi L)^2}$$

and it is nearly impossible to estimate the location $\vec{\mathbf{y}}$ from it because it is approximately constant across the aperture. We need to keep the deterministic phase, the travel time $\tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})$, in order to estimate $\vec{\mathbf{y}}$. At the same, we should reduce the random phase $\omega v_\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}})$.

The CINT imaging approach accomplishes this by migrating to $\vec{\mathbf{y}}^s$ local cross-correlations of the data instead of the data themselves. The local cross-correlations

are defined by

$$\begin{aligned} \mathcal{C}(t, \tilde{t}; \vec{\mathbf{x}}, \vec{\mathbf{x}}') &= \int_{-\infty}^{\infty} ds \Omega \Phi[\Omega(t-s)] p(s + \tilde{t}/2, \vec{\mathbf{x}}) \bar{p}(s - \tilde{t}/2, \vec{\mathbf{x}}') \\ &= \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \int_{-\infty}^{\infty} \frac{d\tilde{\omega}}{2\pi} \hat{\Phi}\left(\frac{\tilde{\omega}}{\Omega}\right) \hat{p}(\omega + \tilde{\omega}/2, \vec{\mathbf{x}}) \bar{\hat{p}}(\omega - \tilde{\omega}/2, \vec{\mathbf{x}}') \\ &\quad e^{-i\tilde{\omega}t - i\omega\tilde{t}}. \end{aligned} \quad (138)$$

They are calculated around the time t , in a time window Φ of duration $1/\Omega$ determined by the decoherence frequency Ω with a purpose! To explain the advantage of working with the cross-correlations (138), we analyze them in section “Analysis of the Cross-Correlations for a Point Source” for the case of imaging a point source. Then we study in sections “Resolution Analysis of the CINT Imaging Function” and “CINT Images for Passive Arrays as the Smoothed Wigner Transform” the resolution of the CINT imaging method with passive arrays. It forms an image by migrating to search points $\vec{\mathbf{y}}^s$ in the imaging domain the cross-correlations (138). Explicitly, the imaging function is given by

$$\begin{aligned} \mathcal{J}(\vec{\mathbf{y}}^s) &= \sum_{r,r'=1}^N \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \int_{-\infty}^{\infty} \frac{d\tilde{\omega}}{2\pi} \Psi\left[\frac{\mathbf{x}_r - \mathbf{x}_{r'}}{X(\omega)}\right] \hat{\Phi}\left(\frac{\tilde{\omega}}{\Omega}\right) \hat{p}(\omega + \tilde{\omega}/2, \vec{\mathbf{x}}_r) \\ &\quad \bar{\hat{p}}(\omega - \tilde{\omega}/2, \vec{\mathbf{x}}_{r'}) \\ &\times e^{-i\tilde{\omega}\left[\frac{\tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) + \tau_o(\vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}}^s)}{2}\right] - i\omega[\tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) - \tau_o(\vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}}^s)]}, \end{aligned} \quad (139)$$

where Ψ is another window function that keeps the cross-range offsets $\mathbf{x}_r - \mathbf{x}_{r'}$ within the distance $X(\omega)$. As was the case with the time window above, the support $X(\omega)$ is chosen equal to the decorrelation length with a purpose. Recalling from (117) that in our scaling regime $X(\omega) \approx X(\omega_o)$ and using (138), we can approximate the CINT imaging function as

$$\mathcal{J}(\vec{\mathbf{y}}^s) \approx \sum_{r,r'=1}^N \Psi\left[\frac{\mathbf{x}_r - \mathbf{x}_{r'}}{X(\omega_o)}\right] \mathcal{C}(\bar{\tau}_o(\vec{\mathbf{x}}_r, \vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}}^s), \tilde{\tau}_o(\vec{\mathbf{x}}_r, \vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}}^s); \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_{r'}). \quad (140)$$

This is just the superposition of the migrated local cross-correlations (138) at nearby receivers. The migration amounts to evaluating the cross-correlations at the average and differences of the travel times from the receivers to the search point

$$\begin{aligned} t &= \bar{\tau}_o(\vec{\mathbf{x}}_r, \vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}}^s) = \frac{\tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) + \tau_o(\vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}}^s)}{2}, \\ \tilde{t} &= \tilde{\tau}_o(\vec{\mathbf{x}}_r, \vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}}^s) = \tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) - \tau_o(\vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}}^s). \end{aligned} \quad (141)$$

The resolution analysis below applies to any window functions, but for the sake of explicit and simpler formulas, we consider the Gaussian windows

$$\Phi(s) = e^{-s^2/2}, \quad \Psi(\mathbf{u}) = e^{-|\mathbf{u}|^2/2}. \quad (142)$$

Analysis of the Cross-Correlations for a Point Source

The model of the Fourier transform of the measurements is given by (137), with $\hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}})$ approximated by (122). Using a notation similar to (141) for the average and differences of the travel times, and the Gaussian pulse (104), we get

$$\begin{aligned} \mathcal{C}(t, \tilde{t}; \vec{\mathbf{x}}, \vec{\mathbf{x}}') &\approx \frac{1}{2\pi(4\pi L)^2 B^2} \int_{-\infty}^{\infty} d\omega e^{-\frac{(\omega-\omega_o)^2}{B^2}} \int_{-\infty}^{\infty} d\tilde{\omega} \hat{\Phi}\left(\frac{\tilde{\omega}}{\Omega}\right) e^{-\frac{\tilde{\omega}^2}{4B^2} + i\omega[\tilde{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}', \vec{\mathbf{y}}) - \tilde{t}]} \\ &\times e^{i\tilde{\omega}[\tilde{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}', \vec{\mathbf{y}}) - t] + i(\omega + \tilde{\omega}/2)v_t(\vec{\mathbf{x}}, \vec{\mathbf{y}}) - i(\omega - \tilde{\omega}/2)v_t(\vec{\mathbf{x}}', \vec{\mathbf{y}})}. \end{aligned} \quad (143)$$

We calculate first the coherent part of \mathcal{C} , its statistical expectation, to show that it peaks at times

$$t = \bar{\tau}_o(\vec{\mathbf{x}}_r, \vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}}) \quad \text{and} \quad \tilde{t} = \tilde{\tau}_o(\vec{\mathbf{x}}_r, \vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}}).$$

Then we estimate the SNR at the peak to assess its statistical stability with respect to the realizations of the random medium.

The expectation of (143) follows from (109)

$$\begin{aligned} \mathbb{E}[\mathcal{C}(t, \tilde{t}; \vec{\mathbf{x}}, \vec{\mathbf{x}}')] &\approx \frac{1}{2\pi(4\pi L)^2 B^2} e^{-\frac{|\mathbf{x}-\mathbf{x}'|^2}{2X^2(\omega_o)}} \int_{-\infty}^{\infty} d\omega e^{-\frac{(\omega-\omega_o)^2}{B^2} + i\omega[\tilde{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}', \vec{\mathbf{y}}) - \tilde{t}]} \\ &\int_{-\infty}^{\infty} d\tilde{\omega} \hat{\Phi}\left(\frac{\tilde{\omega}}{\Omega}\right) e^{-\frac{\tilde{\omega}^2}{2}\left(\frac{1}{\Omega^2} + \frac{1}{2B^2}\right) + i\tilde{\omega}[\tilde{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}', \vec{\mathbf{y}}) - t]}, \end{aligned} \quad (144)$$

where we approximated the decorrelation length by that at the central frequency ω_o , as stated in the scaling relation (117). Note that the essential support of $\tilde{\omega}$ in the second integral is limited to $|\tilde{\omega}| \lesssim \min\{\Omega, B\}$, because the pulse has finite bandwidth, and the waves decorrelate over frequency offsets that are larger than Ω . Thus, if we had a window Φ with Fourier transform supported over a larger frequency interval than Ω , it would make no difference in (144). However, we will see later that it will result in lower SNR, so we would lose in statistical stability. Could we take a smaller frequency support of $\hat{\Phi}$ than Ω ? Such a choice would reduce the variance of the fluctuations of \mathcal{C} , but it would broaden the peak along the t axis. This follows from the evaluation of the $\tilde{\omega}$ integral in (144). The optimal choice of the frequency support is the decoherence frequency Ω , as we take it in (144).

The Mean

Using the Gaussian window defined in (142), and integrating over ω and $\tilde{\omega}$ in (144), we obtain the following expression of the mean of the correlations

$$\begin{aligned} \mathbb{E} [\mathcal{C}(t, \tilde{t}; \vec{x}, \vec{x}')] &\approx \frac{\sqrt{2\pi} e^{-\frac{|\vec{x}-\vec{x}'|^2}{2X^2(\omega_0)}}}{(4\pi L)^2 \sqrt{4B^2/\Omega^2 + 1}} \\ &\quad e^{-i\omega_0 [\tilde{\tau}_o(\vec{x}, \vec{x}', \vec{y}) - \tilde{t}] - \frac{B^2[\tilde{\tau}_o(\vec{x}, \vec{x}', \vec{y}) - \tilde{t}]^2}{4} - \frac{B^2[\tilde{\tau}_o(\vec{x}, \vec{x}', \vec{y}) - \tilde{t}]^2}{(4B^2/\Omega^2 + 1)}}. \end{aligned} \quad (145)$$

They are indeed peaked at $t = \bar{\tau}_o(\vec{x}, \vec{x}', \vec{y})$ and $\tilde{t} = \tilde{\tau}_o(\vec{x}, \vec{x}', \vec{y})$. The width of the peak in \tilde{t} is inherited from the $O(1/B)$ support of the pulse. The width of the peak in t is $O(\sqrt{1/B^2 + 4/\Omega^2})$. It is similar to the width of the pulse $f(t)$ when the bandwidth satisfies $B \lesssim \Omega$, but it is much broader than $f(t)$ for larger bandwidths $B \gg \Omega$. The peak value of the mean is

$$\begin{aligned} \max_{t, \tilde{t}} \mathbb{E} [\mathcal{C}(t, \tilde{t}; \vec{x}, \vec{x}')] &= \mathbb{E} [\mathcal{C}(\bar{\tau}_o(\vec{x}, \vec{x}', \vec{y}), \tilde{\tau}_o(\vec{x}, \vec{x}', \vec{y}); \vec{x}, \vec{x}')] \\ &\approx \frac{\sqrt{2\pi} e^{-\frac{|\vec{x}-\vec{x}'|^2}{2X^2(\omega_0)}}}{(4\pi L)^2 \sqrt{4B^2/\Omega^2 + 1}}. \end{aligned} \quad (146)$$

It decays exponentially with the cross-range offset, which is why we restrict it with the window Ψ in the CINT function (140). This is essential for improving the SNR of the imaging function, as we show next.

The SNR

We assess the statistical stability of the peak of the cross-correlations by estimating the SNR, which is the ratio of (146) and the standard deviation of $\mathcal{C}(\bar{\tau}_o, \tilde{\tau}_o; \vec{x}, \vec{x}')$. We need the second moment

$$\begin{aligned} \mathbb{E} [\left| \mathcal{C}(\bar{\tau}_o(\vec{x}, \vec{x}', \vec{y}), \tilde{\tau}_o(\vec{x}, \vec{x}', \vec{y}); \vec{x}, \vec{x}') \right|^2] &= \frac{1}{(32\pi^3 L^2)^2 B^4} \iint_{-\infty}^{\infty} d\omega_1 d\omega_2 e^{-\frac{(\omega_1 - \omega_0)^2}{B^2} - \frac{(\omega_2 - \omega_0)^2}{B^2}} \iint_{-\infty}^{\infty} d\tilde{\omega}_1 d\tilde{\omega}_2 \\ &\times \hat{\Phi}\left(\frac{\tilde{\omega}_1}{\Omega_\phi}\right) \overline{\hat{\Phi}}\left(\frac{\tilde{\omega}_2}{\Omega_\phi}\right) e^{-\frac{\tilde{\omega}_1^2 + \tilde{\omega}_2^2}{4B^2}} \mathbb{E} \left[e^{i(\omega_1 - \omega_2 + \frac{\tilde{\omega}_1 - \tilde{\omega}_2}{2}) v_r(\vec{x}, \vec{y}) - i(\omega_1 - \omega_2 - \frac{\tilde{\omega}_1 - \tilde{\omega}_2}{2}) v_r(\vec{x}', \vec{y})} \right], \end{aligned} \quad (147)$$

where we let the support of the windows be Ω_ϕ , not necessarily the same as Ω , in order to demonstrate how it affects the SNR. The peak value of the mean for this choice is a slight modification of (146)

$$\mathbb{E} [\mathcal{C}(\bar{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}', \vec{\mathbf{y}}), \tilde{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}', \vec{\mathbf{y}}); \vec{\mathbf{x}}, \vec{\mathbf{x}}')] \approx \frac{\sqrt{2\pi} e^{-\frac{|\mathbf{x}-\mathbf{x}'|^2}{2X^2(\omega_o)}}}{(4\pi L)^2 \sqrt{2B^2/\Omega^2 + 2B^2/\Omega_\Phi^2 + 1}}, \quad (148)$$

and the second moment follows from the calculation in Appendix 2

$$\begin{aligned} \mathbb{E} \left[|\mathcal{C}(\bar{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}', \vec{\mathbf{y}}), \tilde{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}', \vec{\mathbf{y}}); \vec{\mathbf{x}}, \vec{\mathbf{x}}')|^2 \right] &\approx \frac{\left(\frac{2B^2}{\Omega^2} + 1 \right)^{-\frac{1}{2}}}{128\pi^3 L^4} \\ &\left[\frac{2B^2}{\Omega^2} \left(1 - \int_0^1 dt e^{-\frac{t^2|\mathbf{x}-\mathbf{x}'|^2}{2\ell^2}} \right) + 1 \right]^{-\frac{1}{2}} \times \\ &\left[\frac{2B^2}{\Omega^2} \left(1 - \int_0^1 dt e^{-\frac{t^2|\mathbf{x}-\mathbf{x}'|^2}{2\ell^2}} \right) + \frac{2B^2}{\Omega_\Phi^2} + 1 \right]^{-\frac{1}{2}}. \end{aligned} \quad (149)$$

We distinguish two regimes:

1. When $|\mathbf{x} - \mathbf{x}'| \gg X(\omega_o)$ the mean (148) and therefore the SNR are exponentially small. The cross-correlations have large random fluctuations in this regime and in CINT we make sure that we do not use them by restricting $|\mathbf{x} - \mathbf{x}'| \lesssim X(\omega_o)$ with the window function Ψ .
2. When $|\mathbf{x} - \mathbf{x}'| \lesssim X(\omega_o)$, we can expand the exponential in (149) in series of $|\mathbf{x} - \mathbf{x}'|/\ell \ll 1$ to obtain

$$\frac{2B^2}{\Omega^2} \left(1 - \int_0^1 dt e^{-\frac{t^2|\mathbf{x}-\mathbf{x}'|^2}{2\ell^2}} \right) \approx \frac{B^2}{\omega_o^2} \frac{|\mathbf{x} - \mathbf{x}'|^2}{X^2(\omega_o)} \ll 1,$$

and simplify (149) as

$$\mathbb{E} \left[|\mathcal{C}(\bar{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}', \vec{\mathbf{y}}), \tilde{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}', \vec{\mathbf{y}}); \vec{\mathbf{x}}, \vec{\mathbf{x}}')|^2 \right] \approx \frac{\left(\frac{2B^2}{\Omega_\Phi^2} + 1 \right)^{-1}}{128\pi^3 L^4}. \quad (150)$$

The SNR is bounded by its value at $\mathbf{x} = \mathbf{x}'$, in which case Eqs. (148) and (150) give

$$\text{SNR} \lesssim \frac{|\mathbb{E} [\mathcal{C}(\bar{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}, \vec{\mathbf{y}}), \tilde{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}, \vec{\mathbf{y}}); \vec{\mathbf{x}}, \vec{\mathbf{x}})]|}{\sqrt{\text{Var} [\mathcal{C}(\bar{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}, \vec{\mathbf{y}}), \tilde{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}, \vec{\mathbf{y}}); \vec{\mathbf{x}}, \vec{\mathbf{x}}]}]} \approx \sqrt{\frac{\Omega^2}{\Omega_\Phi^2} + \frac{\Omega^2}{2B^2}}. \quad (151)$$

The subtraction of the random phases in the local cross-correlations (143) at nearby receivers reduces substantially the random fluctuations and the SNR is no

longer exponentially small. However, the SNR may still not be large enough and it decreases when we increase Ω_ϕ , as stated before. A small Ω_ϕ gives a larger SNR but it also reduces the resolution as discussed previously, so $\Omega_\phi \approx \Omega$ is a good compromise. Equation (151) shows that the stronger the random medium effects (i.e., the smaller Ω) the lower the SNR. The local cross-correlations are less sensitive to the realization of the random medium than the data themselves, but still they are not statistically stable. They have random fluctuations that are of the same order as the mean. These fluctuations are averaged out in the CINT imaging function (140) by the summation over the sensors, if the aperture is large enough. This is how we can achieve a statistically stable image, as we show in the next section.

Resolution Analysis of the CINT Imaging Function

We calculate first the mean of the imaging function to estimate the resolution of the expected focusing. Then we estimate the SNR and state the conditions under which CINT is statistically stable.

The Mean Point Spread Function

In the case of a point source at \vec{y} , the expectation of the imaging function follows directly from (140) and (145). Using the Gaussian window Ψ defined in (142) and the approximation (126) of the differences of travel times, we obtain

$$\begin{aligned} \mathbb{E}[\mathcal{J}(\vec{y}^s; \vec{y})] &\approx \frac{\sqrt{2\pi} N^2}{(4\pi L)^2 |\mathcal{A}|^2 \sqrt{4B^2/\Omega^2 + 1}} \iint_{\mathcal{A}} \\ & d\mathbf{x} d\mathbf{x}' e^{-\frac{|\mathbf{x}-\mathbf{x}'|^2}{X^2(\omega_o)} + ik_o \frac{(\mathbf{y}^s - \mathbf{y}) \cdot (\mathbf{x} - \mathbf{x}')}{L} - \frac{B^2}{4c_o^2} \left[\frac{(\mathbf{y}^s - \mathbf{y}) \cdot (\mathbf{x} - \mathbf{x}')}{L} \right]^2} \times e^{-\frac{B^2}{c_o^2(4B^2/\Omega^2+1)} \left[\eta^s - \eta + \frac{(\mathbf{y}^s - \mathbf{y}) \cdot (\mathbf{x}/2 - \mathbf{x}')}{L} \right]^2}. \end{aligned} \quad (152)$$

Here we used the same notation as in the previous section for the point spread function $\mathcal{J}(\vec{y}^s; \vec{y})$ to emphasize that the source is a point at \vec{y} .

It is convenient to change variables in the integral in (152) to centered and difference offsets

$$\bar{\mathbf{x}} = \frac{\mathbf{x} + \mathbf{x}'}{2}, \quad \tilde{\mathbf{x}} = \mathbf{x} - \mathbf{x}',$$

and since only $|\tilde{\mathbf{x}}| \lesssim X(\omega_o) \ll \ell \lesssim a$ is in the essential support of the Gaussian, we can approximate the right hand side in (152) by extending the integral over $\tilde{\mathbf{x}}$ to the whole \mathbb{R}^2 . Moreover, we note that under our scaling assumptions

$$\frac{B}{c_o} \left| \frac{(\mathbf{y}^s - \mathbf{y}) \cdot (\mathbf{x} - \mathbf{x}')}{L} \right| \lesssim \frac{B}{\omega_o} \frac{k_o |\mathbf{y}^s - \mathbf{y}| X(\omega_o)}{L} \ll 1,$$

so we can neglect the third term in the exponential in (152). This is for search points $\vec{\mathbf{y}}^s$ satisfying

$$1 \lesssim \frac{|\mathbf{y}^s - \mathbf{y}|}{\lambda_o L / X(\omega_o)} \ll \frac{\omega_o}{B},$$

where $\lambda_o L / X(\omega_o)$ turns out to be the cross-range resolution limit, as shown below. We obtain after integrating in $\tilde{\mathbf{x}}$ that

$$\begin{aligned} \mathbb{E} [\mathcal{J}(\vec{\mathbf{y}}^s; \vec{\mathbf{y}})] &\approx \frac{\sqrt{2/\pi} N^2 X^2(\omega_o)}{16L^2 |\mathcal{A}| \sqrt{4B^2/\Omega^2 + 1}} e^{-\frac{1}{4} \left[\frac{k_o X(\omega_o) |\mathbf{y}^s - \mathbf{y}|}{L} \right]^2} \\ &\quad \int_{\mathcal{A}} \frac{d\tilde{\mathbf{x}}}{|\mathcal{A}|} e^{-\frac{B^2}{c_o^2(4B^2/\Omega^2 + 1)} \left[\eta^s - \eta + \frac{(\mathbf{y}^s - \mathbf{y}) \cdot \tilde{\mathbf{x}}}{L} \right]^2}, \end{aligned} \quad (153)$$

and note that the right-hand side peaks at $\vec{\mathbf{y}}^s = \vec{\mathbf{y}}$, as it should.

Range Resolution When we evaluate (153) at $\mathbf{y}^s = \mathbf{y}$, we obtain

$$\mathbb{E} [\mathcal{J}(\vec{\mathbf{y}}^s = (\mathbf{y}, \eta^s); \vec{\mathbf{y}})] \approx \frac{\sqrt{2/\pi} N^2 X^2(\omega_o)}{16L^2 |\mathcal{A}| \sqrt{4B^2/\Omega^2 + 1}} e^{-\frac{B^2(\eta^s - \eta)^2}{c_o^2(4B^2/\Omega^2 + 1)}}. \quad (154)$$

The range resolution is given by

$$|\eta^s - \eta| \lesssim \frac{c_o}{B} \sqrt{4B^2/\Omega^2 + 1}. \quad (155)$$

It is worse than in the homogeneous medium because of the factor $\sqrt{4B^2/\Omega^2 + 1}$. This factor is large when the decoherence frequency satisfies $\Omega \ll B$ and reduces the range resolution to $O(c_o/\Omega)$.

Cross-Range Resolution Evaluating (153) at $\eta^s = \eta$, we obtain

$$\begin{aligned} \mathbb{E} [\mathcal{J}(\vec{\mathbf{y}}^s; \vec{\mathbf{y}})] &\approx \frac{\sqrt{\pi/2} N^2 X^2(\omega_o)}{32L^2 |\mathcal{A}| \sqrt{4B^2/\Omega^2 + 1}} e^{-\frac{1}{4} \left[\frac{k_o X(\omega_o) |\mathbf{y}^s - \mathbf{y}|}{L} \right]^2} \\ &\quad \prod_{j=1}^2 \frac{\operatorname{erf} \left[\frac{aB}{2Lc_o \sqrt{4B^2/\Omega^2 + 1}} (y_j^s - y_j) \right]}{\frac{aB}{2Lc_o \sqrt{4B^2/\Omega^2 + 1}} (y_j^s - y_j)}. \end{aligned}$$

Both factors are peaked at $\mathbf{y}^s = \mathbf{y}$, so we estimate the resolution by the width of the tighter peak

$$|\mathbf{y}^s - \mathbf{y}| \lesssim \min \left\{ \frac{\lambda_o L}{X(\omega_o)}, \frac{\lambda_o L}{a} \sqrt{\frac{4\omega_o^2}{\Omega^2} + \frac{\omega_o^2}{B^2}} \right\}. \quad (156)$$

This is worse than the resolution $\lambda_o L/a$ in homogeneous media because in our scaling $X(\omega_o) \ll a$ and $\sqrt{\frac{4\omega_o^2}{\Omega^2} + \frac{\omega_o^2}{B^2}} \gg 1$.

The SNR

To calculate the SNR, we need the variance of $\mathcal{J}(\vec{\mathbf{y}}^s; \vec{\mathbf{y}})$ and therefore the fourth-order moments of the Green's function. Their calculation is straightforward, due to the Gaussianity of v_τ , but laborious. We state directly the result which distinguishes between two cases:

1. When $|\Delta \mathbf{x}| = |\mathbf{x} - \mathbf{x}'| \gg \ell$, the fourth moments

$$\begin{aligned} \mathcal{M}_4(\omega, \omega', \tilde{\omega}, \tilde{\omega}', \mathbf{x}, \mathbf{x}', \tilde{\mathbf{x}}, \tilde{\mathbf{x}}') = & \mathbb{E} \left[e^{i(\omega + \frac{\tilde{\omega}}{2})v_\tau(\tilde{\mathbf{x}} + \frac{\tilde{\mathbf{x}}'}{2}, \vec{\mathbf{y}}) - i(\omega - \frac{\tilde{\omega}}{2})v_\tau(\tilde{\mathbf{x}} - \frac{\tilde{\mathbf{x}}'}{2}, \vec{\mathbf{y}})} \right. \\ & \times e^{-i(\omega' + \frac{\tilde{\omega}'}{2})v_\tau(\tilde{\mathbf{x}}' + \frac{\tilde{\mathbf{x}}}{2}, \vec{\mathbf{y}}) + i(\omega' - \frac{\tilde{\omega}'}{2})v_\tau(\tilde{\mathbf{x}}' - \frac{\tilde{\mathbf{x}}}{2}, \vec{\mathbf{y}})} \left. \right] \end{aligned}$$

factorize in the product of second moments

$$\mathcal{M}_4(\omega, \omega', \tilde{\omega}, \tilde{\omega}', \mathbf{x}, \mathbf{x}', \tilde{\mathbf{x}}, \tilde{\mathbf{x}}') \approx \mathcal{M}_2(\omega, \tilde{\omega}, \mathbf{x}, \tilde{\mathbf{x}}) \overline{\mathcal{M}_2(\omega', \tilde{\omega}', \mathbf{x}', \tilde{\mathbf{x}}')},$$

where

$$\mathcal{M}_2(\omega, \tilde{\omega}, \mathbf{x}, \tilde{\mathbf{x}}) = \mathbb{E} \left[e^{i(\omega + \frac{\tilde{\omega}}{2})v_\tau(\tilde{\mathbf{x}} + \frac{\tilde{\mathbf{x}}}{2}, \vec{\mathbf{y}}) - i(\omega - \frac{\tilde{\omega}}{2})v_\tau(\tilde{\mathbf{x}} - \frac{\tilde{\mathbf{x}}}{2}, \vec{\mathbf{y}})} \right] \approx e^{-\frac{\tilde{\omega}^2}{2\Omega^2} - \frac{|\tilde{\mathbf{x}}|^2}{2X^2(\omega_o)}},$$

and $\tilde{\mathbf{x}} = (\mathbf{x}, L)$, $\tilde{\tilde{\mathbf{x}}} = (\tilde{\mathbf{x}}, 0)$. The same notation applies for the prime variables.

2. When $|\Delta \mathbf{x}| \lesssim \ell$, we have the expression

$$\begin{aligned} \mathcal{M}_4(\omega, \omega', \tilde{\omega}, \tilde{\omega}', \mathbf{x}, \mathbf{x}', \tilde{\mathbf{x}}, \tilde{\mathbf{x}}') \approx & \mathcal{M}_2(\omega, \tilde{\omega}, \mathbf{x}, \tilde{\mathbf{x}}) \overline{\mathcal{M}_2(\omega', \tilde{\omega}', \mathbf{x}', \tilde{\mathbf{x}}')} \\ & \times \exp \left\{ \int_0^1 dt e^{-\frac{t^2|\Delta \mathbf{x}|^2}{2\ell^2}} \left[\frac{\tilde{\omega}\tilde{\omega}'}{\Omega^2} + 3\frac{t^2\tilde{\mathbf{x}} \cdot \tilde{\mathbf{x}}'}{X^2(\omega_o)} \left(1 - \frac{t^2|\Delta \mathbf{x}|^2}{2\ell^2} \right) \right. \right. \\ & \left. \left. - \sqrt{3}t^2 \frac{\Delta \mathbf{x}}{\ell} \cdot \left(\frac{\tilde{\omega}'\tilde{\mathbf{x}}}{\Omega X(\omega_o)} - \frac{\tilde{\omega}\tilde{\mathbf{x}}'}{\Omega X(\omega_o)} \right) \right] \right\}. \end{aligned}$$

We no longer have the factorization of the moments, and the exponential factor is bounded above and below by constants of order one.

The factorization of the moments for $|\Delta\mathbf{x}| \gg \ell$ means that only the set $\{\mathbf{x}, \mathbf{x}' \in \mathcal{A}, |\mathbf{x} - \mathbf{x}'| \lesssim \ell\}$ contributes to the calculation of the variance of $\mathcal{J}(\vec{\mathbf{y}}^s)$. Explicitly, we have

$$\begin{aligned} \text{Var} [\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})] &\approx \frac{N^4}{64|\mathcal{A}|^4 \pi^5 L^4 B^4} \iint_{-\infty}^{\infty} d\omega d\omega' \iint_{-\infty}^{\infty} d\tilde{\omega} d\tilde{\omega}' \iint_{\mathcal{A}} d\mathbf{x} d\mathbf{x}' 1_{[0, \ell]} \\ &(|\mathbf{x} - \mathbf{x}'|) \iint_{\mathbb{R}^2} d\tilde{\mathbf{x}} d\tilde{\mathbf{x}}' \times e^{-\frac{(\omega - \omega_0)^2 + (\omega' - \omega_0)^2}{B^2} - (\tilde{\omega}^2 + \tilde{\omega}'^2) \left(\frac{1}{\Omega^2} + \frac{1}{4B^2} \right) - \frac{|\tilde{\mathbf{x}}|^2 + |\tilde{\mathbf{x}}'|^2}{2X^2(\omega_0)}} \\ &\times \left\{ e^{\int_0^1 dt e^{-\frac{t^2 |\Delta\mathbf{x}|^2}{2\ell^2}} \left[\frac{\tilde{\omega}\tilde{\omega}'}{\Omega^2} + 3 \frac{t^2 \tilde{\mathbf{x}} \cdot \tilde{\mathbf{x}}'}{X^2(\omega_0)} \left(1 - \frac{t^2 |\Delta\mathbf{x}|^2}{2\ell^2} \right) - \sqrt{3} t^2 \frac{\Delta\mathbf{x}}{\ell} \cdot \left(\frac{\tilde{\omega}' \tilde{\mathbf{x}}}{\Omega X(\omega_0)} - \frac{\tilde{\omega} \tilde{\mathbf{x}}'}{\Omega X(\omega_0)} \right) \right]} - 1 \right\}. \end{aligned}$$

This is a complicated expression but we can estimate it by replacing the last factor by an order one constant. We obtain that

$$\text{Var} [\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})] \sim \frac{\ell^2}{|\mathcal{A}|} |\mathbb{E} [\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})]|^2, \quad (157)$$

where the symbol \sim means approximate, up to a multiplicative constant of order one. The SNR at the peak is given by

$$\text{SNR} [\mathcal{J}(\vec{\mathbf{y}}; \vec{\mathbf{y}})] \sim \frac{a}{\ell}, \quad (158)$$

where we used that $|\mathcal{A}| = a^2$. Thus, the CINT point spread function $\mathcal{J}(\vec{\mathbf{y}}^s; \vec{\mathbf{y}})$ has a robust (statistically stable) focusing at the location $\vec{\mathbf{y}}$ of the source only if the array has aperture $a \gg \ell$. This is a significant improvement over the result in Sect. 7, where for the migration method to be stable we needed that a/ℓ be much larger than a huge number, not one like above.

Remark 4. Our analysis above is restricted to the CINT point spread function. It extends easily to the case of a distributed source density. We do not do it here because the calculations are long and the result does not bring any significant insight to the problem.

CINT Images for Passive Arrays as the Smoothed Wigner Transform

The Wigner transform, also called the Wigner distribution, is a classic tool for studying high frequency limits of the wave equation. It is very useful in imaging because it allows us to extract the important phase information from the measurements at the array: the travel times and the direction of arrival of the waves from the unknown source location.

The Wigner transform of the wave field $\hat{p}(\omega, (\mathbf{x}, L))$ evaluated in the plane of the array, at range L from the source, is defined by

$$\begin{aligned}\mathcal{W}(\omega, \mathbf{x}; t, \mathbf{K}) = & \int_{\mathbb{R}^2} \frac{d\tilde{\mathbf{x}}}{(2\pi)^2} \int_{-\infty}^{\infty} \frac{d\tilde{\omega}}{2\pi} \hat{p}\left(\omega + \frac{\tilde{\omega}}{2}, \left(\mathbf{x} + \frac{\tilde{\mathbf{x}}}{2}, L\right)\right) \\ & \bar{\hat{p}}\left(\omega - \frac{\tilde{\omega}}{2}, \left(\mathbf{x} - \frac{\tilde{\mathbf{x}}}{2}, L\right)\right) e^{-i\omega\mathbf{K}\cdot\tilde{\mathbf{x}} - i\tilde{\omega}t}.\end{aligned}\quad (159)$$

We cannot compute it in practice because the measurements of \hat{p} are limited to the aperture, but we shall see in this section how \mathcal{W} is related to the CINT imaging function. Note that \mathcal{W} is real valued and its integral over the last two arguments gives the intensity of the wave field

$$\int_{\mathbb{R}^2} d\mathbf{K} \omega^2 \int_{-\infty}^{\infty} dt \mathcal{W}(\omega, \mathbf{x}; t, \mathbf{K}) = |\hat{p}(\omega, (\mathbf{x}, L))|^2. \quad (160)$$

Thus, we may think of W as the “energy density” of the waves resolved over the phase space variables t and \mathbf{K} , although \mathcal{W} is not positive in general. The variable t is dual to the frequency offset $\tilde{\omega}$, so it has units of time. The variable \mathbf{K} is dual to the cross-range offset, and is called the slowness vector because its units are time over length, like $1/c_o$.

We use the paraxial approximation (112) of the travel time and assumption (118) to rewrite the expression (139) of the CINT imaging function $\mathcal{J}(\vec{\mathbf{y}}^s)$ evaluated at $\vec{\mathbf{y}}^s = (\mathbf{y}^s, \eta^s)$ as

$$\begin{aligned}\mathcal{J}(\vec{\mathbf{y}}^s) \approx & \frac{N^2}{(2\pi)^2 |\mathcal{A}|^2} \int_{-\infty}^{\infty} d\omega \int_{-\infty}^{\infty} d\tilde{\omega} \hat{\Phi}\left(\frac{\tilde{\omega}}{\Omega}\right) \int_{\mathcal{A}} d\mathbf{x} \int_{\mathbb{R}^2} d\tilde{\mathbf{x}} \Psi\left[\frac{\tilde{\mathbf{x}}}{X(\omega_o)}\right] \\ & \times \hat{p}\left(\omega + \frac{\tilde{\omega}}{2}, \left(\mathbf{x} + \frac{\tilde{\mathbf{x}}}{2}, L\right)\right) \bar{\hat{p}}\left(\omega - \frac{\tilde{\omega}}{2}, \left(\mathbf{x} - \frac{\tilde{\mathbf{x}}}{2}, L\right)\right) \\ & e^{-i\tilde{\omega}\tau_o((\mathbf{x}, L), \vec{\mathbf{y}}^s) - i\frac{\omega}{c_o}(\mathbf{x} - \vec{\mathbf{y}}^s) \cdot \tilde{\mathbf{x}}}.\end{aligned}\quad (161)$$

The cross-range variables \mathbf{x} and $\tilde{\mathbf{x}}$ should take values in the set defined by the constraint $\mathbf{x} \pm \tilde{\mathbf{x}}/2 \in \mathcal{A}$, so that the wave field is evaluated in the aperture of the array. Nevertheless, since the window Ψ restricts $|\tilde{\mathbf{x}}|$ to the decorrelation length $X(\omega_o)$, which is much smaller than the aperture a , we can approximate $\mathcal{J}(\vec{\mathbf{y}}^s)$ by extending the integral over $\tilde{\mathbf{x}}$ to the whole plane and letting \mathbf{x} vary in \mathcal{A} .

The relation between $\mathcal{J}(\vec{\mathbf{y}}^s)$ and \mathcal{W} follows from (161), after inverting the transform in (159),

$$\begin{aligned}\mathcal{J}(\vec{\mathbf{y}}^s) \approx & \frac{N^2 \Omega X^2(\omega_o)}{2\pi |\mathcal{A}|^2} \int_{-\infty}^{\infty} d\omega \int_{\mathcal{A}} d\mathbf{x} \int_{-\infty}^{\infty} dt \int_{\mathbb{R}^2} d\mathbf{K} \omega^2 \mathcal{W}(\omega, \mathbf{x}; t, \mathbf{K}) \\ & \times \Phi\left[\Omega(\tau_o((\mathbf{x}, L), \vec{\mathbf{y}}^s) - t)\right] \hat{\Psi}\left[\omega_o X(\omega_o) \left(\mathbf{K} - \frac{\mathbf{x} - \vec{\mathbf{y}}^s}{c_o L}\right)\right].\end{aligned}\quad (162)$$

Thus $\mathcal{J}(\vec{\mathbf{y}}^s)$ is given by the Wigner transform smoothed over all its arguments. The smoothing is by the integration over the bandwidth and the aperture and by the convolution with the windows. The time window Φ has support of order $1/\Omega$, and the convolution is evaluated at the travel time from the search point $\vec{\mathbf{y}}^s$ to the receiver location $\tilde{\mathbf{x}} = (\mathbf{x}, L)$ in the array. The window $\hat{\Psi}$ over the slowness vectors has support of order $\omega_o X(\omega_o) = \sqrt{3}\Omega\ell$, and the convolution is evaluated at the slowness vector $(\mathbf{x} - \vec{\mathbf{y}}^s)/(c_o L)$, which is approximately the cross-range gradient of the travel time $\nabla_{\mathbf{x}}\tau_o(\tilde{\mathbf{x}}, \vec{\mathbf{y}}^s)$.

Remark 5. It turns out that the Wigner transform is weakly self-averaging for a wide range of wave scattering regimes in random media. That is to say, although $\mathcal{W}(\omega, \mathbf{x}; t, \mathbf{K})$ is random when evaluated pointwise, it becomes deterministic when integrated against some test function $\varphi(\omega, \mathbf{x}; t, \mathbf{K})$, as in (162). The weak self-averaging property of the Wigner transform is the basis of the proofs of statistical stability of the time reversal process [3, 27] and of CINT imaging in random media [9]. It is an asymptotic result obtained by taking various limits, depending on the scaling regime. The smoothed Wigner transform is not deterministic in practice because the limit is never realized, but its random fluctuations at the peaks are small, i.e., the SNR is large.

Calculation of the Wigner Transform

Here we calculate the Wigner transform in order to show explicitly the role of the smoothing by the windows Φ and Ψ used in the local cross-correlations of the array data. Again, we assume for simplicity a point source at $\vec{\mathbf{y}}$.

Using the model (137) of the array data with Green's function (122) in the definition (159) of the Wigner transform, we obtain

$$\begin{aligned} \mathcal{W}(\omega, \mathbf{x}; t, K) &\approx \frac{1}{(4\pi L)^2(2\pi)^3} \int_{\mathbb{R}^2} d\tilde{\mathbf{x}} \int_{-\infty}^{\infty} d\tilde{\omega} \hat{f}\left(\omega + \frac{\tilde{\omega}}{2}\right) \overline{\hat{f}}\left(\omega - \frac{\tilde{\omega}}{2}\right) \\ &\times e^{i\omega[\tau((\mathbf{x} + \frac{\tilde{\mathbf{x}}}{2}, L), \vec{\mathbf{y}}) - \tau((\mathbf{x} - \frac{\tilde{\mathbf{x}}}{2}, L), \vec{\mathbf{y}}) - \mathbf{K} \cdot \tilde{\mathbf{x}}] + i\frac{\tilde{\omega}}{2}[\tau((\mathbf{x} + \frac{\tilde{\mathbf{x}}}{2}, L), \vec{\mathbf{y}}) + \tau((\mathbf{x} - \frac{\tilde{\mathbf{x}}}{2}, L), \vec{\mathbf{y}}) - 2t]}. \end{aligned} \quad (163)$$

Here τ is the random travel time

$$\tau(\tilde{\mathbf{x}}, \vec{\mathbf{y}}) = \tau_o(\tilde{\mathbf{x}}, \vec{\mathbf{y}}) + v_\tau(\tilde{\mathbf{x}}, \vec{\mathbf{y}}),$$

and assuming that the pulse \hat{f} is modeled by the Gaussian (105), we can integrate over $\tilde{\omega}$ in (163)

$$\begin{aligned} \mathcal{W}(\omega, \mathbf{x}; t, K) &\approx \frac{e^{-(\omega - \omega_o)^2/B^2}}{(4\pi L)^2 2\pi^{3/2} B} \int_{\mathbb{R}^2} d\tilde{\mathbf{x}} e^{-\frac{B^2}{4}[\tau((\mathbf{x} + \frac{\tilde{\mathbf{x}}}{2}, L), \vec{\mathbf{y}}) + \tau((\mathbf{x} - \frac{\tilde{\mathbf{x}}}{2}, L), \vec{\mathbf{y}}) - 2t]^2} \\ &\times e^{i\omega[\tau((\mathbf{x} + \frac{\tilde{\mathbf{x}}}{2}, L), \vec{\mathbf{y}}) - \tau((\mathbf{x} - \frac{\tilde{\mathbf{x}}}{2}, L), \vec{\mathbf{y}}) - \mathbf{K} \cdot \tilde{\mathbf{x}}]}. \end{aligned} \quad (164)$$

It remains to evaluate the $\tilde{\mathbf{x}}$ integral which we cannot do explicitly in (164) because there is no restriction on the cross-range offset $\tilde{\mathbf{x}}$. However, when we smooth \mathcal{W} over the slowness vectors, as we do in the convolution with the window $\hat{\Psi}$ in (164), we see that only small cross-range offsets contribute to the results. Explicitly, we have

$$\int_{\mathbb{R}^2} d\mathbf{K}' \hat{\Psi} [\omega_o X(\omega_o)(\mathbf{K}' - \mathbf{K})] \mathcal{W}(\omega, \mathbf{x}; t; \mathbf{K}') \approx \frac{2\sqrt{\pi} e^{-(\omega-\omega_o)^2/B^2}}{(4\pi L)^2 B[\omega_o X(\omega_o)]^2} \\ e^{-B^2[\tau((\mathbf{x}, L), \vec{\mathbf{y}}) - t]^2} \times \int_{\mathbb{R}^2} d\tilde{\mathbf{x}} \Psi \left(\frac{\tilde{\mathbf{x}}}{X(\omega_o)} \right) e^{i\omega_o [\nabla_{\mathbf{x}} \tau((\mathbf{x}, L), \vec{\mathbf{y}}) - \mathbf{K}] \cdot \tilde{\mathbf{x}}}, \quad (165)$$

where we used our scaling assumptions to approximate

$$\frac{B}{2} \left[\tau \left((\mathbf{x} + \frac{\tilde{\mathbf{x}}}{2}, L), \vec{\mathbf{y}} \right) + \tau \left((\mathbf{x} - \frac{\tilde{\mathbf{x}}}{2}, L), \vec{\mathbf{y}} \right) \right] \approx B \tau((\mathbf{x}, L), \vec{\mathbf{y}}), \\ \omega \left[\tau \left((\mathbf{x} + \frac{\tilde{\mathbf{x}}}{2}, L), \vec{\mathbf{y}} \right) - \tau \left((\mathbf{x} - \frac{\tilde{\mathbf{x}}}{2}, L), \vec{\mathbf{y}} \right) \right] \approx \omega_o \nabla_{\mathbf{x}} \tau((\mathbf{x}, L), \vec{\mathbf{y}}),$$

for cross-range offsets in the support of Ψ , satisfying $|\tilde{\mathbf{x}}| \lesssim X(\omega_o)$. Now we can integrate over $\tilde{\mathbf{x}}$ in (165) and over ω

$$\int_{\mathbb{R}^2} d\mathbf{K}' \hat{\Psi} [\omega_o X(\omega_o)(\mathbf{K}' - \mathbf{K})] \int_{-\infty}^{\infty} d\omega \mathcal{W}(\omega, \mathbf{x}; t; \mathbf{K}') \\ \approx \frac{2\pi}{(4\pi L)^2 \omega_o^2} e^{-B^2[\tau((\mathbf{x}, L), \vec{\mathbf{y}}) - t]^2} \times \hat{\Psi} [\omega_o X(\omega_o) (\nabla_{\mathbf{x}} \tau((\mathbf{x}, L), \vec{\mathbf{y}}) - \mathbf{K})]. \quad (166)$$

We conclude from (166) and the paraxial approximation (112) of the deterministic travel time τ_o that the Wigner transform smoothed over the slowness vector peaks at the random arguments

$$t = \tau_o((\mathbf{x}, L), \vec{\mathbf{y}}) + v_{\tau}((\mathbf{x}, L), \vec{\mathbf{y}}) \quad \text{and} \quad \mathbf{K} = \frac{\mathbf{x} - \mathbf{y}}{c_o L} + \nabla_{\mathbf{x}} v_{\tau}((\mathbf{x}, L), \vec{\mathbf{y}}). \quad (167)$$

The peak dances around the point $(\tau_o((\mathbf{x}, L), \vec{\mathbf{y}}), \frac{\mathbf{x} - \mathbf{y}}{c_o L})$ in the (t, \mathbf{K}) phase space, as modeled by v_{τ} in the t direction and by $\nabla_{\mathbf{x}} v_{\tau}$ in the plane of the slowness vectors \mathbf{K} . In the CINT imaging function (163) we evaluate (166) at the expected peak location $(\tau_o((\mathbf{x}, L), \vec{\mathbf{y}}^s), \frac{\mathbf{x} - \mathbf{y}^s}{c_o L})$ supposing that the source is at $\vec{\mathbf{y}}^s$. The role of the window $\hat{\Psi}$ is to mitigate the peak dancing in \mathbf{K} . The standard deviation of the location of the peaks is quantified in our model as $O(1/(\omega_o X(\omega_o)))$, which is precisely the support of $\hat{\Psi}$ in (166). Thus, in CINT we are essentially taking the envelope of the random peaks in \mathbf{K} to stabilize statistically the image, and thus increase the SNR.

The standard deviation of the peak location in t is $O(1/\Omega)$ in our model, and the peak dancing is significant in (166) when $B \gg \Omega$. The CINT imaging function

(163) is statistically stable because of the convolution with the window Φ of support $O(1/\Omega)$.

Remark 6. The results above reveal that on one hand the windows used in the calculation of the local cross-correlations are needed to stabilize the imaging process, but on the other hand they blur the peaks of \mathcal{W} and therefore of the image. In practice it is unlikely that we would know the statistics of the medium fluctuations so we cannot calculate the decorrelation length $X(\omega_o)$ and the decoherence frequency Ω using the formulas (103) and (109). In fact these formulas may not even apply because the random travel time model may not be a good approximation of the net scattering effects of the medium. It is the form of the second moment formulas (109) which is general, and not the detailed definition of Ω and $X(\omega_o)$ that the CINT imaging methodology should use. The scales $X(\omega_o)$ and Ω should not be set based on a specific model, they should be estimated as part of the imaging process. This can be done in principle directly from the data, by calculating for example empirical correlations and estimating how they decay with the frequency and cross-range offsets. Alternatively, we may estimate $X(\omega_o)$ and Ω while we form the image, by exploiting the trade-off between the resolution (sharpness) of the image and its SNR. The latter approach is known as adaptive CINT. It uses a figure of merit of the quality of the image and estimates $X(\omega_o)$ and Ω by optimizing it during the image formation [8].

CINT Imaging with Active Arrays

The CINT imaging function for active arrays back-propagates the local cross-correlations of the array measurements $\hat{p}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)$ to the search points $\vec{\mathbf{y}}^s$, using the roundtrip travel times

$$\tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_s) = \tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s) + \tau_0(\vec{\mathbf{x}}_s, \vec{\mathbf{y}}^s). \quad (168)$$

Here $\vec{\mathbf{x}}_r = (\mathbf{x}_r, L)$ and $\vec{\mathbf{x}}_s = (\mathbf{x}_s, L)$ denote the location of the receivers and sources in the aperture \mathcal{A} , and the imaging function is given by

$$\begin{aligned} \mathcal{J}(\vec{\mathbf{y}}^s) &= \sum_{r,r'=1}^{N_r} \sum_{s,s'=1}^{N_s} \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \Psi \left[\frac{\mathbf{x}_r - \mathbf{x}_{r'}}{X(\omega_o)} \right] \Psi \left[\frac{\mathbf{x}_s - \mathbf{x}_{s'}}{X(\omega_o)} \right] \int_{-\infty}^{\infty} \frac{d\tilde{\omega}}{2\pi} \hat{\Phi} \left(\frac{\tilde{\omega}}{\Omega} \right) \\ &\hat{p} \left(\omega + \frac{\tilde{\omega}}{2}, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s \right) \times \bar{\hat{p}} \left(\omega - \frac{\tilde{\omega}}{2}, \vec{\mathbf{x}}_{r'}, \vec{\mathbf{x}}_{s'} \right) \\ &e^{-i\tilde{\omega} \left[\frac{\tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_s) + \tau_o(\vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_{s'})}{2} \right] - i\omega [\tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_s) - \tau_o(\vec{\mathbf{x}}_{r'}, \vec{\mathbf{y}}^s, \vec{\mathbf{x}}_{s'})]}. \end{aligned} \quad (169)$$

The resolution analysis of (169) is more involved than that for passive arrays, even for the Born model of the data

$$\begin{aligned}\hat{p}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s) &\approx \hat{f}(\omega) \int d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \hat{G}(\omega, \vec{\mathbf{x}}_s, \vec{\mathbf{y}}) \\ &\approx \frac{\hat{f}(\omega)}{(4\pi L)^2} \int d\vec{\mathbf{y}} \rho(\vec{\mathbf{y}}) e^{i\omega\tau_o(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}, \vec{\mathbf{x}}_s) + i\omega\nu_\tau(\vec{\mathbf{x}}_r, \vec{\mathbf{y}}) + i\omega\nu_\tau(\vec{\mathbf{x}}_s, \vec{\mathbf{y}})},\end{aligned}\quad (170)$$

because it requires higher moments of the random travel time perturbation ν_τ . We do not include it here because it does not bring any new insight. We only highlight the relation between the imaging function and the Wigner transform, in the case of a point-like reflector at $\vec{\mathbf{y}}$.

Using the model

$$\hat{p}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s) \approx \hat{f}(\omega) \hat{G}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{y}}) \hat{G}(\omega, \vec{\mathbf{x}}_s, \vec{\mathbf{y}}),$$

we can rewrite (169) in terms of the Wigner transform $W(\omega, \mathbf{x}; t, \mathbf{K})$ of $\hat{f}(\omega)^{1/2} \hat{G}(\omega, \vec{\mathbf{x}}, \vec{\mathbf{y}})$, which is like the square root of the data. Explicitly, we have that

$$\begin{aligned}W(\omega, \mathbf{x}; t, \mathbf{K}) &= \int_{\mathbb{R}^2} \frac{d\tilde{\mathbf{x}}}{(2\pi)^2} \int_{-\infty}^{\infty} \frac{d\tilde{\omega}}{2\pi} \hat{f}^{1/2} \left(\omega + \frac{\tilde{\omega}}{2} \right) \overline{\hat{f}^{1/2}} \left(\omega - \frac{\tilde{\omega}}{2} \right) \\ &\quad \hat{G} \left(\omega + \frac{\tilde{\omega}}{2}, \left(\mathbf{x} + \frac{\tilde{\mathbf{x}}}{2}, L \right) \right) \overline{\hat{G}} \left(\omega - \frac{\tilde{\omega}}{2}, \left(\mathbf{x} - \frac{\tilde{\mathbf{x}}}{2}, L \right) \right) e^{-i\omega\mathbf{K}\cdot\tilde{\mathbf{x}} - i\tilde{\omega}t},\end{aligned}$$

and (169) becomes

$$\begin{aligned}\mathcal{J}(\vec{\mathbf{y}}^s) &\approx \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \iint_{\mathbb{R}^2} d\mathbf{K} d\mathbf{K}' \iint_{-\infty}^{\infty} dt dt' \sum_{r,r'=1}^{N_r} \omega^2 W(\omega, \bar{\mathbf{x}}_r; t, \mathbf{K}) \Psi \left[\frac{\tilde{\mathbf{x}}_r}{X(\omega_o)} \right] \\ &\quad \times e^{i\omega \left(\mathbf{K} - \frac{\bar{\mathbf{x}}_r - \vec{\mathbf{y}}^s}{L} \right) \cdot \tilde{\mathbf{x}}_r} \times \sum_{s,s'=1}^{N_s} \omega^2 W(\omega, \bar{\mathbf{x}}_s; t', \mathbf{K}') \Psi \left[\frac{\tilde{\mathbf{x}}_s}{X(\omega_o)} \right] e^{i\omega \left(\mathbf{K}' - \frac{\bar{\mathbf{x}}_s - \vec{\mathbf{y}}^s}{L} \right) \cdot \tilde{\mathbf{x}}_s} \\ &\quad \times \Omega \Phi[\Omega(\tau_o((\mathbf{x}_r, L), \vec{\mathbf{y}}^s) - t + \tau_o((\mathbf{x}_s, L), \vec{\mathbf{y}}^s) - t')],\end{aligned}\quad (171)$$

where we let

$$\bar{\mathbf{x}}_r = \frac{\mathbf{x}_r + \mathbf{x}_{r'}}{2} \quad \text{and} \quad \tilde{\mathbf{x}}_r = \mathbf{x}_r - \mathbf{x}_{r'},$$

integrated over $\tilde{\omega}$, and used the paraxial approximation (112) of the travel time and the assumption (118) on the decorrelation length.

The result (171) is similar to that for passive arrays. To see this more explicitly, let us suppose that $N_r = N_s$ and use the continuum aperture approximation to rewrite (171) as

$$\begin{aligned}
\mathcal{J}(\vec{\mathbf{y}}^s) \approx & \frac{N^4 \Omega [\omega_o X(\omega_o)]^4}{2\pi |\mathcal{A}|^4} \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \iint_{-\infty}^{\infty} dt dt' \\
& \iint_{\mathcal{A}} d\mathbf{x} d\mathbf{x}' \Phi \left[\Omega \left(\tau_o((\mathbf{x}, L), \vec{\mathbf{y}}^s) - t + \tau_o((\mathbf{x}', L), \vec{\mathbf{y}}^s) - t' \right) \right] \\
& \times \int_{\mathbb{R}^2} d\mathbf{K} W(\omega, \mathbf{x}; t, \mathbf{K}) \hat{\Psi} \left[\omega_o X(\omega_o) \left(\mathbf{K} - \frac{\mathbf{x} - \mathbf{y}^s}{L} \right) \right] \\
& \times \int_{\mathbb{R}^2} d\mathbf{K}' W(\omega', \mathbf{x}'; t', \mathbf{K}') \hat{\Psi} \left[\omega_o X(\omega_o) \left(\mathbf{K}' - \frac{\mathbf{x}' - \mathbf{y}^s}{L} \right) \right]. \quad (172)
\end{aligned}$$

The \mathbf{K} and \mathbf{K}' integrals are just like (165), except that now we have the square root of the pulse, so we can write directly the result from there,

$$\begin{aligned}
\int_{\mathbb{R}^2} d\mathbf{K} W(\omega, \mathbf{x}; t, \mathbf{K}) \hat{\Psi} \left[\omega_o X(\omega_o) \left(\mathbf{K} - \frac{\mathbf{x} - \mathbf{y}^s}{L} \right) \right] \approx & \frac{2e^{-\frac{(\omega-\omega_o)^2}{2B^2}}}{(4\pi L)^2 \omega_o^2} e^{-2B^2[\tau((\mathbf{x}, L), \vec{\mathbf{y}}) - t]^2} \\
& \times \hat{\Psi} \left[\omega_o X(\omega_o) \left(\nabla_{\mathbf{x}} \tau((\mathbf{x}, L), \vec{\mathbf{y}}) - \frac{\mathbf{x} - \mathbf{y}^s}{L} \right) \right].
\end{aligned}$$

We see the same random peak dancing as before, which is mitigated in the slowness plane by the window $\hat{\Psi}$ of width chosen appropriately as $1/(\omega_o X(\omega_o))$. The peak dancing in t is visible in the case $B \gg \Omega$, but it is mitigated in the imaging function by the convolution with the window Φ . This can be seen from (172), once we use the Gaussian window (142) and integrate in t and t'

$$\begin{aligned}
\mathcal{J}(\vec{\mathbf{y}}^s) \approx & \frac{N^4 X^4(\omega_o) (2B^2/\Omega^2 + 1)^{-1/2}}{\sqrt{2\pi}(4\pi L)^4 |\mathcal{A}|^4} \\
& \iint_{\mathcal{A}} d\mathbf{x} d\mathbf{x}' \hat{\Psi} \left[\omega_o X(\omega_o) \left(\nabla_{\mathbf{x}} \tau((\mathbf{x}, L), \vec{\mathbf{y}}) - \frac{\mathbf{x} - \mathbf{y}^s}{L} \right) \right] \\
& \times \hat{\Psi} \left[\omega_o X(\omega_o) \left(\nabla_{\mathbf{x}} \tau((\mathbf{x}', L), \vec{\mathbf{y}}) - \frac{\mathbf{x}' - \mathbf{y}^s}{L} \right) \right] \\
& \times e^{-\frac{B^2}{2B^2/\Omega^2 + 1} [\tau((\mathbf{x}, L), \vec{\mathbf{y}}) + \tau((\mathbf{x}', L), \vec{\mathbf{y}}) - \tau_o((\mathbf{x}, L), \vec{\mathbf{y}}) - \tau_o((\mathbf{x}', L), \vec{\mathbf{y}})]^2}. \quad (173)
\end{aligned}$$

Numerical Simulations

We illustrate with numerical results the point spread function of CINT with active arrays. The array data $\hat{p}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)$ is simulated with the random travel time approximation (78) of the Green's function in a medium with wave speed modeled by (73) for a constant $\bar{c} = c_o$. The standard deviation of the fluctuations of $c(\vec{\mathbf{x}})$ is either $\sigma = 0.04\%$ or $\sigma = 0.1\%$, and the correlation length is $\ell = 100\lambda_o$. The array has aperture $a = 4\ell$. It is centered at the cross-range location \mathbf{y} of the reflector, and at range $L = 99\ell$ from it. There are $N = 101$ sensors in each direction. All

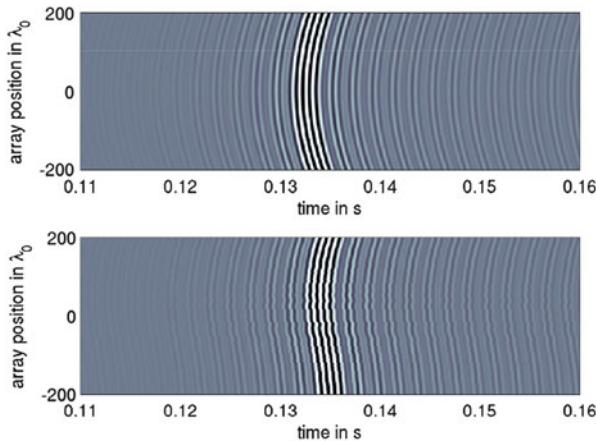

Fig. 8 Traces $p(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)$ in the homogeneous medium (*top*) and in one realization of the random medium, for $\sigma = 0.1\%$. The traces are similar, except for the wavefront distortion noted in the *bottom plot*

of them are receivers except for the central one, which is also a source. It emits a pulse $f(t)$ that is a modulated sinc function, with constant Fourier coefficients in the bandwidth [125, 175] kHz. The central wavelength is $\lambda_o = 2$ cm.

We display in Fig. 8 the simulated data (traces) $p(t, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)$ at the receiver locations along one cross-range line in the array, with the source in the middle. Each trace is obtained by Fourier synthesis of $\hat{p}(\omega, \vec{\mathbf{x}}_r, \vec{\mathbf{x}}_s)$, for a discretization of the bandwidth in one hundred equidistant frequency intervals of 0.5 kHz. The top plot in Fig. 8 is for the homogeneous medium and the bottom plot for one realization of the random medium, with $\sigma = 0.1\%$. The traces look similar, but we note in the bottom plot that the wavefront is distorted.

We show in Fig. 9 the sample estimates of the mean Kirchhoff migration and CINT imaging functions, normalized by the standard deviation at their peak, which is at the reflector location \bar{y} . We display the square root for the CINT image, so we can compare the resolution of the two methods. If we did not have the windows in CINT, the imaging function would be the square of the migration one, which is why we take the square root in Fig. 9. We note that, as predicted by the theory, the CINT image is blurrier than the migration one, but it has a much higher SNR at \bar{y} . Kirchhoff migration gives a very small SNR, so the images are expected to change a lot with the realizations of the random medium. The SNR of the CINT image is of order one in this simulation because the aperture a is not very large. Thus, the CINT images change with the realizations as well, but the changes are smaller and never exceed the mean. The peak is expected to stay close to \bar{y} , independent of the realization. This is illustrated in Fig. 10 where we display the migration images (top row) and CINT images (bottom row) in three realizations of the random medium.

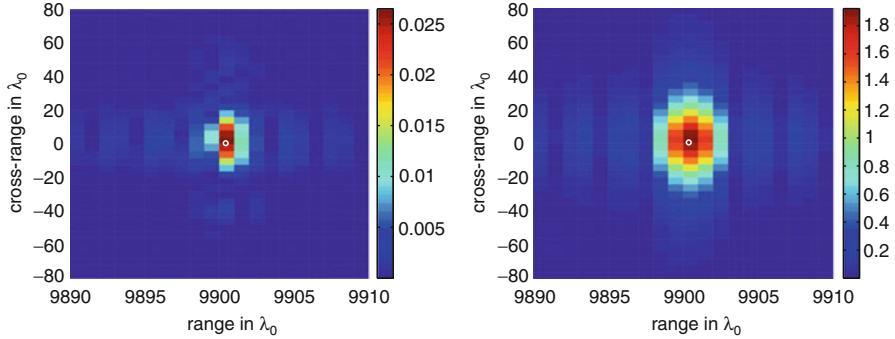

Fig. 9 The mean of the Kirchhoff migration (*left*) and square root of CINT images (*right*) divided by their standard deviation at the peak. The *colorbar* shows that the SNR of CINT is approximately 100 times larger than that of Kirchhoff migration. The axes are range and cross-range in λ_0 , measured from the source at the array. The true reflector location is in the middle of the search domain, and it is indicated with the *white circle*

The migration images are quite different from each other: the first image is not as well focused as the others and the peak changes its location. The CINT images change much less with the realization and are very similar to their mean displayed in the right plot in Fig. 9.

9 Appendix 1: Second Moments of the Random Travel Time

We obtain by direct calculation from (75) and (84) that

$$\begin{aligned} \mathbb{E} \left[v(\vec{x}, \vec{y}) v(\vec{x}', \vec{y}') \right] &= \frac{\mathcal{L}}{\sqrt{2\pi}\ell} \int_0^1 dt \int_0^1 dt' \\ \mathbb{E} \left[\mu \left(\frac{(1-t)\vec{y}}{\ell} + \frac{t\vec{x}}{\ell} \right) \mu \left(\frac{(1-t')\vec{y}'}{\ell} + \frac{t'\vec{x}'}{\ell} \right) \right] \\ &= \frac{\mathcal{L}}{\sqrt{2\pi}\ell} \int_0^1 dt \int_0^1 dt' \mathcal{R} \left[\frac{(t'-t)(\vec{x} - \vec{y})}{\ell} + \frac{(1-t')(\vec{y}' - \vec{y}) + t'(\vec{x}' - \vec{x})}{\ell} \right] \\ &= \frac{1}{\sqrt{2\pi}} \int_0^1 dt' \int_{-\mathcal{L}/\ell}^{\mathcal{L}/\ell} d\tilde{t} \mathcal{R} \left[\tilde{t} \vec{n} + \frac{(1-t')(\vec{y}' - \vec{y}) + t'(\vec{x}' - \vec{x})}{\ell} \right], \end{aligned} \quad (174)$$

where we made the change of variables $(t, t') \rightsquigarrow (\tilde{t}, t')$ with

$$t' - t = \frac{\ell}{\mathcal{L}} \tilde{t}.$$

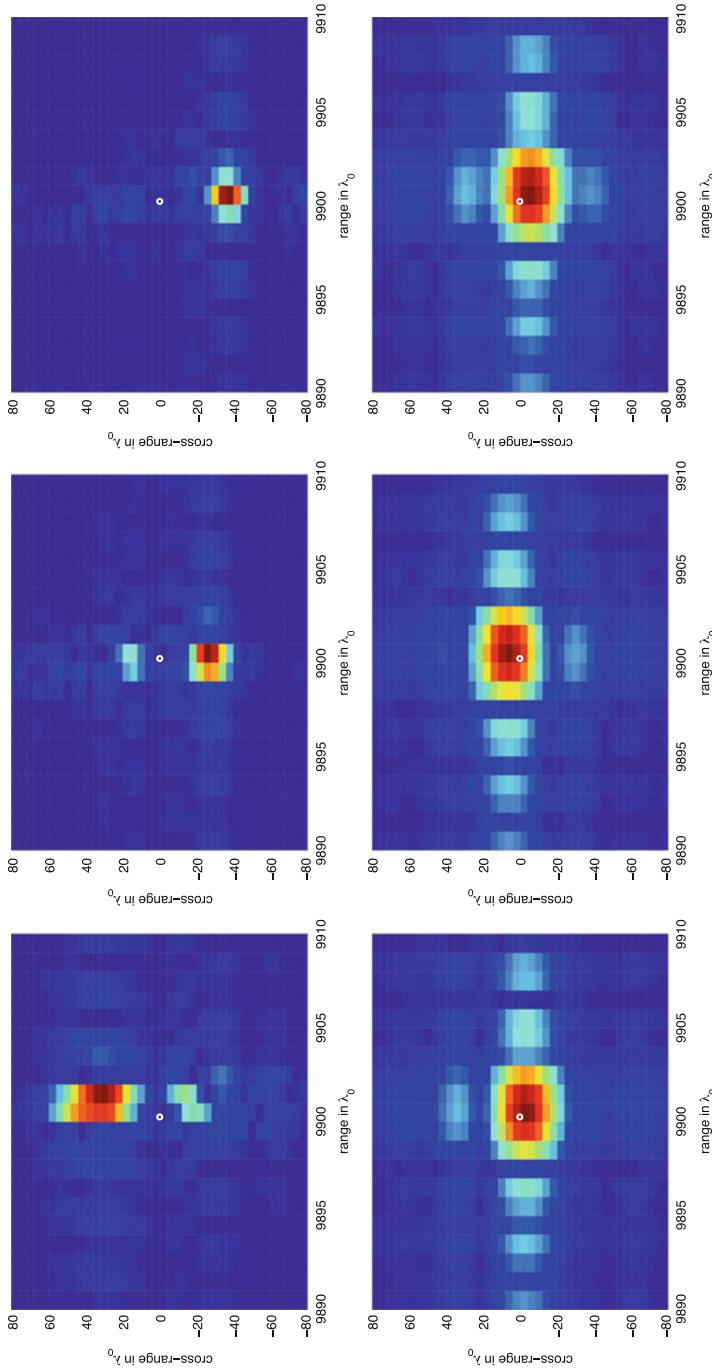

Fig. 10 *Top row:* Kirchhoff migration images in three realizations of the random medium. *Bottom row:* Square root of the CINT images in the same three realizations of the random medium. The axes are range and cross-range in λ_0 , measured from the source in the array

We can rewrite the result as

$$\begin{aligned} \mathbb{E} [v(\vec{\mathbf{x}}, \vec{\mathbf{y}}) v(\vec{\mathbf{x}}', \vec{\mathbf{y}}')] &= \int_0^1 dt' \int_{-\infty}^{\infty} \frac{d\tilde{t}}{\sqrt{2\pi}} 1_{[-\mathcal{L}/\ell, \mathcal{L}/\ell]}(\tilde{t}) \mathcal{R} \\ &\quad \left[\tilde{t} \vec{\mathbf{n}} + \frac{(1-t')(\vec{\mathbf{y}}' - \vec{\mathbf{y}}) + t'(\vec{\mathbf{x}}' - \vec{\mathbf{x}})}{\ell} \right], \end{aligned} \quad (175)$$

and note that the integrand converges to $\mathcal{R} \left[\tilde{t} \vec{\mathbf{n}} + \frac{(1-t')(\vec{\mathbf{y}}' - \vec{\mathbf{y}}) + t'(\vec{\mathbf{x}}' - \vec{\mathbf{x}})}{\ell} \right]$ pointwise, from below, as $\mathcal{L}/\ell \rightarrow \infty$. Since \mathcal{R} is integrable by assumption, we obtain from the Lebesgue dominated convergence theorem that

$$\begin{aligned} \mathbb{E} [v(\vec{\mathbf{x}}, \vec{\mathbf{y}}) v(\vec{\mathbf{x}}', \vec{\mathbf{y}}')] &\approx \lim_{\mathcal{L}/\ell \rightarrow \infty} \int_0^1 dt' \int_{-\infty}^{\infty} \frac{d\tilde{t}}{\sqrt{2\pi}} 1_{[-\mathcal{L}/\ell, \mathcal{L}/\ell]}(\tilde{t}) \\ &\quad \mathcal{R} \left[\tilde{t} \vec{\mathbf{n}} + \frac{(1-t')(\vec{\mathbf{y}}' - \vec{\mathbf{y}}) + t'(\vec{\mathbf{x}}' - \vec{\mathbf{x}})}{\ell} \right] \\ &= \int_{-\infty}^{\infty} \frac{d\tilde{t}}{\sqrt{2\pi}} \mathcal{R} \left[\tilde{t} \vec{\mathbf{n}} + \frac{(1-t')(\vec{\mathbf{y}}' - \vec{\mathbf{y}}) + t'(\vec{\mathbf{x}}' - \vec{\mathbf{x}})}{\ell} \right], \end{aligned} \quad (176)$$

as stated in (86).

10 Appendix 2: Second Moments of the Local Cross-Correlations

Using the Gaussian windows in (147), we obtain

$$\begin{aligned} \mathbb{E} \left[\left| \mathcal{C}(\bar{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}', \vec{\mathbf{y}}), \tilde{\tau}_o(\vec{\mathbf{x}}, \vec{\mathbf{x}}', \vec{\mathbf{y}}); \vec{\mathbf{x}}, \vec{\mathbf{x}}') \right|^2 \right] &= \frac{2\pi}{(32\pi^3 L^2)^2 B^4} \iint_{-\infty}^{\infty} \\ d\omega_1 d\omega_2 e^{-\frac{(\omega_1-\omega_0)^2}{B^2} - \frac{(\omega_2-\omega_0)^2}{B^2}} &\times \iint_{-\infty}^{\infty} \\ d\tilde{\omega}_1 d\tilde{\omega}_2 e^{-\frac{(\tilde{\omega}_1^2 + \tilde{\omega}_2^2)}{2} \left(\frac{1}{\Omega_\Phi^2} + \frac{1}{2B^2} \right)} & \\ \mathbb{E} \left[e^{i \left(\omega_1 - \omega_2 + \frac{\tilde{\omega}_1 - \tilde{\omega}_2}{2} \right) v_\tau(\vec{\mathbf{x}}, \vec{\mathbf{y}}) - i \left(\omega_1 - \omega_2 - \frac{\tilde{\omega}_1 - \tilde{\omega}_2}{2} \right) v_\tau(\vec{\mathbf{x}}', \vec{\mathbf{y}})} \right], \end{aligned} \quad (177)$$

and it remains to evaluate the expectation. Because v_τ is approximately Gaussian, we have

$$\mathbb{E} \left[e^{i \left(\Delta\omega + \frac{\Delta\tilde{\omega}}{2} \right) v_\tau(\vec{\mathbf{x}}, \vec{\mathbf{y}}) - i \left(\Delta\omega - \frac{\Delta\tilde{\omega}}{2} \right) v_\tau(\vec{\mathbf{x}}', \vec{\mathbf{y}})} \right] \approx e^{-\frac{1}{2} \mathbb{E} \left[\left(\Delta\omega + \frac{\Delta\tilde{\omega}}{2} \right) v_\tau(\vec{\mathbf{x}}, \vec{\mathbf{y}}) - \left(\Delta\omega - \frac{\Delta\tilde{\omega}}{2} \right) v_\tau(\vec{\mathbf{x}}', \vec{\mathbf{y}}) \right]^2},$$

where we let $\Delta\omega = \omega_1 - \omega_2$ and $\Delta\tilde{\omega} = \tilde{\omega}_1 - \tilde{\omega}_2$. The exponent follows from (84) and (91)

$$\begin{aligned} \mathbb{E} \left[\left(\Delta\omega + \frac{\Delta\tilde{\omega}}{2} \right) v_\tau(\vec{x}, \vec{y}) - \left(\Delta\omega - \frac{\Delta\tilde{\omega}}{2} \right) v_\tau(\vec{x}', \vec{y}) \right]^2 &\approx \frac{2[(\Delta\omega)^2 + \frac{(\Delta\tilde{\omega})^2}{4}]}{\Omega^2} \\ &\quad \left[1 - \int_0^1 dt e^{-\frac{t^2|\vec{x}-\vec{x}'|^2}{2\ell^2}} \right]. \end{aligned}$$

Substituting in (177), we obtain

$$\begin{aligned} \mathbb{E} \left[|\mathcal{C}(\bar{\tau}_o(\vec{x}, \vec{x}', \vec{y}), \tilde{\tau}_o(\vec{x}, \vec{x}', \vec{y}); \vec{x}, \vec{x}')|^2 \right] \\ \approx \frac{2\pi}{(32\pi^3 L^2)^2 B^4} \iint_{-\infty}^{\infty} d\omega_1 d\omega_2 e^{-\frac{(\omega_1-\omega_0)^2}{B^2} - \frac{(\omega_2-\omega_0)^2}{B^2}} \\ \times \iint_{-\infty}^{\infty} d\tilde{\omega}_1 d\tilde{\omega}_2 e^{-\frac{(\tilde{\omega}_1^2+\tilde{\omega}_2^2)}{2} \left(\frac{1}{\Omega_\Phi^2} + \frac{1}{2B^2} \right) - \left[\frac{(\omega_1-\omega_2)^2}{\Omega^2} + \frac{(\tilde{\omega}_1-\tilde{\omega}_2)^2}{4\Omega^2} \right]} \left[1 - \int_0^1 dt e^{-\frac{t^2|\vec{x}-\vec{x}'|^2}{2\ell^2}} \right], \end{aligned} \quad (178)$$

and after evaluating the Gaussian integrals, we obtain (149).

11 Conclusion

This article reviews basic results on coherent array imaging in random media. The random model is motivated by the uncertainty of the small-scale fluctuations of the wave speed in complex media with numerous inhomogeneities. We consider a simple model of wave propagation in random media that captures nevertheless canonical scattering effects on the coherent part of the waves, and consider two imaging methods: migration imaging and CINT imaging. They are both related to an approximation of the solution of the least squares data fit formulation of the inverse problem. Migration imaging is superficially connected to the time reversal process, in the sense that it involves the back-propagation to the imaging region of the time reversed waves measured at the receivers in the array. However, the back-propagation is in a surrogate medium, not in the real one as in the time reversal process, because the medium is not known in imaging. We know only its smooth part, but not its inhomogeneities, which is why we model it as random. This subtle difference between imaging and time reversal has profound effects in random media. We give an explicit and self-contained study of these effects and show that migration imaging is not useful when the waves propagate longer than a scattering mean-free path in random media. The CINT method images by back-propagating to the imaging region local cross-correlations of the measurements at the array. We analyze in detail these local cross-correlations in order to explain why they are useful in

imaging. Moreover, we give an explicit resolution analysis of CINT, which includes an assessment of its statistical stability, and illustrate the results with numerical simulations.

Acknowledgments This article reviews results obtained in collaboration with Josselin Garnier from Université Paris VII, George Papanicolaou from Stanford University, and Chrysoula Tsogka from University of Crete. These results are published in [8, 9, 11, 12]. The work of L. Borcea was partially supported by the AFSOR Grant FA9550-12-1-0117 and the ONR Grant N00014-14-1-0077.

Abstract

The theme of this chapter is statistical methods in imaging, with a marked emphasis on the Bayesian perspective. The application of statistical notions and techniques in imaging requires that images and the available data are redefined in terms of random variables, the genesis and interpretation of randomness playing a major role in deciding whether the approach will be along frequentist or Bayesian guidelines. The discussion on image formation from indirect information, which may come from non-imaging modalities, is coupled with an overview of how statistics can be used to overcome the hurdles posed by the inherent ill-posedness of the problem. The statistical counterpart to classical inverse problems and regularization approaches to contain the potentially disastrous effects of ill-posedness is the extraction and implementation of complementary information in imaging algorithms. The difficulty in expressing quantitative and uncertain notions about the imaging problem at hand in qualitative terms, which is a major challenge in a deterministic context, can be more easily overcome once the problem is expressed in probabilistic terms. An outline of how to translate some typical qualitative traits into a format which can be utilized by statistical imaging algorithms is presented. In line with the Bayesian paradigm favored in this chapter, basic principles for the construction of priors and likelihoods are presented, together with a discussion of numerous computational statistics algorithms, including maximum likelihood estimators, maximum a posteriori and conditional mean estimators, expectation maximization, Markov chain Monte Carlo, and hierarchical Bayesian models. Rather than aiming to be a comprehensive survey, the present chapter hopes to convey a wide and opinionated overview of statistical methods in imaging.

1 Introduction

Images, alone or in sequences, provide a very immediate and effective way of transferring information, as the human eye–brain complex is extremely well adapted at extracting quickly their salient features, let them be edges, textures, anomalies, or movement. While the amount of information that can be compressed in an image is tremendously large and varied, the image processing ability of the human eye is so advanced to outperform the most advanced of algorithms. One of the reasons why the popularity of statistical tools in imaging continues to grow is the flexibility that this modality offers when it comes to utilizing qualitative attributes of the images or to recover them from indirect, corrupt specimens. The utilization of qualitative clues to augment scarce data is akin to the process followed by the eye–brain system.

Statistics, which according to Pierre-Simon Laplace, is “common sense expressed in terms of numbers,” is well suited for quantifying qualitative attributes. The opportunity to augment poor quality data with complementary information which may be based on our preconception of what we are looking for or on

information coming from sources other than the data makes statistical methods particularly attractive in imaging applications.

In this chapter, we present a brief overview of some of the key concepts and most popular algorithms in statistical imaging, highlighting the similarity and the differences with the closest deterministic counterparts. A particular effort is made to demonstrate that the statistical methods lead to new ideas and algorithms that the deterministic methods do not give.

2 Background

Images in the Statistical Setting

The mathematical vessel that we will use here to describe a black and white image is a matrix with nonnegative entries, each representing the light intensity at one pixel of the discretized image. Color images can be thought of as the result of superimposing a few color intensity matrices; in most application, a color image is represented by three matrices, for example, encoding the red, green, and blue intensity at each pixel. While color imaging applications can also be approached with statistical methods, here we will only consider gray-scale images. Thus, an image \mathbf{X} is represented as a matrix

$$\mathbf{X} = [x_{ij}], \quad 1 \leq i \leq n, \quad 1 \leq j \leq m, \quad x_{ij} \geq 0.$$

In our treatment, we will not worry about the range of the image pixel values, assuming that, if necessary, the values are appropriately normalized. Notice that this representation tacitly assumes that we restrict our discussion to rectangular images discretized into rectangular arrays of pixels. This hypothesis is neither necessary nor fully justified, but it simplifies the notation in the remainder of the chapter. In most imaging algorithms, the first step consists of storing the image into a vector by reshaping the rectangular matrix. We use here a columnwise stacking, writing

$$\mathbf{X} = [x^{(1)} \ x^{(2)} \ \dots \ x^{(m)}], \quad x^{(j)} \in \mathbb{R}^n, \quad 1 \leq j \leq m,$$

and further

$$x = \text{vec}(\mathbf{X}) = \begin{bmatrix} x^{(1)} \\ \vdots \\ x^{(m)} \end{bmatrix} \in \mathbb{R}^N, \quad N = n \times m.$$

Images can be either directly observed or represent a function of interest, as is, for example, the case for tomographic images.

Randomness, Distributions, and Lack of Information

We start this section by introducing some notations. A multivariate random variable $X : \Omega \rightarrow \mathbb{R}^N$ is a measurable mapping from a probability space Ω equipped with a σ -algebra and a probability measure P . The elements of \mathbb{R}^N , as well as the realizations of X , are denoted by lowercase letters, that is, for $\omega \in \Omega$ given, $X(\omega) = x \in \mathbb{R}^N$. The probability distribution μ_X is the measure defined as

$$\mu_X(B) = P(X^{-1}(B)), \quad B \subset \mathbb{R}^N \text{ measurable.}$$

If μ_X is absolutely continuous with respect to the Lebesgue measure, there is a measurable function π_X , the Radon–Nikodym derivative of μ_X with respect to the Lebesgue measure such that

$$\mu_X(B) = \int_B \pi_X(x) dx.$$

For the sake of simplicity, we shall assume that all the random variables define probability distributions which are absolutely continuous with respect to the Lebesgue measure.

Consider two random variables $X : \Omega \rightarrow \mathbb{R}^N$ and $Y : \Omega \rightarrow \mathbb{R}^M$. The joint probability density is defined first over Cartesian products,

$$\mu_{X,Y}(B \times D) = P(X^{-1}(B) \cap Y^{-1}(D)),$$

and then extended to the whole product σ -algebra over $\mathbb{R}^N \times \mathbb{R}^M$. Under the assumption of absolute continuity, the joint density can be written as

$$\mu_{X,Y}(B \times D) = \int_B \int_D \pi_{X,Y}(x, y) dy dx,$$

where $\pi_{X,Y}$ is a measurable function. This definition extends naturally to the case of more than two random variables.

Since the notation just introduced here gets quickly rather cumbersome, we will simplify it by dropping the subscripts, writing $\pi_{X,Y}(x, y) = \pi(x, y)$, that is, letting x and y be at the same time variables and indicators of their parent uppercase random variables. Furthermore, since the ordering of the random variables is irrelevant – indeed, $P(X^{-1}(B) \cap Y^{-1}(D)) = P(Y^{-1}(D) \cap X^{-1}(B))$ – we will occasionally interchange the roles of x and y in the densities, without assuming that the probability densities should be symmetric in x and y . In other words, we will use π as a generic symbol for “probability density.”

With these notations, given two random variables X and Y , define the marginal densities

$$\pi(x) = \int_{\mathbb{R}^M} \pi(x, y) dy, \quad \pi(y) = \int_{\mathbb{R}^N} \pi(x, y) dx,$$

which express the probability densities of X and Y , respectively, on their own, while the other variable is allowed to take on any value. By fixing y , and assuming that $\pi(y) \neq 0$, we have that

$$\int_{\mathbb{R}^N} \frac{\pi(x, y)}{\pi(y)} dx = 1;$$

hence, the nonnegative function

$$x \mapsto \pi(x \mid y) \stackrel{\text{def}}{=} \frac{\pi(x, y)}{\pi(y)} \quad (1)$$

defines a probability distribution for X referred to as the conditional density of X , given $Y = y$. Similarly, we define the conditional density of Y given $X = x$ as

$$\pi(y \mid x) \stackrel{\text{def}}{=} \frac{\pi(x, y)}{\pi(x)}. \quad (2)$$

This rather expedite way of defining the conditional densities does not fully explain why this interpretation is legitimate; a more rigorous explanation can be found in textbooks on probability theory [8, 18].

The concept of probability measure does not require any further interpretation to yield a meaningful framework for analysis, and this indeed is the viewpoint of theoretical probability. When applied to real-world problems, however, an interpretation is necessary, and this is exactly where the opinions of statisticians start to diverge. In frequentist statistics, the probability of an event is its asymptotic relative frequency of occurrence as the number of repeated experiments tend to infinity, and the probability density can be thought of as a limit of histograms. A different interpretation is based on the concept of information. If the value of a quantity is either known or it is at potentially retrievable from the available information, there is no need to leave the deterministic realm. If, on the other hand, the value of a quantity is uncertain in the sense that the available information is insufficient to determine it, to view it as a random variable appears natural. In this interpretation of randomness, it is immaterial whether the lack of information is contingent (“imperfect measurement device, insufficient sampling of data”) or fundamental (“quantum physical description of an observable”). It should also be noted that the information, and therefore the concept of probability, is subjective, as the value of a quantity may be known to one observer and unknown to another [14, 18]. Only in the latter case the concept of probability is needed. The interpretation of probability in this chapter follows mostly the subjective, or Bayesian tradition, although most of the time the distinction is immaterial. Connections to non-Bayesian statistics are made along the discussion.

Most imaging problems can be recast in the form of a statistical inference problem. Classically, inverse problems are stated as follows: *Given an observation of a vector $y \in \mathbb{R}^M$, find an estimate of the vector $x \in \mathbb{R}^N$, based on the forward*

model mapping x to y . Statistical inference, on the other hand, is concerned with identifying a probability distribution that the observed data is presumably drawn from. In the frequentist statistics, the observation y is seen as a realization of a random variable Y , the unknown x being a deterministic parameter that determines the underlying distribution $\pi(y | x)$, or *likelihood density*, and hence the estimation of x is the object of interest. In contrast, in the Bayesian setting, both variables x and y are first extended to random variables, Y and X , respectively, as discussed in more detail in the following sections. The marginal density $\pi(x)$, which is independent of the observation y , is called the *prior density* and denoted by $\pi_{\text{prior}}(x)$, while the likelihood is the conditional density $\pi(y | x)$. Combining the formulas (1) and (2), we obtain

$$\pi(x | y) = \frac{\pi_{\text{prior}}(x)\pi(y | x)}{\pi(y)},$$

which is the celebrated Bayes' formula [3]. The conditional distribution $\pi(x | y)$ is the *posterior distribution* and, in the Bayesian statistical framework, the solution of the inverse problem.

Imaging Problems

A substantial body of classical imaging literature is devoted to problems where the data consists of an image, represented here as a vector $y \in \mathbb{R}^M$ that is either a noisy, blurred, or otherwise corrupt version of the image $x \in \mathbb{R}^N$ of primary interest. The canonical model for this class of imaging problems is

$$y = \mathbf{A}x + \text{“noise,”} \quad (3)$$

where the properties of the matrix \mathbf{A} depend on the imaging problem at hand. A more general imaging problems is of the form

$$y = F(x) + \text{“noise,”} \quad (4)$$

where the function $F : \mathbb{R}^N \mapsto \mathbb{R}^M$ may be a nonlinear function and the data y need not even represent an image. This is a common setup in medical imaging applications with a nonlinear forward model.

In classical, nonstatistical framework, imaging problems, and more generally, inverse problems, are often, somewhat arbitrarily, classified as being linear or nonlinear, depending on whether the forward model F in (4) is linear or nonlinear. In the statistical framework, this classification is rather irrelevant. Since probability densities depend not only on the forward map but also on the noise and, in the Bayesian case, the prior models, even a linear forward map can result in a nonlinear

estimation problem. We review some widely studied imaging problems to highlight this point.

1. *Denoising*: Denoising refers to the problem of removing noise from an image which is otherwise deemed to be a satisfactory representation of the information. The model for denoising can be identified with (3), with $M = N$ and the identity $\mathbf{A} = \mathbf{I} \in \mathbb{R}^{N \times N}$ as forward map.
2. *Deblurring*: Deblurring is the process of removing a blur, due, for example, to an imaging device being out of focus, to motion of the object during imaging (“motion blur”), or to optical disturbances in atmosphere during image formation. Since blurred images are often contaminated by exogenous noise, denoising is an integral part of the deblurring process. Given the image matrix $\mathbf{X} = [x_{ij}]$, the blurring is usually represented as

$$y_{ij} = \sum_{k,\ell} a_{ij,k\ell} x_{k\ell} + \text{“noise.”}$$

Often, but not without loss of generality, the blurring matrix can be assumed to be a convolution kernel,

$$a_{ij,k\ell} = a_{i-k,j-\ell},$$

with the obvious abuse of notations. It is a straightforward matter to arrange the elements, so that the above problem takes on the familiar matrix–vector form $\mathbf{y} = \mathbf{Ax}$, and in the presence of noise, the model coincides with (3).

3. *Inpainting*: Here, it is assumed that part of the image x is missing due to an occlusion, a scratch, or other damages. The problem is to paint in the occlusion based on the visible part of the image. In this case, the matrix \mathbf{A} in the linear model (3) is a sampling matrix, picking only those pixels of $x \in \mathbb{R}^N$ that are present in $y \in \mathbb{R}^M$, $M < N$.
4. *Image formation*: Image formation is the process of translating data into the form of an image. The process is common in medical imaging, and the description of the forward model connecting the sought image to data may involve linear or nonlinear transformations. An example of a linear model arises in tomography: The image is explored one line at the time, in the sense that the data consist of line integrals indirectly measuring the amount of radiation absorbed in the trajectory from source to detector or the number of photons emitted at locations along the trajectory between pairs of detectors. The problem is of the form (3). An example of a nonlinear imaging model (4) arises in near-infrared optical tomography, in which the object of interest is illuminated by near-infrared light sources, and the transmitted and scattered light intensity is measured in order to form an image of the interior optical properties of the body.

Some of these examples will be worked out in more details below.

3 Mathematical Modeling and Analysis

Prior Information, Noise Models, and Beyond

The goal in Bayesian statistical methods in imaging is to identify and explore probability distributions of images rather than looking for single images, while in the non-Bayesian framework, one seeks to infer on deterministic parameter vectors defining the distribution that the observations are drawn from. The main player in non-Bayesian statistics is the likelihood function, in the notation of section “Randomness, Distributions and Lack of Information,” $\pi(y | x)$, where $y = y_{\text{observed}}$. In Bayesian statistics, the focus is on the posterior density $\pi(x | y)$, $y = y_{\text{observed}}$, the likelihood function being a part of it as indicated by Bayes’ formula.

We start the discussion with the Bayesian concept of prior distribution, the non-Bayesian modeling paradigm being discussed in connection with the likelihood function.

Accumulation of Information and Priors

To the question, what should be in a prior for an imaging problem, the best answer is whatever can be built using available information about the image which can supplement the measured data. The information to be accounted by the prior can be gathered in many different ways. Any visually relevant characteristic of the sought image is suitable for a prior, including but not limited to texture, light intensity, and boundary structure. Although it is often emphasized that in a strict Bayesian framework the prior and the likelihood must be constructed separately, in several imaging problems, the setup may be impractical, and the prior and likelihood need to be set up simultaneously. This is the case, for example, when the noise is correlated with the signal itself. Furthermore, some algorithms may contain intermediate steps that formally amount to updating of the a priori belief, a procedure that may seem dubious in the traditional formal Bayesian setting but can be justified in the framework of hierarchical models. For example, in the restoration of images with sharp contrasts from severely blurred, noisy copies, an initially very vague location of the gray-scale discontinuities can be made more precise by extrapolation from intermediate restorations, leading to a Bayesian learning model.

It is important to understand that in imaging, the use of complementary information to improve the performance of the algorithms at hand is a very natural and widespread practice and often necessary to link the solution of the underlying mathematical problem to the actual imaging application. There are several constituents of an image that are routinely handled under the guidance of a prior belief even in fully deterministic settings. A classical example is the assignment of

boundary conditions for an image, a problem which has received a lot of attention over the span of a couple of decades (see, e.g., [21] and references therein). In fact, since it is certainly difficult to select the most appropriate boundary condition for a blurred image, ultimately the choice is based on a combination of a priori belief and algorithmic considerations. The implementation of boundary conditions in deterministic algorithms can therefore be interpreted as using a prior, expressing an absolute belief in the selected boundary behavior. The added flexibility which characterizes statistical imaging methodologies makes it possible to import in the algorithm the postulated behavior of the image at the boundary with a certain degree of uncertainty.

The distribution of gray levels within an image and the transition between areas with different gray-scale intensities are the most likely topics of a priori beliefs, hence primary targets for priors. In the nonstatistical imaging framework, a common choice of regularization, for the underlying least squares problems is a regularization functional, which penalizes growth in the norm of the derivative of the solution, thus discouraging solutions with highly oscillatory components. The corresponding statistical counterpart is a Markov model, based, for example, on the prior assumption that the gray-scale intensity at each pixel is a properly weighted average of the intensities of its neighbors plus a random innovation term which follows a certain statistical distribution. As an example, assuming a regular quadrilateral grid discretization, the typical local model can be expressed in terms of probability densities of pixel values X_j conditioned on the values of its neighboring pixels labeled according to their relative position to X_j as X_{up} , X_{down} , X_{left} , and X_{right} , respectively. The conditional distribution is derived by writing

$$\begin{aligned} X_j | (X_{\text{up}} = x_{\text{up}}, X_{\text{down}} = x_{\text{down}}, X_{\text{left}} = x_{\text{left}}, X_{\text{right}} = x_{\text{right}}) \\ = \frac{1}{4}(x_{\text{up}} + x_{\text{down}} + x_{\text{left}} + x_{\text{right}}) + \Phi_j, \end{aligned} \quad (5)$$

where Φ_j is a random innovation process. For boundary pixels, an appropriate modification reflecting the a priori belief of the extension of the image outside the field of view must be incorporated. In a large variety of application, Φ_j is assumed to follow a normal distribution

$$\Phi_j \sim \mathcal{N}\left(0, \sigma_j^2\right),$$

the variance σ_j^2 reflecting the expected deviation from the average intensity of the neighboring pixels. The Markov model can be expressed in matrix–vector form as

$$\mathbf{L}\mathbf{X} = \Phi,$$

where the matrix \mathbf{L} is the five-point stencil discretization of the Laplacian in two dimensions and the vector $\Phi \in \mathbb{R}^N$ contains the innovation terms Φ_j . As we assume the innovation terms to be independent, the probability distribution of Φ is

$$\Phi \sim \mathcal{N}(0, \Sigma), \quad \Sigma = \begin{bmatrix} \sigma_1^2 & & & \\ & \sigma_2^2 & & \\ & & \ddots & \\ & & & \sigma_N^2 \end{bmatrix},$$

and the resulting prior model is a *second-order Gaussian smoothness prior*,

$$\pi_{\text{prior}}(x) \propto \exp\left(-\frac{1}{2}\|\Sigma^{-1/2}\mathbf{L}x\|^2\right).$$

Observe that the variances σ_j^2 allow a spatially inhomogeneous a priori control of the texture of the image. Replacing the averaging weights $1/4$ in (5) by more general weights p_k , $1 \leq k \leq 4$ leads to a smoothness prior with directional sensitivity. Random draws from such anisotropic Gaussian priors are shown in Fig. 1, where each pixel with coordinate vector r_j in a quadrilateral grid has eight neighboring pixels with coordinates r_j^k , and the corresponding weights p_k are chosen as

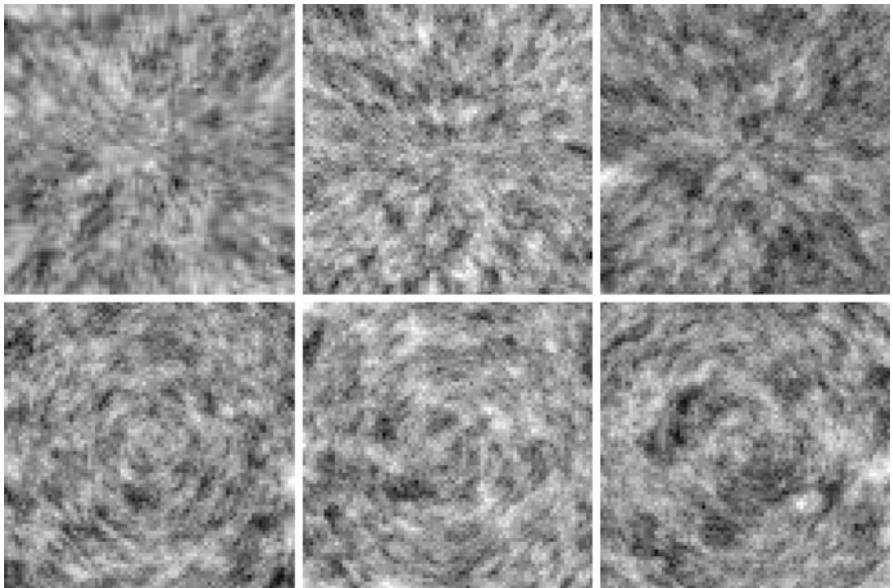

Fig. 1 Random draws from anisotropic Markov models. In the *top row*, the Markov model assumes stronger dependency between neighboring pixels in the radial than in angular direction, while in the *bottom row*, the roles of the directions are reversed. See text for a more detailed discussion

$$p_k = \frac{1}{\tau} \frac{\left(v_j^\top (r_j - r_j^k) \right)^2}{|r_j - r_j^k|^2}, \quad \tau = 1.1,$$

and the unit vector v_j is chosen either as a vector pointing out of the center of the image (top row) or in a perpendicular direction (bottom row). The former choice thus assumes that pixels are more strongly affected by the adjacent values in the radial direction, while in the latter case, they have less influence than those in the angular direction. The factor τ is added to make the matrix diagonally dominated.

The just described construction of the smoothness prior is a particular instance of priors based on the assumption that the image is a *Markov random field*, (MRF). Similarly to the four-point average example, Markov random fields assume that the conditional probability distribution of a single pixel value X_j conditioned on the remaining image depends only on the neighbors of X_j ,

$$\pi(x_j | x_k, k \neq j) = \pi(x_j | x_k \in N_j),$$

where N_j is the list of neighbor pixels of X_j , such as the four adjacent pixels in the model (5). In fact, the *Hammersley–Clifford theorem* (see [5]) states that prior distributions of MRF models are of the form

$$\pi_{\text{prior}}(x) \propto \exp \left(- \sum_{j=1}^N V_j(x) \right),$$

where the function $V_j(x)$ depends only on x_j and its neighbors. The simplest model in this family is a Gaussian white noise prior, where $N_j = \emptyset$ and $V_j(x) = x_j^2/(2\sigma^2)$, that is,

$$\pi_{\text{prior}}(x) \propto \exp \left(- \frac{1}{2\sigma^2} \|x\|^2 \right).$$

Observe that this prior assumes mutual independency of the pixels, which has qualitative repercussions on the images based on it.

There is no theoretical reason to restrict the MRFs to Gaussian fields, and in fact, some of the non-Gaussian fields have had a remarkable popularity and success in the imaging context. Two non-Gaussian priors are particularly worth mentioning here, the ℓ^1 -prior, where $N_j = \emptyset$ and $V_j(x) = \alpha|x_j|$, that is,

$$\pi_{\text{prior}}(x) \propto \exp(-\alpha\|x\|_1), \quad \|x\|_1 = \sum_{j=1}^N |x_j|,$$

and the closely related total variation (TV) prior,

$$\pi_{\text{prior}}(x) \propto \exp(-\alpha \text{TV}(x)), \quad \text{TV}(x) = \sum_{j=1}^N V_j(x),$$

with

$$V_j(x) = \frac{1}{2} \sum_{k \in N_j} |x_j - x_k|.$$

The former is suitable for imaging sparse images, where all but few pixels are believed to coincide with the background level that is set to zero. The latter prior is particularly suitable for blocky images, that is, for images consisting of piecewise smooth simple shapes. There is a strong connection to the recently popular concept of *compressed sensing*, see, for example, [11].

MRF priors, or priors with only local interaction between pixels, are by far the most commonly used priors in imaging. It is widely accepted and to some extent demonstrated (see [6] and the discussion in it) that the posterior density is sensitive to local properties of the prior only, while the global properties are predominantly determined by the likelihood. Thus, as far as the role of priors is concerned, it is important to remember that until the likelihood is taken into account, there is no connection with the measured data, hence no reason to believe that the prior should generate images that in the large scale resemble what we are looking for. In general, priors are usually designed to carry very general often qualitative and local information, which will be put into proper context with the guidance of the data through the integration with the likelihood. To demonstrate the local structure implied by different priors, in Fig. 2, we show some random draws from the priors discussed above.

Likelihood: Forward Model and Statistical Properties of Noise

If an image is worth a thousand words, a proper model of the noise corrupting it is worth at least a thousand more, in particular when the processing is based on the statistical methods. So far, the notion of noise has remained vague, and its role unclear. It is the noise, and in fact its statistical properties, that determines the likelihood density. We start by considering two very popular noise models.

Additive, nondiscrete noise: An additive noise model assumes that the data and the unknown are in a functional relation of the form

$$y = F(x) + e, \tag{6}$$

where e is the noise vector. If the function F is linear, or it has been linearized, the problem simplifies to

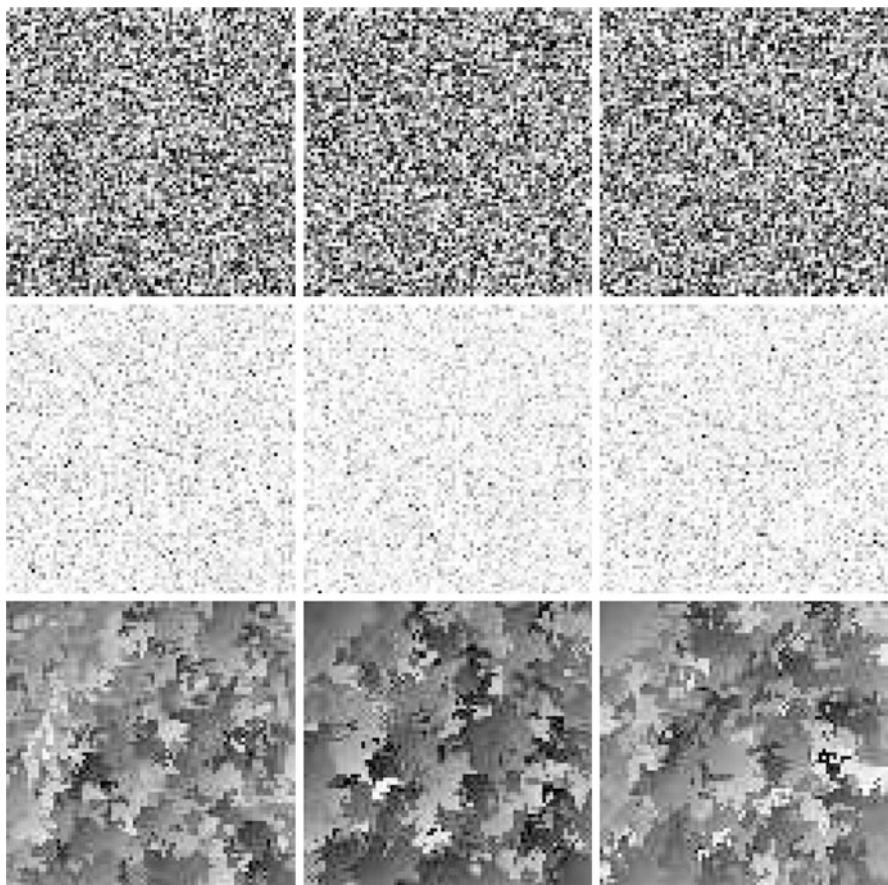

Fig. 2 Random draws from various MRF priors. *Top row:* white noise prior. *Middle row:* sparsity prior or ℓ^1 -prior with positivity constraint. *Bottom row:* total variation prior

$$y = \mathbf{A}x + e. \quad (7)$$

The stochastic extension of (6) is

$$Y = F(X) + E,$$

where Y , X , and E are multivariate random vectors.

The form of the likelihood is determined not only by the assumed probability distributions of Y , X , and E but also by the dependency between pairs of these variables. In the simplest case, X and E are assumed to be mutually independent and the probability density of the noise vector known,

$$E \sim \pi_{\text{noise}}(e),$$

resulting in a likelihood function of the form

$$\pi(y | x) \propto \pi_{\text{noise}}(y - F(x)),$$

which is one of the most commonly used in applications. A particularly popular model for additive noise is a Gaussian noise,

$$E \sim \mathcal{N}(0, \Sigma),$$

where the covariance matrix Σ is positive definite. Therefore, if we write $\Sigma^{-1} = D^T D$, where D can be the Cholesky factor of Σ^{-1} or $D = \Sigma^{-1/2}$, the likelihood can be written as

$$\begin{aligned} \pi(y | x) &\propto \exp\left(-\frac{1}{2}(y - F(x))^T \Sigma^{-1} (y - F(x))\right) \\ &= \exp\left(-\frac{1}{2}\|D(y - F(x))\|^2\right). \end{aligned} \quad (8)$$

In the general case where X and E are not independent, we need to specify the joint density

$$(X, E) \sim \pi(x, e)$$

and the corresponding conditional density

$$\pi_{\text{noise}}(e | x) = \frac{\pi(x, e)}{\pi_{\text{prior}}(x)}.$$

In this case, the likelihood becomes

$$\pi(y | x) \propto \pi_{\text{noise}}(y - F(x) | x).$$

This clearly demonstrates the problems which may arise if we want to adhere to the claim that “likelihood should be independent of the prior.” Because the interdependency of the image x and the noise is much more common than we might be inclined to believe, the independency of noise and signal is often in conflict with reality. An instance of such situation occurs in electromagnetic brain imaging using magnetoencephalography (MEG) or electroencephalography (EEG), when the eye muscle during a visual task acts as noise source but can hardly be considered as independent from the brain activation due to a visual stimulus. Another example related to boundary conditions will be discussed later on. Also, since the noise term should account not only for the exogenous measurement noise but also for the shortcomings of the model, including discretization errors, the interdependency is in fact a ubiquitous phenomenon too often neglected.

Most additive noise models assume that the noise follows a Gaussian distribution, with zero mean and given covariance. The computational advantages of a Gaussian likelihood are rather formidable and have been a great incentive to use Gaussian approximations of non-Gaussian densities. While it is commonplace and somewhat justified, for example, to approximate Poisson densities with Gaussian densities when the mean is sufficiently large [14], there are some important imaging applications where the statistical distribution of the noise must be faithfully represented in the likelihood.

Counting noise: The weakness of a signal can complicate the deblurring and denoising problem, as is the case in some image processing applications in astronomy [49, 57, 63], microscopy [45, 68], and medical imaging [29, 60]. In fact, in the case of weak signals, a charge-coupled device (CCD), instead of recording an integrated signal over a time window, counts individual photons or electrons. This leads to a situation where the noise corrupting the recorded signal is no longer exogenous but rather an intrinsic property of the signal itself, that is, the input signal itself is a random process with an unpredictable behavior. Under rather mild assumptions – stationarity, independency of increments, and zero probability of coincidence – it can be shown (see, e.g., [62]) that the counting signal follows a Poisson distribution. Consider, for example, the astronomical image of a very distant object, collected with an optical measurement device whose blurring is described by a matrix \mathbf{A} . The classical description of such data would follow (7), with the error term collecting the background noise and the thermal noise of the device. The corresponding counting model is

$$y_j \sim \text{Poisson} ((\mathbf{Ax})_j + b), \quad y_j, y_k \text{ independent if } j \neq k,$$

or, explicitly,

$$\pi(y \mid x) = \prod_{j=1}^m \frac{((\mathbf{Ax})_j + b)^{y_j}}{(y_j)!} \exp(-(Ax)_j + b),$$

where $b \geq 0$ is a background radiation level, assumed known. Observe that while the data are counts, therefore integer numbers, the expectation need not to be.

Similar or slightly modified likelihoods can be used to model the positron emission tomography (PET) and single-photon emission computed tomography (SPECT) signals; see [29, 54].

The latter example above demonstrates clearly that the description of imaging problems as linear or nonlinear, without a specification of the noise model, in the context of statistical methods, does not play a significant role: Even if the expectation is linear, traditional algorithms for solving linear inverse problems are useless, although they may turn out to be useful within iterative solvers for solving locally linearized steps.

Maximum Likelihood and Fisher Information

When switching to a parametric non-Bayesian framework, the statistical inference problem amounts to estimating a deterministic parameter that identifies the probability distribution from which the observations are drawn. To apply this framework in imaging problems, the underlying image x , which in the Bayesian context was itself a random variable, can be thought of as a parameter vector that specifies the likelihood function,

$$f(y; x) = \pi(y | x),$$

as implied by the notation $f(y; x)$ also.

In the non-Bayesian interpretation, a measure of how much information about the parameter x is contained in the observation is given in terms of the *Fisher information matrix* \mathbf{J} ,

$$\mathbf{J}_{j,k} = \mathbb{E} \left\{ \frac{\partial \log f}{\partial x_j} \frac{\partial \log f}{\partial x_k} \right\} = \int \frac{\partial \log f(y; x)}{\partial x_j} \frac{\partial \log f(y; x)}{\partial x_k} f(y; x) dy. \quad (9)$$

In this context, the observation y only is a realization of a random variable Y , whose probability distribution is entirely determined by the distribution of the noise. The gradient of the logarithm of the likelihood function is referred to as the *score*, and the Fisher information matrix is therefore the covariance of the score.

Assuming that the likelihood is twice continuously differentiable and regular enough to allow the exchange of integration and differentiation, it is possible to derive another useful expression for the information matrix. It follows from the identity

$$\frac{\partial \log f}{\partial x_k} = \frac{1}{f} \frac{\partial f}{\partial x_k}, \quad (10)$$

that we may write the Fisher information matrix as

$$\mathbf{J}_{j,k} = \int \frac{\partial \log f}{\partial x_j} \frac{\partial f}{\partial x_k} dy = \frac{\partial}{\partial x_k} \int \frac{\partial \log f}{\partial x_j} f dy - \int \frac{\partial^2 \log f}{\partial x_j \partial x_k} f dy.$$

Using the identity (10) with k replaced by j , we observe that

$$\int \frac{\partial \log f}{\partial x_j} f dy = \int \frac{\partial f}{\partial x_j} dy = \frac{\partial}{\partial x_j} \int f dy = 0,$$

since the integral of f is one, which leads us to the alternative formula

$$\mathbf{J}_{j,k} = - \int \frac{\partial^2 \log f}{\partial x_j \partial x_k} f dy = -\mathbb{E} \left\{ \frac{\partial^2 \log f}{\partial x_j \partial x_k} \right\}. \quad (11)$$

The Fisher information matrix is closely related to non-Bayesian estimation theory. This will be discussed later in connection with maximum likelihood estimation.

Informative or Noninformative Priors?

Not seldom the use of priors in imaging applications is blamed for biasing the solution in a direction not supported by the data. The concern of the use of committal priors has led to the search of “noninformative priors” [39] or weak priors that would “let the data speak.”

The strength or weakness of a prior is a rather elusive concept, as the importance of the prior in Bayesian imaging is in fact determined by the likelihood: the more information we have about the image in data, the less has to be supplied by the prior. On the other hand, in imaging applications where the likelihood is built on very few data points, the prior needs to supply the missing information, hence has a much more important role. As pointed out before, it is a common understanding that in imaging applications, prior should carry small-scale information about the image that is missing from the likelihood that in turn carries information about the large-scale features and in that sense complements the data.

Adding Layers: Hierarchical Models

Consider the following simple denoising problem with additive Gaussian noise,

$$Y = X + N, \quad N \sim \mathcal{N}(0, \Sigma),$$

with noise covariance matrix Σ presumed known, whose likelihood model is tantamount to saying that

$$Y | X = x \sim \mathcal{N}(x, \Sigma).$$

From this perspective, the denoising problem is reduced to estimating the mean of a Gaussian density in the non-Bayesian spirit, and the prior distribution is a *hierarchical* model, expressing the degree of uncertainty of the mean x .

Parametric models are common when defining the prior densities, but similarly to the above interpretation of the likelihood, the parameters are often poorly known. For example, when introducing a prior

$$X \sim \mathcal{N}(\theta, \Gamma)$$

with unknown θ , we are expressing a qualitative prior belief that “ X differs from an unknown value by an error with a given Gaussian statistics,” which says very little about the values of X itself unless information about θ is provided. Similarly as in the denoising problem, it is natural to augment the prior with another layer of

information concerning the parameter θ . This layering of the inherent uncertainty is at the core of *hypermodels*, or Bayesian hierarchical models. Hierarchical models are not restricted to uncertainties in the prior, but can be applied to lack of information of the likelihood model as well.

In hierarchical models, both the likelihood and the prior may depend on additional parameters,

$$\pi(y | x) \rightarrow \pi(y | x, \gamma), \quad \pi_{\text{prior}}(x) \rightarrow \pi_{\text{prior}}(x | \theta),$$

with both parameters γ and θ poorly known. In this case, it is natural to augment the model with *hyperpriors*. Assuming for simplicity that the parameters γ and θ are mutually independent so that we can define the hyperprior distributions $\pi_1(\gamma)$ and $\pi_2(\theta)$, the joint probability distribution of all the unknowns is

$$\pi(x, y, \theta, \gamma) = \pi(y | x, \gamma) \pi_{\text{prior}}(x | \theta) \pi_1(\gamma) \pi_2(\theta).$$

From this point on, the Bayesian inference can proceed along different paths. It is possible to treat the hyperparameters as nuisance parameters and marginalize them out by computing

$$\pi(x, y) = \int \int \pi(x, y, \theta, \gamma) d\theta d\gamma$$

and then proceed as in a standard Bayesian inference problem. Alternatively, the hyperparameters can be included in the list of unknowns of the problem and their posterior density

$$\pi(\xi | y) = \frac{\pi(x, y, \theta, \gamma)}{\pi(y)}, \quad \xi = \begin{bmatrix} x \\ \theta \\ \gamma \end{bmatrix}$$

needs to be explored. The estimation of the hyperparameters can be based on the optimization or on the *evidence*, as will be illustrated below with a specific example.

To clarify the concept of a hierarchical model itself, we consider some examples where hierarchical models arise naturally.

Blind deconvolution: Consider the standard deblurring problem defined in section ‘‘Imaging Problems.’’ Usually, it is assumed that the blurring kernel \mathbf{A} is known, and the likelihood, with additive Gaussian noise with covariance Σ , becomes

$$\pi(y | x) \propto \exp\left(-\frac{1}{2}(y - \mathbf{A}x)^T \Sigma^{-1} (y - \mathbf{A}x)\right). \quad (12)$$

In some cases, although \mathbf{A} is poorly known, its parametric expression is known and the uncertainty only affects the values of some parameters, as is the case when the shape of the continuous convolution kernel $a(r - s)$ is known but the actual width is not. If we express the kernel a as a function of a width parameter,

$$a(r-s) = a_\gamma(r-s) = \frac{1}{\gamma} a_1(\gamma(r-s)), \quad \gamma > 0,$$

and denote by \mathbf{A}_γ the corresponding discretized convolution matrix, the likelihood becomes

$$\pi(y | x, \gamma) \propto \exp\left(-\frac{1}{2}(y - \mathbf{A}_\gamma x)^\top \Sigma^{-1}(y - \mathbf{A}_\gamma x)\right),$$

and additional information concerning γ , for example, bound constraints, can be included via a hyperprior density.

The procedure just outlined can be applied to many problems arising from adaptive optics imaging in astronomy [52]; while the uncertainty in the model is more complex than in the explanatory example above, the approach remains the same.

Conditionally Gaussian hypermodels: Gaussian prior models are often criticized for being a too restricted class, not being able to adequately represent prior beliefs concerning, for example, the sparsity or piecewise smoothness of the solution. The range of qualitative features that can be expressed with normal densities can be considerably expanded by considering *conditionally Gaussian* families instead. As an example, consider the problem of finding a sparse image from linearly blurred noisy copy of it. The likelihood model in this case may be written as in (12). To set up an appropriate prior, consider a conditionally Gaussian prior

$$\begin{aligned} \pi_{\text{prior}}(x | \theta) &\propto \left(\frac{1}{\theta_1 \cdots \theta_N}\right)^{1/2} \exp\left(-\frac{1}{2} \sum_{j=1}^N \frac{x_j^2}{\theta_j}\right) \\ &= \exp\left(-\frac{1}{2} \sum_{j=1}^N \left[\frac{x_j^2}{\theta_j} + \log \theta_j\right]\right). \end{aligned} \quad (13)$$

If $\theta_j = \theta_0 = \text{constant}$, we obtain the standard white noise prior which cannot be expected to favor sparse solutions. On the other hand, since θ_j is the variance of the pixel X_j , sparse images correspond to vectors θ with most of the components close to zero. Since we do not know a priori which of the variances should significantly differ from zero, when choosing a stochastic model for θ , it is reasonable to select a hyperprior that favors sparsity without actually specifying the location of the outliers. Two distributions that are particularly well suited for this are the *gamma distribution*,

$$\theta_j \sim \text{Gamma}(k, \theta_0), \quad k, \theta_0 > 0, \quad \pi(\theta_j) = \theta_j^{k-1} \exp\left(-\frac{\theta_j}{\theta_0}\right),$$

and the *inverse gamma distribution*,

$$\theta_j \sim \text{InvGamma}(k, \theta_0), \quad k, \theta_0 > 0, \quad \pi(\theta_j) = \theta_j^{-k-1} \exp\left(-\frac{\theta_0}{\theta_j}\right).$$

The parameters k and θ_0 are referred to as the shape and the scaling, respectively. The inverse gamma distribution corresponds to assuming that the *precision*, defined as $1/\theta_j$, is distributed according to the gamma distribution $\text{Gamma}(k, 1/\theta_0)$. The computational price of introducing hyperparameters is that instead of one image x , we need to estimate the image x and its variance image θ . Fortunately, for conditionally Gaussian families, there are efficient algorithms for computing these estimates, which will be discussed in the section concerning algorithms.

The hyperprior based on the gamma distribution, in turn, contains parameters (k and θ_0) to be determined. Nothing prevents us from defining another layer of hyperpriors concerning these values. It should be noted that in hierarchical models, the selection of the parameters higher up in the hierarchy tends to have less direct effect on the parameters of primary interest. Since this last statement has not been formally proved to be true, it should be considered as a piece of computational folklore.

Conditionally Gaussian hypermodels have been successfully applied in machine learning [66], in electromagnetic brain activity mapping [16], and in imaging applications for restoring blocky images [15]. Recently, their use in compressed sensing has been proposed [40].

4 Numerical Methods and Case Examples

The solution of an imaging inverse problem in the statistical framework is the posterior probability density. Because this format of the solution is not practical for most applications, it is common to summarize the distribution in one or a few images. This leads to the challenging problem of exploring the posterior distributions and finding single estimators supported by the distribution.

Estimators

In this section, we review some of the commonly used estimators and subsequently discuss some of the popular algorithms suggested in the literature to compute the corresponding estimates.

Prelude: Least Squares and Tikhonov Regularization

In the case where the forward model is linear, the problem of estimating an image from a degraded, noisy recording is equivalent in a determinist setting to looking for a solution of a linear system of equations of the form

$$\mathbf{A}\mathbf{x} = \mathbf{y}, \tag{14}$$

where the right-hand side is corrupt by noise. When \mathbf{A} is not a square matrix and/or it is ill conditioned, one needs to specify what a “solution” means. The most straightforward way is to specify it as a least squares solution.

There is a large body of literature, and a wealth of numerical algorithms, for the solution of large-scale least squares problems arising from problems similar to imaging applications (see, e.g., [9]). Since dimensionality alone makes these problems computationally very demanding, they may require an unreasonable amount of computer memory and operations unless a compact representation of the matrix \mathbf{A} can be exploited. Many of the available algorithms make additional assumptions about either the underlying image or the structure of the forward model regardless of whether there is a good justification.

In a determinist setting, the entries of the least squares solution of (14) with a right-hand side corrupted by noise are not necessarily in the gray-scale range of the image pixels. Moreover, the inherent ill conditioning of the problem, which varies with the imaging modality and the conditions under which the observations were collected, usually requires regularization, see, for example, [4, 33, 34, 41]. A standard regularization method is to replace the original ill-posed least squares problem by a nearby well-posed problem by introducing a penalty term to avoid that the computed solution is dominated by amplified noise components, reducing the problem to minimizing a functional of the form

$$T(x) = \|\mathbf{Ax} - y\|^2 + \alpha J(x), \quad (15)$$

where $J(x)$ is the penalty functional and $\alpha > 0$ is the regularization parameter. The minimizer of the functional (15) is the *Tikhonov regularized solution*. The type of additional information used in the design of the penalty term may include upper bounds on the norm of the solution or of its derivatives, nonnegative constraints for its entries, or bounds on some of the components. Often, expressing characteristics that are expected of the sought image in qualitative terms is neither new nor difficult: the translation of these beliefs into mathematical terms and their implementation is a more challenging step.

Maximum Likelihood and Maximum A Posteriori

We begin with the discussion of the maximum likelihood estimator in the framework of non-Bayesian statistics and denote by x a deterministic parameter determining the likelihood distribution of the data, modeled as a random variable. Let $\hat{x} = \hat{x}(y)$ denote an estimator of x , based on the observations y . Obviously, \hat{x} is also a random variable, because of its dependency on the stochastic observations y ; moreover, it is an *unbiased estimator* if

$$\mathbb{E}\{\hat{x}(y)\} = x,$$

that is, if, in the average, it returns the exact value. The covariance matrix \mathbf{C} of an unbiased estimator therefore measures the statistical variation around the true value,

$$\mathbf{C}_{j,k} = \mathbb{E} \{(\hat{x}_j - x_j)(\hat{x}_k - x_k)\},$$

thus the name mean square error. Evidently, the smaller the mean square error, for example, in the sense of quadratic forms, the higher the expected fidelity of the estimator. The Fisher information matrix (9) gives a lower bound for the covariance matrix of all unbiased estimators. Assuming that \mathbf{J} is invertible, the *Cramér–Rao lower bound* states that for an unbiased estimator,

$$\mathbf{J}^{-1} \leq \mathbf{C}$$

in the sense of quadratic forms, that is, for any vector

$$u^T \mathbf{J}^{-1} u \leq u^T \mathbf{C} u.$$

An estimator is called *efficient* if the error covariance reaches the Cramér–Rao bound.

The maximum likelihood estimator $\hat{x}_{\text{ML}}(y)$ is the maximizer of the function $x \mapsto f(x; y)$, and in practice, it is found by locating the zero(s) of the score,

$$\nabla_x \log f(x; y) = 0 \Rightarrow x = \hat{x}_{\text{ML}}(y).$$

Notice that in the non-Bayesian context, likelihood refers solely to the likelihood of the observations y , and the maximum likelihood estimation is a way to choose the underlying parametric model so that the observations become as likely as possible.

The popularity of the maximum likelihood estimator, in addition to being an intuitively obvious choice, stems from the fact that it is asymptotically efficient estimator in the sense that when the number of independent observations of the data increases, the covariance of the estimator converges toward the inverse of the Fisher information matrix, assuming that it exists. More precisely, assuming a sequence y^1, y^2, \dots of independent observations and defining $\hat{x}^n = \hat{x}(y^1, \dots, y^n)$ as

$$\hat{x}^n = \operatorname{argmax} \left\{ \frac{1}{n} \sum_{j=1}^n f(x, y^j) \right\},$$

asymptotically the probability distribution of \hat{x}^n approaches a Gaussian distribution with mean x and covariance \mathbf{J}^{-1} .

The assumption of the regularity of the Fisher information matrix limits the use of the ML estimator in imaging applications. To understand this claim, consider the simple case of linear forward model and additive Gaussian noise,

$$Y = \mathbf{A}x + E, \quad E \sim \mathcal{N}(0, \Sigma).$$

The likelihood function in this case is

$$f(x; y) = \left(\frac{1}{2\pi|\Sigma|} \right)^{1/N} \exp \left(-\frac{1}{2}(y - Ax)^\top \Sigma^{-1} (y - Ax) \right),$$

from which it is obvious that by formula (11),

$$J = A^\top \Sigma^{-1} A.$$

In the simplest imaging problems such as of denoising, the invertibility of J is not an issue. However, in more realistic and challenging applications such as deblurring, the ill conditioning of A renders J singular, and the Cramér–Rao bound becomes meaningless. It is not uncommon to regularize the information matrix by adding a diagonal weight to it which, from the Bayesian viewpoint, is tantamount to adding prior information but in a rather uncontrolled manner.

For further reading of mathematical methods in estimation theory, we refer to [17, 46, 50].

We consider the maximum likelihood estimator in the context of regularization and Bayesian statistics. In the case of a Gaussian additive noise observation model, under the assumption that the noise at each pixel is independent of the signal and that the forward map is linear, $F(x) = Ax$, the likelihood (8) is of the form

$$\pi(y | x) \propto \exp \left(-\frac{1}{2} \|D(Ax - y)\|^2 \right),$$

where Σ is the noise covariance matrix and $D^\top D = \Sigma^{-1}$ is the Cholesky decomposition of its inverse. The maximizer of the likelihood function is the solution of the minimization problem

$$x_{ML} = \operatorname{argmin} \{ \|D(Ax - y)\|^2 \},$$

which, in turn, is the least squares solution of the linear system

$$DAx = Dy.$$

Thus, we can reinterpret least squares solutions as maximum likelihood estimates under an additive, independent Gaussian error model. Within the statistical framework, the maximum likelihood estimator is defined analogously for any error model which admits a maximizer for the likelihood, but in the general case, the computation of the minimizer cannot be reduced to the solution of a linear least squares problem.

In a statistical framework, the addition of a penalty terms to keep the solution of the least squares problem from becoming dominated by amplified noise components is tantamount to using a prior to augment the likelihood. If the observation model is linear, the prior and the likelihood are both Gaussian,

$$\pi_{\text{prior}}(x) \propto \exp\left(-\frac{1}{2}x^\top \Gamma^{-1} x\right),$$

and the noise is independent of the signal, the corresponding posterior is of the form

$$\pi(x | y) \propto \exp\left(-\frac{1}{2} (\|D(Ax - y)\|^2 + \|Rx\|^2)\right),$$

where R satisfies $R^\top R = \Gamma^{-1}$, so typically it is the Cholesky factor of Γ^{-1} or alternatively, $R = \Gamma^{-1/2}$.

The maximizer of the posterior density, or the maximum a posteriori (MAP) estimate, is the minimizer of the negative exponent, hence the solution of the minimization problem

$$\begin{aligned} x_{\text{MAP}} &= \operatorname{argmin}\{\|D(Ax - y)\|^2 + \|Rx\|^2\} \\ &= \operatorname{argmin}\left\{\left\|\begin{bmatrix} DA \\ R \end{bmatrix}x - \begin{bmatrix} Dy \\ 0 \end{bmatrix}\right\|^2\right\}, \end{aligned}$$

or, equivalently, the Tikhonov solution (15) with penalty $J(x) = \|Rx\|^2$ and regularization parameter $\alpha = 1$. Again, it is important to note that the direct correspondence between the Tikhonov regularization and the MAP estimate only holds for linear observation models and Gaussian likelihood and prior. The fact that the MAP estimate in this case is the least squares solution of the linear system

$$\begin{bmatrix} DA \\ R \end{bmatrix}x = \begin{bmatrix} Dy \\ 0 \end{bmatrix} \quad (16)$$

is a big incentive to stay with Gaussian likelihood and Gaussian priors as long as possible.

As in the case of the ML estimate, the definition of MAP estimate is independent of the form of the posterior, hence applied also to non-Gaussian, nonindependent noise models, with the caveat that in the general case, the search for a maximizer of the posterior may require much more sophisticated optimization tools.

Conditional Means

The recasting in statistical terms of imaging problems effectively shifts the interest from the image itself to its probability density. The ML and MAP estimators discussed in the previous section suffer from the limitations, which come from summarizing an entire distribution with one realization. The ML estimator is known to suffer from instabilities due to the typical ill conditioning of the forward map in imaging problems, and it will not be discussed further here. The computed MAP estimate, on the other hand, may correspond to an isolated spike in the probability density away from the bulk of the mass of the density, and its computation may suffer from numerical complications. Furthermore, a conceptually more serious

limitation is the fact that MAP estimators do not carry information about the statistical dispersion of the distribution. A tight posterior density suggests that any ensemble of images which are in statistical agreement with the data and the given prior show little variability; hence, any realization from that ensemble can be thought of as very representative of the entire family. A wide posterior, on the other hand, suggests that there is a rather varied family of images that are in agreement with the data and the prior, hence lowering the representative power of any individual realization.

In the case where either the likelihood or the prior is not Gaussian, the mean of the posterior density, often referred to as conditional mean (CM) or posterior mean, may be a better choice because it is the estimator with least variance (see [3, 41]). Observe, however, that in the fully Gaussian case, the MAP and CM estimate coincides.

The CM estimate is, by definition,

$$x_{\text{CM}} = \int_{\mathbb{R}^N} x \pi(x | y) dx,$$

while the a posteriori covariance matrix is

$$\Gamma_{\text{CM}} = \int_{\mathbb{R}^N} (x - x_{\text{CM}})(x - x_{\text{CM}})^T \pi(x | y) dx,$$

hence requiring the evaluation of the high-dimensional integrals. When the integrals have no closed form solution, as is the case for many imaging problems where, for example, the a priori information contains bounds on pixel values, a numerical approximation of the integral must be used to estimate x_{CM} and Γ_{CM} . The large dimensionality of the parameter space, which easily is of the order of hundreds of thousands when x represents an image, rules out the use of standard numerical quadratures, leaving Monte Carlo integration the only currently known feasible alternative.

The conceptual simplicity of Monte Carlo integration, which estimates the integral value as the average of a large sample of the integrand evaluated over the support of the integration, requires a way of generating a large sample from the posterior density. The generation of a sample from a given distribution is a well-known problem in statistical inference, which has inspired families of sampling schemes generically referred to as Markov chain Monte Carlo (MCMC) methods, which will be discussed in section “Markov Chain Monte Carlo Sampling.”

Once a representative sample from the posterior has been generated, the CM estimate is approximately the sample mean. By definition, the CM estimate must be near the bulk of the density, although it is not necessarily a highly probable point. In fact, for multimodal distributions, the CM estimate may fall between the modes of the density and even belong to a subset of \mathbb{R}^N with probability zero, although such a situation is rather easy to detect. There is evidence, however, that in some imaging applications the CM estimate is more stable than the MAP estimate; see

[23]. While the robustness of the CM estimate does not compensate for the lack of information about the width of the posterior, the possibility of estimating the posterior covariance matrix via sampling is an argument for the sampling approach, since the sample can also be used to estimate the posterior width.

Algorithms

The various estimators based on the posterior distribution are simple to define, but the actual computation may be a major challenge. In the case of Gaussian likelihood and prior, combined with linear forward map, the MAP and CM estimates coincide and an explicit formula exists. If the problem is very high dimensional, even this case may be computationally challenging. Before going to specific algorithms, we review the linear Gaussian theory.

The starting point is the linear additive model

$$Y = \mathbf{A}X + E, \quad X \sim \mathcal{N}(0, \Gamma), \quad E \sim \mathcal{N}(0, \Sigma).$$

Here, we assume that the mean of X and the noise E both vanish, an assumption that is easy to remove. Above, X and E need not be mutually independent, and we may postulate that they are jointly Gaussian and the cross-correlation matrix

$$\mathbf{C} = \mathbb{E}\{XE^T\} \in \mathbb{R}^{N \times M}$$

may not vanish. The joint probability distribution of X and Y is also Gaussian, with zero mean and variance

$$\begin{aligned} \mathbb{E}\left\{\begin{bmatrix} X \\ Y \end{bmatrix} \begin{bmatrix} X^T & Y^T \end{bmatrix}\right\} &= \mathbb{E}\left\{\begin{bmatrix} XX^T & X(\mathbf{A}X + E)^T \\ (\mathbf{A}X + E)X^T & (\mathbf{A}X + E)(\mathbf{A}X + E)^T \end{bmatrix}\right\} \\ &= \begin{bmatrix} \Gamma & \Gamma\mathbf{A}^T + \mathbf{C} \\ \mathbf{A}\Gamma + \mathbf{C}^T & \mathbf{A}\Gamma\mathbf{A}^T + \Sigma \end{bmatrix}. \end{aligned}$$

Let $\mathbf{L} \in \mathbb{R}^{(N+M) \times (N+M)}$ denote the inverse of the above matrix, assuming that it exists, and write a partitioning of it in blocks according to the dimensions N and M ,

$$\mathbf{L} = \begin{bmatrix} \Gamma & \Gamma\mathbf{A}^T + \mathbf{C} \\ \mathbf{A}\Gamma + \mathbf{C}^T & \mathbf{A}\Gamma\mathbf{A}^T + \Sigma \end{bmatrix}^{-1} = \begin{bmatrix} \mathbf{L}_{11} & \mathbf{L}_{12} \\ \mathbf{L}_{21} & \mathbf{L}_{22} \end{bmatrix}.$$

With this notation, the joint probability distribution of X and Y is

$$\pi(x, y) \propto \exp\left(-\frac{1}{2}(x^T \mathbf{L}_{11} x + x^T \mathbf{L}_{12} y + y^T \mathbf{L}_{21} x + y^T \mathbf{L}_{22} y)\right).$$

To find the posterior density, one completes the square in the exponent with respect to x ,

$$\pi(x \mid y) \propto \exp\left(-\frac{1}{2} (x - L_{11}^{-1} L_{12} y)^T L_{11} (x - L_{11}^{-1} L_{12} y)\right),$$

where terms independent of x that contribute only to the normalization are left out. Therefore,

$$X \mid Y = y \sim \mathcal{N}(L_{11}^{-1} L_{12} y, L_{11}^{-1}).$$

Finally, we need to express the matrix blocks L_{ij} in terms of the matrices of the model. The expressions follow from the classical matrix theory of Schur complements [24]: We have

$$L_{11}^{-1} = \Gamma - (\mathbf{A}\mathbf{A}^T + \mathbf{C})(\mathbf{A}\Gamma\mathbf{A}^T + \Sigma)^{-1}(\mathbf{A}\Gamma + \mathbf{C}^T), \quad (17)$$

and

$$L_{11}^{-1} L_{12} y = (\mathbf{A}\mathbf{A}^T + \mathbf{C})(\mathbf{A}\Gamma\mathbf{A}^T + \Sigma)^{-1} y. \quad (18)$$

Although a closed form solution, to evaluate the expression (18) for the posterior mean may require iterative solvers.

When the image and the noise are mutually independent, implying that $\mathbf{C} = 0$, we find a frequently encountered form of the MAP estimate arising from writing the Gaussian posterior density directly by using Bayes' formula, that is,

$$\begin{aligned} \pi(x \mid y) &\propto \pi_{\text{prior}}(x)\pi(y \mid x) \\ &\propto \exp\left(-\frac{1}{2}x^T\Gamma^{-1}x - \frac{1}{2}(y - \mathbf{A}x)^T\Sigma^{-1}(y - \mathbf{A}x)\right), \end{aligned}$$

and so the MAP estimate, and simultaneously the posterior mean estimate, is the maximizer of the above expression, or, equivalently, the minimizer of the quadratic functional

$$H(x) = (y - \mathbf{A}x)^T\Sigma^{-1}(y - \mathbf{A}x) + x^T\Gamma^{-1}x.$$

By substituting the factorizations

$$\Sigma^{-1} = \mathbf{D}^T\mathbf{D}, \quad \Gamma^{-1} = \mathbf{R}^T\mathbf{R},$$

the minimization problem becomes the previously discussed standard least squares problem of minimizing

$$H(x) = \|\mathbf{D}(y - \mathbf{A}x)\|^2 + \|\mathbf{R}x\|^2, \quad (19)$$

leading to the least squares problem (16). Whether one should use this formula or (18) depends on the application and, in particular, on the sparsity properties of the covariance matrices and their inverses.

Iterative Linear Least Squares Solvers

The computation of the ML or MAP estimate under the Gaussian additive linear noise model and, in the latter case, with a Gaussian prior, amounts to the solution of system of linear equations (14), (16), or (18) in the least squares sense. Since the dimensions of the problem are proportional to the number of pixels in the image except when the observation model has a particular structure or sparsity properties which can be exploited to reduce the memory allocation, solution by direct methods is unfeasible, hence making in general the iterative solvers the methods of choice.

Among the iterative methods specifically designed for the solution of least squares problems, the LSQR version with shifts [55, 56] of the Conjugate Gradient for Least Squares (CGLS) method originally proposed in [37] combines robustness and numerical efficiency. CGLS-type iterative methods have been designed to solve the system $\mathbf{A}x = y$, minimize $\|\mathbf{A}x - y\|^2$, or minimize $\|\mathbf{A}x - y\|^2 + \delta\|x\|^2$, where the matrix \mathbf{A} may be square or rectangular – either overdetermined or underdetermined – and may have any rank. The matrix \mathbf{A} does not need to be stored, but instead its action is represented by a routine for computing matrix–vector products of the forms $v \mapsto \mathbf{A}v$ and $u \mapsto \mathbf{A}^T u$.

Minimizing the expression (19) may be transformed in a standard form by writing it as

$$\min \left\{ \| \mathbf{D} (y - \mathbf{A}\mathbf{R}^{-1}w) \|^2 + \| w \|^2 \right\}, \quad w = \mathbf{R}x$$

In practice, the matrix \mathbf{R}^{-1} should not be computed, unless it is trivial to obtain. Rather, \mathbf{R}^{-1} acts as a preconditioner, and its action should be implemented together with the action of the matrix \mathbf{A} as a routine called from the iterative linear solver. The interpretation of the action of the prior as a preconditioner has led to the concept of prior conditioner; see [12, 14] for details.

Nonlinear Maximization

In the more general case where either the observation model is nonlinear or the likelihood and prior are non-Gaussian, the computation of the ML and MAP estimates requires the solution of a maximization problem. Maximizers of nonlinear functions can be found by quasi-Newton methods with global convergence strategy. Since Newton-type methods proceed by solving a sequence of linearized problems whose dimensions are proportional to the size of the image, iterative linear solvers are typically used for the solution of the linear subproblem [20, 43]. In imaging applications, it is not uncommon that the a priori information includes nonnegativity constraints on the pixel values or bounds on their range. In these cases, the computation of the MAP estimate amounts to a constrained maximization problem and may be very challenging. Algorithms for maximization problems with nonnegativity constraints arising in imaging applications based on the projected

gradient have been proposed in the literature; see [2] and references therein. We shall not review Newton-based methods here, since usually the fine points are related to the particular applications at hand and not so much to the statistical description of the problem. Instead, we review some algorithms that stem directly from the statistical setting of the problem and are therefore different from the methods used in regularized deterministic literature.

EM Algorithm

The MAP estimator is the maximizer of the posterior density $\pi(x \mid y)$, or, equivalently, the maximizer the logarithm of it,

$$L(x \mid y) = \log \pi(x \mid y) = \log \pi(y \mid x) + \log \pi_{\text{prior}}(x) + \text{constant},$$

where the simplest form of Bayes' rule was used to represent the posterior density as a product of the likelihood and the prior. However, note that above, the vector x may represent the unknown of primary interest, or if hierarchical models are used, the model parameters related to the likelihood and/or prior may be included in it.

The *expectation–maximization* algorithm is a method developed originally for maximizing the likelihood function and later extended to the Bayesian setting to maximize the posterior density, in a situation where part of the data is “missing.” While in many statistical application the concept of missing data appears natural, for example, when incomplete census data or patient data are discussed, in imaging applications, this concept is a rather arbitrary and to some extent artificial. However, during the years, EM has found its way to numerous imaging applications, partly because it often leads to algorithms that are easy to implement. Early versions of the imaging algorithms with counting data such as the Richardson–Lucy iteration [49, 57], popular in astronomical imaging, were independently derived. Later, similar EM-based algorithms were rederived in the context of medical imaging [29, 36, 60]. Although EM algorithms are discussed in more detail elsewhere in this book, we include a brief discussion here in order to put EM in the context of general statistical imaging formalism.

As pointed out above, in imaging problems, data is not missing: Data, *per definitionem*, is what one is able to observe and register. Therefore, the starting point of the EM algorithm in image applications is to augment the actual data y by *fictitious*, nonexistent data z that would make the problem significantly easier to handle.

Consider the statistical inference problem of estimating a random variable X based on an observed realization of Y , denoted by $Y = y = y_{\text{obs}}$. We assume the existence of a third random variable Z and postulate that the joint probability density of these three variables is available and is denoted by $\pi(x, y, z)$. The EM algorithm consists of the following steps:

1. Initialize $x = x^0$ and set $k = 0$.
2. *E-step*: Define the probability distribution, or a fictitious likelihood density,

$$\pi^k(z) = \pi(z | x^k, y) \propto \pi(x^k, y, z), \quad y = y_{\text{obs}},$$

and calculate the integral

$$Q^k(x) = \int L(x | y, z) \pi^k(z) dz, \quad L(x | y, z) = \log(\pi(x | y, z)). \quad (20)$$

3. *M-step*: Update x^k by defining

$$x^{k+1} = \operatorname{argmax} Q^k(x). \quad (21)$$

4. If a given convergence criterion is satisfied, exit; otherwise, increase k by one and repeat from step 2 until convergence.

The E-step above can be interpreted as computing the expectation of the real-valued random variable $\log(\pi(x, y, Z))$, x and y fixed, with respect to a conditional measure of Z conditioned on $X = x^j$ and $Y = y = y_{\text{obs}}$, hence the name expectation step.

The use of the EM algorithm is often advocated on the basis of the convergence proof given in [19]. Unfortunately, the result is often erroneously quoted as an automatic guarantee of convergence, without verifying the required hypotheses. The validity of the convergence is further obfuscated by the error in the proof (see [70]), and in fact, counterexamples of lack of convergence are well known [10, 69]. We point out that as far as convergence is concerned, global convergence of quasi-Newton algorithm is well established, and compared to the EM algorithm, the algorithm is often more effective [20].

As the concept of missing data is not well defined in general, we outline the use of the EM algorithm in an example that is meaningful in imaging applications.

SPECT imaging: The example discussed here follows the article [29]. Consider the SPECT image formation problem, where the two-dimensional object is divided in N pixels, each one emitting photons that are recorded through collimators by M photon counting devices. If x_j is the expected number of photons emitted by the j th pixel, the photon count at i th photon counter, denoted by Y_i , is an integer-valued random variable and can be modeled by a Poisson process,

$$Y_i \sim \text{Poisson} \left(\sum_{j=1}^M a_{ij} x_j \right) = \text{Poisson}((\mathbf{A}x)_i),$$

the variables Y_i being mutually independent and the matrix elements a_{ij} of $\mathbf{A} \in \mathbb{R}^{M \times N}$ being known. We assume that X , the stochastic extension of the unknown vector $x \in \mathbb{R}^N$, is a priori distributed according to a certain probability distribution,

$$X \sim \pi_{\text{prior}}(x) \propto \exp(-V(x)).$$

To apply the EM algorithm, we need to decide how to define the “missing data.” Photon counter devices detect the emitted photons added over the line of sight; evidently, the problem would be more tractable if we knew the number of emitted photons from each pixel separately. Therefore, we define a fictitious measurement,

$$Z_{ij} \sim \text{Poisson}(a_{ij} x_j),$$

and posit that these variables are mutually independent. Obviously, after the measurement $Y = y$, we have

$$\sum_{j=1}^N Z_{ij} = y_i. \quad (22)$$

To perform the E-step, assuming that x^k is given, consider first the conditional density $\pi^k(z) = \pi(z | x^k, y)$.

A basic result from probability theory states that if N independent random variables Λ_j are a priori Poisson distributed with respective means μ_j , and in addition

$$\sum_{j=1}^N \Lambda_j = K,$$

then, a posteriori, the variables Λ_j conditioned on the above data are binomially distributed,

$$\Lambda_j \mid \left(\sum_{j=1}^N \Lambda_j = K \right) \sim \text{Binom}\left(K, \frac{\mu_j}{\sum_{j=1}^N \mu_j}\right).$$

In particular, the conditional expectation of Λ_j is

$$\mathbb{E} \left\{ \Lambda_j \mid \sum_{j=1}^N \Lambda_j = K \right\} = K \frac{\mu_j}{\sum_{j=1}^N \mu_j}.$$

We therefore conclude that the conditional density $\pi^k(z)$ is a product of binomial distributions of Z_{ij} with a priori means $\mu_j = a_{ij} x_j^k$, $\sum_{j=1}^N \mu_j = (\mathbf{A}x^k)_i$, and $K = y_i$, so in particular,

$$\mathbb{E} \left\{ Z_{ij} \mid \sum_{j=1}^N Z_{ij} = y_i \right\} = \int z_{ij} \pi^k(z) dz = y_i \frac{a_{ij} x_j^k}{(\mathbf{A}x^k)_i} \stackrel{\text{def}}{=} z_{ij}^k. \quad (23)$$

Furthermore, by Bayes' theorem,

$$\pi(x \mid y, z) = \pi(x \mid z) = \pi(z \mid x)\pi_{\text{prior}}(x),$$

where we used the fact that the true observations y add no information on x that would not be included in z , we have, by definition of the Poisson likelihood and the prior,

$$L(x \mid y, z) = \sum_{ij} (z_{ij} \log(a_{ij} x_j) - a_{ij} x_j) - V(x) + \text{constant},$$

and therefore, up to an additive constant, we have

$$Q^k(x) = \sum_{ij} (z_{ij}^k \log(a_{ij} x_j) - a_{ij} x_j) - V(x),$$

where z_{ij}^k is defined in (23). This completes the E-step.

The M-step requires the minimization of $Q^k(x)$ given above. Assuming that V is differentiable, the minimizer should satisfy

$$\frac{1}{x_\ell} \sum_{i=1}^m z_{i\ell}^k - \sum_{i=1}^m a_{i\ell} - \frac{\partial V}{\partial x_\ell}(x) = 0.$$

How complicated it is to find a solution to this condition depends on the prior contribution V and may require an internal Newton iteration. In [29], an approximate “one-step late” (OSL) algorithm was suggested, which is tantamount to a fixed-point iteration: Initiating with $\tilde{x}^0 = x^k$, an update scheme $\tilde{x}^t \rightarrow \tilde{x}^{t+1}$ is given by

$$\tilde{x}_\ell^{t+1} = \frac{\sum_{i=1}^m z_{i\ell}^k}{\sum_{i=1}^m a_{i\ell} + \frac{\partial V}{\partial x_\ell}(\tilde{x}^t)},$$

and this step is repeated until a convergence criterion is satisfied at some $t = t^*$. Finally, the M-step is completed by updating $x^{k+1} = \tilde{x}^{t^*}$.

The EM algorithm has been applied to other imaging problems such as blind deconvolution problem [44] and PET imaging [36, 71].

Markov Chain Monte Carlo Sampling

In Bayesian statistical imaging, the real solution of the imaging problem is the posterior density of the image interpreted as a multivariate random variable. If a closed form of the posterior is either unavailable or not suitable for the tasks at hand, the alternative is to resort to exploring the density by generating a representative sample from it. Markov chain Monte Carlo (MCMC) samplers yield samples from a target distribution by moving from a point in a chain to the next by the transition

rule which characterizes the specific algorithm. MCMC sampling algorithms are usually subdivided into those which are variants of the Metropolis–Hastings (MH) algorithm or the Gibbs sampler. While the foundations of the MH algorithm were laid first [25, 35, 51], Gibbs samplers have sometimes the appeal of being more straightforward to implement.

The basic idea of Monte Carlo integration is rather simple. Assume that $\pi(x)$ is a probability density in \mathbb{R}^N , and let $\{X^1, X^2, X^3, \dots\}$ denote a stochastic process, where the random variables X^i are independent and identically distributed, $X^i \sim \pi(x)$. The central limit theorem asserts that for any measurable $f : \mathbb{R}^N \rightarrow \mathbb{R}$,

$$\frac{1}{n} \sum_{i=1}^n f(X^i) \xrightarrow{n \rightarrow \infty} \int_{\mathbb{R}^N} f(x) \pi(x) dx \quad \text{almost certainly,} \quad (24)$$

and moreover, the convergence takes place asymptotically with the rate $1/\sqrt{n}$, independently of the dimension N . The difficulty is to find a computationally efficient way of drawing independently from a given distribution π . Indeed, when N is large, it may be even difficult to decide where the numerical support of the density is. In MCMC methods, instead of producing an independent chain, the idea is to produce a Markov process $\{X^i\}$ with the property that π is the equilibrium distribution. It can be shown (see [53, 61, 65]) that with rather mild assumptions (irreducibility, aperiodicity), the limit (24) holds, due to the law of large numbers.

In applications to imaging, the computational burden associated with MCMC methods has become proverbial and is often presented as the main obstacle to the use of Bayesian method in imaging. It is easy to imagine that sampling random variable with hundreds of thousands of components will require a large amount of computer resources and that collecting and storing a large number of images will require much more time than estimating a single one. On the other hand, since an ensemble of images from a distribution carries a lot of additional information which cannot be included in single-point estimates, it seems unreasonable to rate methods simply according to computational speed. That said, since collecting a well-mixed, representative sample poses several challenges, in the description of the Gibbs sampling and Metropolis–Hastings algorithms, we will point out references to variants which can improve the independence and mixing of the ensemble; see [30–32].

In its first prominent appearance in the imaging arena [26], the Gibbs sampler was presented as part of a stochastic relaxation algorithm to efficiently compute MAP estimates. The systematic or fully conditional Gibbs sampler algorithm proceeds as follows [61].

Let $\pi(x)$ be a probability density defined on \mathbb{R}^N , denoted by $\pi(x) = \pi(x_1, \dots, x_N)$, $x \in \mathbb{R}^N$ to underline that it is the joint density of the components of X . Furthermore, denote by $\pi(x_j \mid x_{-j})$ the conditional density of the j th component x_j given all the other components, collected in the vector $x_{-j} \in \mathbb{R}^{N-1}$. Let x^1 be the initial element of the Markov chain. Assuming that we are at a point x^i in the chain, we need a rule stating how to proceed to the next point x^{i+1} , i.e.,

we need to describe the updating method of proceeding from the current element x^i to x^{i+1} . This is done by updating sequentially each component as follows.

Fully conditional Gibbs sampling update: Given x^i , compute the next element x^{i+1} by the following algorithm:

$$\begin{aligned} \text{draw } x_1^{i+1} & \text{ from } \pi(x_1 | x_{-1}^i); \\ \text{draw } x_2^{i+1} & \text{ from } \pi(x_2 | x_1^{i+1}, x_3^i, \dots, x_N^i); \\ \text{draw } x_3^{i+1} & \text{ from } \pi(x_3 | x_1^{i+1}, x_2^{i+1}, x_4^i, \dots, x_N^i); \\ & \vdots \\ \text{draw } x_N^{i+1} & \text{ from } \pi(x_N | x_{-N}^{i+1}). \end{aligned}$$

In imaging applications, this Gibbs sampler may be impractical because of the large number of components of the random variable to be updated to generate a new element of the chain. In addition, if some of the components are correlated, updating them independently may slow down the chain to explore the full support of the distribution, due to slow movement at each step. The correlation among components can be addressed by updating blocks of correlated components together, although this will imply that the draws must be from multivariate instead of univariate conditional densities.

It follows naturally from the updating scheme that the speed at which the chain will reach equilibrium is strongly dependent on how the system of coordinate axes relates to the most prominent correlation directions. A modification of the Gibbs sampler that can ameliorate the problems caused by correlated components performs a linear transformation of the random variable using correlation information. Without going into details, we refer to [48, 58, 61] for different variants of Gibbs sampler.

The strategy behind the Metropolis–Hastings samplers is to generate a chain with the target density as equilibrium distribution by constructing at each step the transition probability function from the current $X^i = x$ to next realization of X^{i+1} in the chain in the following way. Given an initial transition probability function $q(x, x')$ with $X^i = x$, x' drawn from $q(x, x')$ is a *proposal* for the value of X^{i+1} . Upon acceptance of $X^{i+1} = x'$, which occurs with probability $\alpha(x, x')$, defined by

$$\alpha(x, x') = \min \left\{ \frac{\pi(x')q(x', x)}{\pi(x, x')}, 1 \right\}, \quad \pi(x)q(x, x') > 0.$$

We add it to the chain; otherwise, we reject the proposed value and we set $X^{i+1} = x$. In the latter case, the chain did not move and the value x is replicated in the chain. The transition probability $p(x, x')$ of the Markov chain thus defined is

$$p(x, x') = q(x, x')\alpha(x, x'),$$

while the probability to stay put is

$$1 - \int_{\mathbb{R}^N} q(x, y) \alpha(x, y) dy.$$

This construction guarantees that the transition probability satisfies the detailed balance equation $\pi(x)p(x, x') = \pi(x')p(x', x)$, from which it follows that, for reasonable choices of the function q , $\pi(x)$ is the equilibrium distribution of the chain.

This algorithm is particularly convenient when the target distribution $\pi(x)$ is a posterior. In fact, since the only way in which π enters is via the ratio of its values at two points, it is sufficient to compute the density modulo a proportionality constant, which is how we usually define the posterior. Specific variants of the MH algorithm correspond to different choices of $q(x, x')$; in the original formulation [51], a symmetric proposal, for example, a random walk, was used, so that $q(x, x') = q(x', x)$, implying that

$$\alpha(x, x') = \min\{\pi(x')/\pi(x), 1\},$$

while the general formulation above is due to Hastings [35]. An overview of the different possible choices for $q(x, x')$ can be found in [65].

A number of hybrid sampling schemes which combine different chains or use MH variants to draw from the conditional densities inside Gibbs samplers have been proposed in the literature; see [48, 61] and references therein. Since the design of efficient MCMC samplers must address the specific characteristics of the target distribution, it is to be expected that as the use of densities becomes more pervasive in imaging, new hybrid MCMC scheme will be proposed.

The convergence of Monte Carlo integration based on MCMC methods is a key factor in deciding when to stop sampling. This is particularly pertinent in imaging applications, where the calculations needed for additions of a point to the chain may be quite time consuming. Due to the lack of a systematic way of translating theoretical convergence results of MCMC chains [7, 65] into pragmatic stopping rules, in practice, the issue is reduced to monitoring the behavior of the already collected sample.

As already pointed out, MCMC algorithms are not sampling independently from the posterior. When computing sample-based estimates for the posterior mean and covariance,

$$\hat{x}_{\text{CM}} = \frac{1}{n} \sum_{j=1}^n x^j, \quad \hat{\Gamma}_{\text{CM}} = \frac{1}{n} \sum_{j=1}^n (x^j - \hat{x}_{\text{CM}})(x^j - \hat{x}_{\text{CM}})^T.$$

A crucial question is how accurately these estimates approximate the posterior mean and covariance. The answer depends on the sample size n and the sampling strategy itself. Ideally, if the sample vectors x^j are realizations of independent identically

distributed random variables, the approximations converge with the asymptotic rate $1/\sqrt{n}$, in agreement with the central limit theorem. In practice, however, the MCMC sampling produces sample points that are mutually correlated, and the convergence is slower.

The convergence of the chain can be investigated using the *autocovariance function* (ACF) of the sample [27, 64]. Assume that we are primarily interested in estimating a real-valued function $f : \mathbb{R}^N \rightarrow \mathbb{R}$ of the unknown, and we have generated an MCMC sample or a realization $\{x^1, \dots, x^n\}$ of a stationary stochastic process $\{X^1, \dots, X^n\}$. The random variables X^j are equally distributed, their distribution being the posterior distribution $\pi(x)$ of a random variable X . The estimation of the mean quantity $f(X)$ can be done by calculating

$$\hat{\mu} = \frac{1}{n} \sum_{j=1}^n f(x^j),$$

while the theoretical mean of $f(X)$ is

$$\mu = \mathbb{E}\{f(X)\} = \int f(x)\pi(x)dx.$$

Each sample yields a slightly different value for $\hat{\mu}$, which is itself a realization of the random variable F defined as

$$F = \frac{1}{n} \sum_{j=1}^n f(X^j).$$

The problem is now how to estimate the variance of F , which gives us an indication of how well the computed realization approximates the mean. The identical distribution of the random variables X^j implies that

$$\mathbb{E}\{F\} = \frac{1}{n} \sum_{j=1}^n \underbrace{\mathbb{E}\{f(X^j)\}}_{=\mu} = \mu,$$

while the variance of F , which we want to estimate starting from the available realization of the by stochastic process, is

$$\text{var}(F) = \mathbb{E}\{F^2\} - \mu^2.$$

To this end, we need to introduce some definitions and notations.

We define the autocovariance function of the stochastic process $f(X^j)$ with lag $k \geq 0$ to be

$$C(k) = \mathbb{E}\{f(X^j)f(X^{j+k})\} - \mu^2$$

which, if the process is stationary, is independent of j . The normalized ACF is defined as

$$c(k) = \frac{C(k)}{C(0)}.$$

The ACF can be estimated from an available realization as follows

$$\hat{C}(k) = \frac{1}{n-k} \sum_{j=1}^{n-k} f(x^j) f(x^{j+k}) - \hat{\mu}^2. \quad (25)$$

It follows from the definition of F that

$$\mathbb{E}\{F^2\} = \frac{1}{n^2} \sum_{i,j=1}^n \mathbb{E}\{f(X^i)f(X^j)\}.$$

Let us now focus on the random matrix $[f(X^i)f(X^j)]_{i,j=1}^n$. The formula above takes its expectation and subsequently computes the average of its entries. By stationarity, the expectation is a symmetric Toeplitz matrix; hence, its diagonal entries are all equal to

$$\mathbb{E}\{f(X^i)f(X^i)\} = C(0) + \mu^2,$$

while the k th subdiagonal entries are all equal to

$$\mathbb{E}\{f(X^i)f(X^{i+k})\} = C(k) + \mu^2.$$

This observation provides us with a simple way to perform the summation by accounting for the elements along the diagonals, leading to the formula

$$\mathbb{E}\{F^2\} = \frac{1}{n^2} \left(nC(0) + 2 \sum_{k=1}^{n-1} (n-k)C(k) \right) + \mu^2,$$

from which it follows that the variance of F is

$$\text{var}(F) = \frac{1}{n} \left(C(0) + 2 \sum_{k=1}^{n-1} \left(1 - \frac{k}{n} \right) C(k) \right).$$

If we assume that the ACF is negligible when $k > n_0$, for some n_0 significantly smaller than the sample size n , we may use the approximation

$$\text{var}(F) \approx \frac{1}{n} \left(C(0) + 2 \sum_{k=1}^{n_0} C(k) \right) = \frac{C(0)}{n} \tau,$$

where

$$\tau = 1 + 2 \sum_{k=1}^{n_0} c(k). \quad (26)$$

If we account fully for all contributions,

$$\tau = 1 + 2 \sum_{k=1}^{n-1} \left(1 - \frac{k}{n}\right) c(k), \quad (27)$$

which is the Cesàro mean of the normalized ACFs or low-pass filtered mean with the triangular filter. The quantity τ is called the *integrated autocorrelation time* (IACT) and can be interpreted as the time that it takes for our MCMC to produce an independent sample. If the convergence rate for independence samplers is $1/\sqrt{n}$, the convergence rate for the MCMC sampler is $1/\sqrt{n}/\tau$. If the variables X_j are independent, then $\tau = 1$, and the result is exactly what we would expect from the central limit theorem, because in this case, $C(0) = n \text{ var}(f(X))$.

The estimate of τ requires an estimate for the normalized ACF, which can be obtained with the formula (25), and a value for n_0 to use in formula (26). In the choice of n_0 , it is important to remember that $\hat{C}(k)$ is a realization of a random sequence $C(k)$, which in practice contains noise. Some practical rules for choosing n_0 are suggested in [27].

In [27], it is shown that since the sequence

$$\gamma(k) = c(2k) + c(2k+1), \quad k = 0, 1, 2, \dots$$

is *strictly positive*, *strictly decreasing*, and *strictly convex*, that is,

$$\gamma(k) > 0, \quad \gamma(k+1) < \gamma(k), \quad \gamma(k+1) < \frac{1}{2}(\gamma(k) + \gamma(k+2)),$$

when the sample-based estimated sequence,

$$\hat{\gamma}(k) = \hat{c}(2k) + \hat{c}(2k+1), \quad k = 0, 1, 2, \dots$$

fails to be so, this is an indication that the contribution is predominantly coming from noise; hence, it is wise to stop summing the terms to estimate τ . Geyer proposes three initial sequence estimators, in the following order:

1. Initial positive sequence estimator (IPSE): Choose n_0 to be the largest integer for which the sequence remains positive,

$$n_0 = n_{\text{IPSE}} = \max\{k \mid \gamma(k) > 0\}.$$

2. Initial monotone sequence estimator (IMSE): Choose n_0 to be the largest integer for which the sequence remains positive and monotone,

$$n_0 = n_{\text{IMSE}} = \max\{k \mid \gamma(k) > 0, \gamma(k) < \gamma(k-1)\}.$$

3. Initial convex sequence estimator (ICSE): Choose n_0 to be the largest integer for which the sequence remains positive, monotone, and convex,

$$\begin{aligned} n_0 = n_{\text{ICSE}} &= \max \left\{ k \mid \gamma(k) > 0, \gamma(k) < \gamma(k-1), \gamma(k-1) \right. \\ &\quad \left. < \frac{1}{2}(\gamma(k) + \gamma(k-2)) \right\}. \end{aligned}$$

From the proof in [27], it is obvious that also the sequence $\{c(k)\}$ itself must be positive and decreasing. Therefore, to find n_0 for IPSE or IMSE, there is no need for passing to the sequence $\{\gamma(k)\}$. As for ICSE, again from the proof in the cited article, it is also clear that the sequence

$$\eta(k) = c(2k+1) + c(2k+2), \quad k = 0, 1, 2, \dots$$

too, is positive, monotonous, and convex. Therefore, to check the condition for ICSE, it might be advisable to form both sequences $\{\gamma(k)\}$ and $\{\eta(k)\}$ and set n_{ICSE} equal to the maximum index for which both $\gamma(k)$ and $\eta(k)$ remain strictly convex.

Summarizing a practical rule, using for instance, the IMSE, to compute τ is:

1. Estimate the ACF sequence $\hat{C}(k)$ from the sample by formula (25) and normalize it by $\hat{C}(0)$ to obtain $\hat{c}(k)$.
2. Find n_0 equal to the largest integer for which the sequence $\hat{c}(0), \hat{c}(1), \dots, \hat{c}(n_0)$ remains positive and strictly decreasing. Notice that the computation of ACFs can be stopped when such an n_0 is reached.
3. Calculate the estimate for the IACT τ ,

$$\tau = 1 + 2 \sum_{k=1}^{n_0} \left(1 - \frac{k}{n}\right) c(k) \approx 1 + 2 \sum_{k=1}^{n_0} c(k). \quad (28)$$

Notice that if n is not much larger than n_0 , the sample is too small.

The accuracy of the approximation of μ by $\hat{\mu}$ is often expressed, with some degree of imprecision, by writing an estimate

$$\mu = \hat{\mu} \pm 2 \left(\frac{C(0)}{n} \tau \right)^{1/2}$$

with the 95 % belief. This interpretation is based on the fact that, with a probability of about 95 %, the values of a Gaussian random variable are within ± 2 STD from

the mean. Such an approximate claim is justified when n is large, in which case the random variable F is asymptotically Gaussian by the central limit theorem.

Statistical Approach: What Is the Gain?

Statistical methods are often pitted against deterministic ones, and the true gain of the approach is sometimes lost, especially if the statistical methods are used only to produce single estimates. Indeed, it is not uncommon that the statistical framework is seen simply as an alternative way of explaining regularization. Another criticism of statistical methods concerns the computation times. While there is no doubt that computing a posterior mean using MCMC methods is more computationally intensive than resorting to optimization-based estimators, it is also obvious that a comparison in these terms does not make much sense, since a sample contains enormously more information of the underlying distribution than an estimate of its mode.

To emphasize what there is to be gained when using the statistical approach, we consider some algorithms that have been found useful and are based on the interpretation images as random variables.

Beyond the Traditional Concept of Noise

The range of interpretation of the concept of noise in imaging is usually very restricted, almost exclusively referring to uncertainties in observed data due to exogenous sources. In the context of deterministic regularization, the noise model is almost always additive, in agreement with the paradigm that only acknowledges noise as the difference between a “true” and “noisy” data, giving no consideration to its statistical properties. Already the proper noise modeling of counting data clearly demonstrates the shortcomings of such models. The Bayesian – or subjective – use of probability as an expression of uncertainty allows to extend the concept of noise to encompass a much richer terrain of phenomena, including shortcomings in the forward model, prior, or noise statistics itself.

To demonstrate the possibilities of the Bayesian modeling, consider an example where it is assumed that a forward model with additive noise,

$$y = F(x) + e. \quad (29)$$

which describes, to the best of our knowledge, as completely as possible, the interdependency of the data y and the unknown. We refer to it as the *detailed model*. Here, the noise e is thought to be exogenous, and its statistical properties are known.

Assume further that the detailed model is computationally too complex to be used with the imaging algorithms and the application at hand for one or several of the following reasons. The dimensionality of the image x may be too high for the model to be practical; the model may contain details such as boundary conditions that need to be simplified in practice; the deblurring kernel may be non-separable, while in practice, a fast algorithm for separable kernels may exist. To

accommodate these difficulties, a simpler model is constructed. Let z be possibly a simpler representation of x , obtained, for example, via a projection to a coarser grid, and let f denote the corresponding forward map. It is a common procedure to write a simplified model of the form

$$y = f(z) + e, \quad (30)$$

which, however, may not explain the data as well as the detailed model (29). To properly account for the errors added by the model reduction, we should write instead

$$\begin{aligned} y &= F(x) + e = f(z) + [F(x) - f(z)] + e \\ &= f(z) + \varepsilon(x, z) + e, \quad \varepsilon(x, z) = F(x) - f(z), \end{aligned} \quad (31)$$

where the term $\varepsilon(x, z)$ is referred to as *modeling error*.

In the framework of deterministic imaging, modeling errors pose unsurmountable problems because they depend on both the unknown image x and its reduced counterpart z . A common way to address errors coming from model reduction is to artificially increase the variance of the noise included in the reduced model until it masks the modeling error. Such an approach introduces a statistical structure in the noise that does not correspond to the modeling error and may easily waste several orders of magnitude of the accuracy of the data. On the other hand, neglecting the error introduced by model reduction may lead to overly optimistic estimates of the performance of algorithms. The very questionable procedure of testing algorithms with data simulated with the same forward map used for the inversion is referred to as *inverse crime* [42]. Inverse criminals, who tacitly assume that $\varepsilon(x, z) = 0$, should not be surprised if the unrealistically good results obtained from simulated data are not robust when using real data.

While modeling error often is neglected also in the statistical framework, its statistical properties can be described in terms of the prior. Consider the stochastic extension of $\varepsilon(x, z)$,

$$\tilde{\varepsilon} = \varepsilon(X, Z),$$

where X and Z are the stochastic extensions of x and z , respectively. Since, unlike an exogenous noise term, the modeling error is not independent of the unknowns Z and X , the likelihood and the prior cannot be described separately, but instead must be specified together.

To illustrate how ubiquitous modeling error is, consider the following example.

Boundary clutter and image truncation: Consider a denoising/deblurring example of the type encountered in astronomy, microscopy, and image processing. Let $u : \mathbb{R}^2 \rightarrow \mathbb{R}$ be a continuous two-dimensional model of a scenery that is recorded through an out-of-focus device. The noiseless model for the continuous problem is a convolution integral,

$$v(r) = \int_{\mathbb{R}^2} a(r-s)u(s)ds, \quad r \in \mathbb{R}^2,$$

the convolution kernel $a(r-s)$ describing the point spread of the device. We assume that $r \mapsto a(r)$ decays rapidly enough to justify an approximation as a compactly supported function.

Let $Q \subset \mathbb{R}^2$ define a bounded *field of view*. We consider the following imaging problem: *Given a noisy version of the blurred image v over the field of view Q , estimate the underlying image u over the field of view Q .*

Assume that a sufficiently fine discretization of Q into N pixels is given, and denote by $r_i \in Q$ the center of the i th pixel. Assume further that the point spread function a is negligibly small outside a disc D of radius $\delta > 0$. By selecting an *extended field of view* Q' such that

$$Q + D = \{s \in \mathbb{R}^2 \mid s = r + r', r \in Q, r' \in D\} \subset Q',$$

we may restrict the domain of integration in the definition of the convolution integral

$$v(r_i) = \int_{\mathbb{R}^2} a(r_i - s)u(s)ds \approx \int_{Q'} a(r_i - s)u(s)ds.$$

After discretizing Q' into N' pixels p_j with center points s_j , N of which are within the field of view, coinciding with R^J we can restate the problem in the form

$$\begin{aligned} v(s_i) &\approx \int_{Q'} a(s_i - s)u(s)ds \approx \sum_{j=1}^{N'} |p_j| a(s_i - s_j)u(s_j) \\ &= a_{ij}u(s_j), \quad a_{ij} = |p_j| a(s_i - s_j), \quad 1 \leq i \leq N. \end{aligned}$$

After accounting for the contribution of exogenous noise at each recorded pixel, we arrive at the complete discrete model

$$y = \mathbf{A}'x + e, \quad \mathbf{A}' \in \mathbb{R}^{N \times N'}, \quad (32)$$

where $x_j = u(s_j)$ and y_i represent the noisy observation of $v(s_i)$. If the pixelization is fine enough, we may consider this model to be a good approximation of the continuous problem.

A word of caution is in order when using this model, because the right-hand side depends not only on pixels within the field of view, where we want to estimate the underlying image, but also on pixels in the frame $C = Q' \setminus Q$ around it. The vector x is therefore partitioned into two vectors, where the first one, denoted by $z \in \mathbb{R}^N$, contains values in the pixels within the field of view, and the second one, $\zeta \in \mathbb{R}^K$, $K = N' - N$, consists of values of pixels in the frame. After suitably rearranging the indices, we may write x in the form

$$x = \begin{bmatrix} z \\ \zeta \end{bmatrix} \in \mathbb{R}^N \times \mathbb{R}^K,$$

and, after partitioning the matrix \mathbf{A}' accordingly,

$$\mathbf{A}' = [\mathbf{A} \ \mathbf{B}] \in \mathbb{R}^{N \times N} \times \mathbb{R}^{N \times K},$$

we can rewrite the model (32) in the form

$$y = \mathbf{A}z + \mathbf{B}\zeta + e = \mathbf{A}z + \varepsilon + e,$$

where the modeling errors are collected in second term ε , which we will refer to as *boundary clutter*. It is well known that ignoring the contribution to the recorded image coming from and beyond the boundary may cause severe artifacts in the estimation of the image x within the field of view. In a determinist framework, the boundary clutter term is often compensated for by extending the image outside the field of view in a manner believed to be closest to the actual image behavior. Periodic extension or extensions obtained by reflecting the image symmetrically or antisymmetrically are quite popular in the literature, because they will significantly simplify the computations; details on such an approach can be found, for example, in [21].

Consider a Gaussian prior and a Gaussian likelihood,

$$X \sim \mathcal{N}(0, \Gamma), \quad E \sim \mathcal{N}(0, \Sigma_{\text{noise}}),$$

and partition the prior covariance matrix according to the partitioning of x ,

$$\Gamma \in \begin{bmatrix} \Gamma_{11} & \Gamma_{12} \\ \Gamma_{21} & \Gamma_{22} \end{bmatrix}, \quad \Gamma_{11} \in \mathbb{R}^{N \times N}, \quad \Gamma_{12} = \Gamma_{21}^T \in \mathbb{R}^{N \times K}, \quad \Gamma_{22} \in \mathbb{R}^{K \times K}.$$

The covariance matrix of the total noise term, which also includes the boundary clutter \tilde{E} , is

$$\mathbb{E} \left\{ (\tilde{E} + E) (\tilde{E} + E)^T \right\} = \mathbf{B} \Gamma_{22} \mathbf{B}^T + \Sigma_{\text{noise}} = \Sigma$$

and the cross covariance of the image within the field of view and the noise is

$$\mathbf{C} = \mathbb{E} \left\{ Z (\tilde{E} + E)^T \right\} = \Gamma_{12} \mathbf{B}^T.$$

The posterior distribution of the vector Z conditioned on $Y = y$ now follows from (17) and (18). The posterior mean is

$$z_{\text{CM}} = (\Gamma_{11}\mathbf{A} + \Gamma_{12}\mathbf{B}^T) (\mathbf{A}\Gamma_{11}\mathbf{A}^T + \mathbf{B}\Gamma_{22}\mathbf{B}^T + \Sigma_{\text{noise}})^{-1} y,$$

and the posterior covariance is

$$\Gamma_{\text{post}} = \Gamma_{11} - (\Gamma_{11}\mathbf{A} + \Gamma_{12}\mathbf{B}^T) (\mathbf{A}\Gamma_{11}\mathbf{A}^T + \mathbf{B}\Gamma_{22}\mathbf{B}^T + \Sigma_{\text{noise}})^{-1} (\Gamma_{11}\mathbf{A} + \Gamma_{12}\mathbf{B}^T)^T.$$

A computationally efficient and robust algorithm for computing the conditional mean is proposed in [13]. For further applications of the modeling error approach in imaging, see [1, 38, 47].

Sparsity and Hypermodels

The problem of reconstructing sparse images or more generally images that can be represented as sparse linear combinations of prescribed basis images using data consisting of few measurements has recently received a lot of attention and has become a central issue in compressed sensing [11]. Bayesian hypermodels provide a very natural framework for deriving algorithms for sparse reconstruction.

Consider a linear model with additive Gaussian noise, the likelihood being given by (12) and a conditionally Gaussian prior (13) with hyperparameter θ . As explained in section ‘‘Adding Layers: Hierarchical Models,’’ if we select the hyperprior $\pi_{\text{hyper}}(\theta)$ in such a way that it favors solutions with variances Θ_j close to zero except for only few outliers, the overall prior for (X, Θ) will be biased toward sparse solutions. Two hyperpriors well suited for sparse solutions are the gamma and the inverse gamma hyperpriors. For the sake of definiteness, consider the inverse gamma hyperprior with mutually independent components,

$$\pi_{\text{hyper}}(\theta_j) = \theta_j^{-k-1} \exp\left(-\frac{\theta_0}{\theta_j}\right) = \exp\left(-\frac{\theta_0}{\theta_j} - (k+1)\log\theta_j\right).$$

Then the posterior distribution for the pair (X, Θ) is of the form

$$\pi(x, \theta | y) \propto \exp\left(-\frac{1}{2}(y - \mathbf{Ax})^T \Sigma^{-1} (y - \mathbf{Ax}) - \frac{1}{2}x^T \mathbf{D}_\theta^{-1} x - \sum_{j=1}^N V(\theta_j)\right)$$

where

$$V(\theta_j) = \frac{\theta_0}{\theta_j} + \left(k + \frac{3}{2}\right) \log\theta_j, \quad \mathbf{D}_\theta = \text{diag}(\theta) \in \mathbb{R}^{N \times N}.$$

An estimate for (X, Θ) can be found by maximizing $\pi(x, \theta | y)$ with respect to the pair (x, θ) using, for example, a quasi-Newton optimization scheme. Alternatively, the following two algorithms that make use of the special form of the expression above can also be used.

In the articles [66, 67] on Bayesian machine learning, the starting point is the observation that the posterior density $x \mapsto \pi(x, \theta | y)$ is Gaussian and therefore it is possible to integrate it explicitly with respect to x . It can be shown, after some tedious but straightforward algebraic manipulations, that the marginal posterior distribution is

$$\begin{aligned}\pi(\theta | y) &= \int_{\mathbb{R}^N} \pi(x, \theta | y) dx \\ &\propto \left(\frac{1}{\det(\mathbf{M}_\theta)} \right)^{1/2} \exp \left(- \sum_{j=1}^N V(\theta_j) + \frac{1}{2} \tilde{y}^\top \mathbf{M}_\theta^{-1} \tilde{y} \right),\end{aligned}$$

where

$$\mathbf{M}_\theta = \mathbf{A}^\top \Sigma^{-1} \mathbf{A} + \mathbf{D}_\theta^{-1}, \quad \tilde{y} = \mathbf{A}^\top \Sigma^{-1} y.$$

The *most probable* estimate or the *maximum evidence* estimator $\hat{\theta}$ of Θ is, by definition, the maximizer of the above marginal, or equivalently, the maximizer of its logarithm,

$$L(\theta) = -\frac{1}{2} \log(\det(\mathbf{M}_\theta)) - \sum_{j=1}^N V(\theta_j) + \frac{1}{2} \tilde{y}^\top \mathbf{M}_\theta^{-1} \tilde{y}$$

which must satisfy

$$\frac{\partial L}{\partial \theta_j} = 0, \quad 1 \leq j \leq N.$$

It turns out that, although the computation of the determinant may in general be a challenge, its derivatives can be expressed in a formally simple form. To this end separate the element depending on θ_j from \mathbf{D}_θ^{-1} , writing

$$\mathbf{D}_\theta^{-1} = \frac{1}{\theta_j} e_j e_j^\top + \mathbf{D}_{\theta'}^\dagger,$$

where e_j is the j th coordinate unit vector, θ' is the vector θ with the j th element replaced by a zero and “ \dagger ” denotes the pseudo-inverse. Then

$$\begin{aligned}\mathbf{M}_\theta &= \mathbf{A}^\top \Sigma^{-1} \mathbf{A} + \mathbf{D}_{\theta'}^\dagger + \frac{1}{\theta_j} e_j e_j^\top = \mathbf{M}_{\theta'} + \frac{1}{\theta_j} e_j e_j^\top \\ &= \mathbf{M}_{\theta'} \left(\mathbf{I} + \frac{1}{\theta_j} q e_j^\top \right), \quad q = \mathbf{M}_{\theta'}^{-1} e_j.\end{aligned}\tag{33}$$

It follows from the properties of the determinant that

$$\det(\mathbf{M}_\theta) = \det\left(1 + \frac{1}{\theta_j} q e_j^\top\right) \det(\mathbf{M}_{\theta'}) = \left(1 + \frac{q_j}{\theta_j}\right) \det(\mathbf{M}_{\theta'}),$$

where $q_j = e_j^\top q$. After expressing the inverse of \mathbf{M}_θ in the expression of $L(\theta)$ via the Sherman–Morrison–Woodbury formula [28] as

$$\mathbf{M}_\theta^{-1} = \mathbf{M}_{\theta'}^{-1} - \frac{1}{\theta_j + q_j} q q^\top,$$

we find that the function $L(\theta)$ can be written as

$$\begin{aligned} L(\theta) &= \frac{1}{2} \log\left(1 + \frac{q_j}{\theta_j}\right) - V(\theta_j) + \frac{1}{2} \frac{(q^\top \tilde{y})^2}{\theta_j + q_j} \\ &\quad + \text{terms that are independent of } \theta_j. \end{aligned}$$

The computation of the derivative of $L(\theta)$ with respect to θ_j and its zeros is now straightforward, although not without challenges because reevaluation of the vector q may potentially be expensive. For details, we refer to the article [67].

After having found an estimate $\hat{\theta}$, an estimate for X can be obtained by observing that the conditional density $\pi(x \mid y, \hat{\theta})$ is Gaussian,

$$\pi(x \mid y, \hat{\theta}) \propto \exp\left(-\frac{1}{2}(y - \mathbf{A}x)^\top \Sigma^{-1}(y - \mathbf{A}x) - \frac{1}{2}x^\top \hat{\theta} x\right),$$

and an estimate for x is obtained by solving in the least squares sense the linear system

$$\begin{bmatrix} \Sigma^{-1/2} \mathbf{A} \\ \mathbf{D}_{\hat{\theta}}^{-1/2} \end{bmatrix} x = \begin{bmatrix} \Sigma^{-1/2} y \\ 0 \end{bmatrix}. \quad (34)$$

In imaging applications, this is a large-scale linear problem and typically, iterative solvers need to be employed [59].

A different approach leading to a fast algorithm of estimating the MAP estimate $(x, \theta)_{\text{MAP}}$ was suggested in [15]. The idea is to maximize the posterior distribution using an alternating iteration: Starting with an initial value $\theta = \theta^1$, $\ell = 1$, the iteration proceeds as follows:

1. Find $x^{\ell+1}$ that maximizes $x \mapsto L(x, \theta^\ell) = \log(\pi(x, \theta^\ell \mid y))$.
2. Update $\theta^{\ell+1}$ by maximizing $\theta \mapsto L(x^{\ell+1}, \theta) = \log(\pi(x^{\ell+1}, \theta \mid y))$.

The efficiency of this algorithm is based on the fact that for $\theta = \theta^\ell$ fixed, the maximization of $L(x, \theta^\ell)$ in the first step is tantamount to minimizing the quadratic expression

$$\frac{1}{2} \|\Sigma^{-1/2}(y - \mathbf{A}x)\|^2 + \frac{1}{2} \left\| \mathbf{D}_{\theta^\ell}^{-1/2} x \right\|^2,$$

the non-quadratic part being independent of x . Thus, step 1 only requires an (approximate) linear least squares solution of the system similar to (34). On the other hand, when $x = x^{\ell+1}$ is fixed, the minimizer of the second step is found as a zero of the gradient of the function $L(x^{\ell+1}, \theta)$ with respect to θ . This step, too, is straightforward, since the component equations are mutually independent,

$$\frac{\partial}{\partial \theta_j} L(x^{\ell+1}, \theta) = - \left(\frac{1}{2} \left(x_j^{\ell+1} \right)^2 + \theta_0 \right) \frac{1}{\theta_j^2} + \left(k + \frac{3}{2} \right) \frac{1}{\theta_j} = 0,$$

leading to the explicit updating formula

$$\theta_j^{\ell+1} = \frac{1}{2k+3} \left(\left(x_j^{\ell+1} \right)^2 + 2\theta_0 \right).$$

For details and performance of the method in image applications, we refer to [15].

5 Conclusion

This chapter gives an overview of statistical methods in imaging. Acknowledging that it would be impossible to give a comprehensive review of all statistical methods in imaging in a chapter, we have put the emphasis on the Bayesian approach, while making repeated forays in the frequentists' field. These editorial choices are reflected in the list of references, which only covers a portion of the large body of literature published on the topic. The use of statistical methods in subproblems of imaging science is much wider than presented here, extending, for example, from image segmentation to feature extraction, interpretation of functional MRI signals, and radar imaging.

Abstract

During the last two decades, support vector machine learning has become a very active field of research with a large amount of both sophisticated theoretical results and exciting real-world applications. This paper gives a brief introduction into the basic concepts of supervised support vector learning and touches some recent developments in this broad field.

1 Introduction

The desire to learn from examples is as old as mankind but has reached a new dimension with the invention of computers. This paper concentrates on learning by support vector machines (SVMs) which meanwhile deliver state-of-the-art performance in many real-world applications. However, it should be mentioned at the beginning that there exist many alternatives to SVMs ranging from classical k -nearest neighbor methods over trees and neural networks to other kernel-based methods. Overviews can be found, e.g., in the books of Mitchell [73], Hastie et al. [47], Duda et al. [34], and Bishop [9].

SVMs are a new-generation learning system based on various components including:

- Statistical learning theory,
- Optimization theory (duality concept),
- Reproducing kernel Hilbert spaces (RKHSs),
- Efficient numerical algorithms.

This synthesis and their excellent performance in practice make SVM-like learning attractive for researchers from various fields. A non-exhaustive list of SVM applications includes *text categorization* (see Joachims [53] and Leopold and Kinderman [64]), *handwritten character recognition* (see LeCun et al. [62]), *texture and image classification* (see Chapelle et al. [23]), *protein homology detection* (see Jaakkola and Haussler [51]), *gene expression* (see Brown et al. [17]), *medical diagnostics* (see Strauss et al. [96]), and *pedestrian and face detection*, (see Osuna et al. [77] and Viola and Jones [110]). There exist various benchmark data sets for testing and comparing new learning algorithms and a good collection of books and tutorials on SVMs as those of Vapnik [105], Burges, [19], Cristianini and Shawe-Taylor [27], Herbrich [48], Schölkopf and Smola [87], and Steinwart and Christmann [93]. The first and latter ones contain a mathematically more rigorous treatment of statistical learning aspects. So-called least squares SVMs are handled in the book of Suykens et al. [98], and SVMs from the approximation theoretic point of view are considered in the book of Cucker and Zhou [29].

Let $\mathcal{X} \subset \mathbb{R}^d$, $\mathcal{Y} \subset \mathbb{R}^{\tilde{d}}$, where for simplicity only $\tilde{d} = 1$ is considered, and $\mathcal{Z} := \mathcal{X} \times \mathcal{Y}$. The aim of the following sections is to learn a target function $\mathcal{X} \rightarrow \mathcal{Y}$ from given training samples $Z := \{(x_1, y_1), \dots, (x_m, y_m)\} \subset \mathcal{Z}$. A distinction is made between classification and regression tasks. In *classification* \mathcal{Y} is a discrete set, in general as large as the number of classes the samples belong to. Here binary classification with just two labels in \mathcal{Y} was most extensively studied. An example where binary classification is useful is SPAM detection. Another example in medical diagnostics is given in Fig. 1. Here it should be mentioned that in many practical applications, the original input variables are pre-processed to transform them into a new useful space which is often easier to handle but preserves the necessary discriminatory information. This process is also known as *feature extraction*.

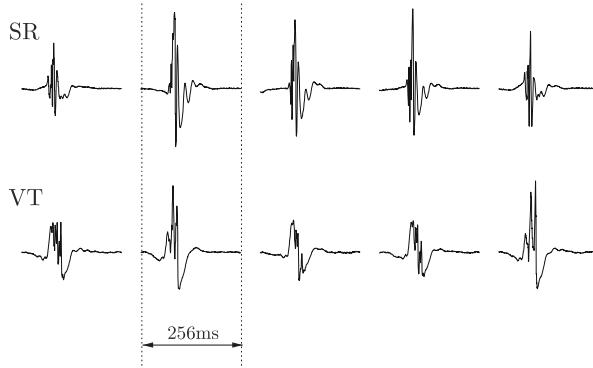

Fig. 1 Examples of physiological (SR) and pathological (VT) electrical heart activity curves measured by an implanted cardioverter-defibrillator. For the classification of such signals, see Strauss and Steidl [95]

In contrast to classification, *regression* aims at approximating the “whole” real-valued function from some function values, so that \mathcal{Y} is not countable here. The above examples, as all problems considered in this paper, are from the area of *supervised learning*. This means that all input vectors come along with their corresponding target function values (labeled data). In contrast, *semi-supervised learning* makes use of labeled and unlabeled Data, and in *unsupervised learning* labeled data are not available, so that one can only exploit the input vectors x_i . The latter methods can be applied for example to discover groups of similar exemplars within the data (clustering), to determine the distribution of the data within the input space (density estimation), or to perform projections of data from high-dimensional spaces to lower-dimensional spaces. There are also learning models which involve more complex interactions between the learner and the environment. An example is *reinforcement learning* which is concerned with the problem of finding suitable actions in a given situation in order to maximize the reward. In contrast to supervised learning, reinforcement learning does not start from given optimal (labeled) outputs but must instead find them by a process of trial and error. For reinforcement learning, the reader may consult the book of Sutton and Barto [97].

Learning models can also differ in the way in which the training data are generated and presented to the learner. For example, a distinction can be made between *batch learning*, where all the data are given at the start of the training phase, and *online learning*, where the learner receives one example at a time and updates the hypothesis function in response to each new example.

This paper is organized as follows: An overview of the historical background is given in Sect. 2. Section 3 contains an introduction into classical SVM methods. It starts with linear methods for (binary) support vector classification and regression and considers also linear least squares classification/regression. Then the kernel trick is explained and used to transfer the linear models into so-called feature spaces which results in nonlinear learning methods. Some other models related to SVM as

well as multi-class classification and multitask learning are addressed at the end of the section. Section 4 provides some mathematical background concerning RKHSs and quadratic optimization. The last subsection sketches very briefly some results in statistical learning theory. Numerical methods to make the classical SVMs efficient in particular for large data sets are presented in Sect. 5. The paper ends with some conclusions in Sect. 6.

2 Historical Background

Modern learning theory has a long and interesting history going back as far as Gauss and Legendre but got its enormous impetus from the advent of computing machines. In the 1930s revolutionary changes took place in understanding the principles of inductive inference from a philosophical perspective, e.g., by Popper, and from the point of view of statistical theory, e.g., by Kolmogorov, Glivenko, and Cantelli, and applied statistics, e.g., by Fisher. A good overview over the leading ideas and developments in this time can be found in the comments and bibliographical remarks of Vapnik's book, Vapnik [105]. The starting point of statistical learning theory which considers the task of minimizing a risk functional based on empirical data dates back to the 1960s. Support vector machines, including their RKHS interpretation, were only discovered in the 1990s and led to an explosion in applications and theoretical analysis.

Let us start with the problem of linear regression which is much older than linear classification. The method of least squares was first published by Legendre [63]. It was considered as a statistical procedure by Gauss [43], who claimed, to the annoyance of Legendre but in accordance with most historians, to have applied this method since 1795. The original least squares approach finds for given points $x_i \in \mathbb{R}^d$ and corresponding $y_i \in \mathbb{R}$, $i = 1, \dots, m$ a hyperplane $f(x) = \langle w, x \rangle + b$ having minimal least squares distance from the points (x_i, y_i) :

$$\sum_{i=1}^m (\langle w, x_i \rangle + b - y_i)^2 \rightarrow \min_{w,b}. \quad (1)$$

This leads to the solution of a linear system of equations which can be ill conditioned or possess several solutions. Therefore, regularized versions were introduced later. The linear least squares approach is optimal in the case of linear targets corrupted by Gaussian noise. Sometimes it is useful to find a linear function which does not minimize the least squares error, but, for example, the ℓ_1 -error

$$\sum_{i=1}^m |\langle w, x_i \rangle + b - y_i| \rightarrow \min_{w,b}$$

which is more robust against outliers. This model with the constraint that the sum of the errors is equal to zero was already studied by Laplace in 1799; see Laplace

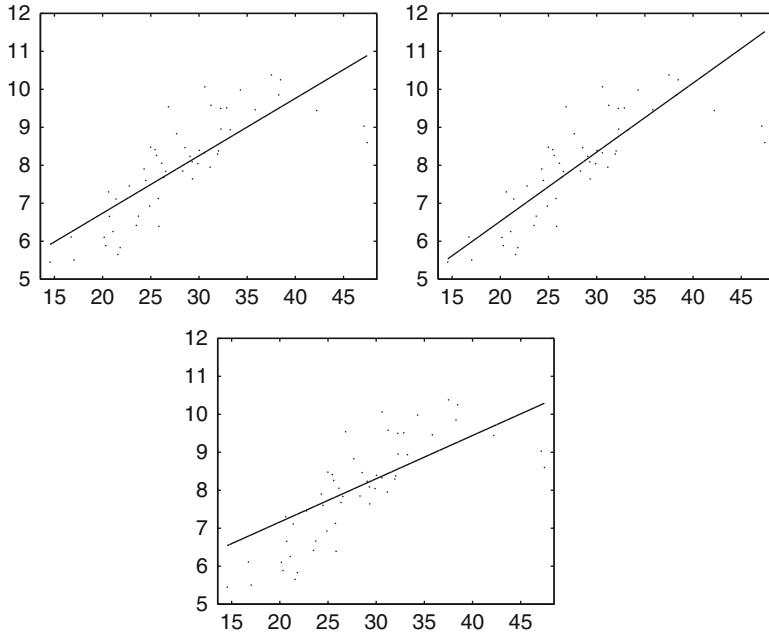

Fig. 2 Linear approximation with respect to the ℓ_2 -, ℓ_1 - and ℓ_∞ -norm of the error (left to right). The ℓ_1 approximation is more robust against outliers while the ℓ_∞ -norm takes them better into account

[61]. Another popular choice is the ℓ_∞ -error

$$\max_{i=1,\dots,m} |\langle w, x_i \rangle + b - y_i| \rightarrow \min_{w,b}$$

which better incorporates outliers. In contrast to the least squares method, the solutions of the ℓ_1 - and ℓ_∞ -problems cannot be computed via linear systems of equations but require to solve linear optimization problems. Figure 2 shows a one-dimensional example, where data are approximated by lines with minimal ℓ_2 , ℓ_1 - and ℓ_∞ error norm, respectively. For more information on (regularized) least squares problems, the reader may consult, e.g., the books of Golub and Van Loan [45] and of Björck [10].

Regularized least squares methods which penalize the quadratic weight $\|w\|^2$ as in section ‘‘Linear Least Squares Classification and Regression’’ were examined under the name *ridge regression* by Hoerl and Kennard [49]. This method can be considered as a special case of the regularization theory for ill-posed problems developed by Tikhonov and Arsenin [102]. Others than the least squares loss function like the ϵ -insensitive loss were brought into play by Vapnik [105]. This loss function enforces a sparse representation of the weights in terms of so-called support vectors which are (small) subsets of the training samples $\{x_i : i = 1, \dots, m\}$.

The simplest form of classification is *binary classification*, where one has just to separate between two classes. Linear hyperplanes $H(w, b)$ separating points, also called *linear discriminants* or *perceptrons*, were already studied by Fisher [41] and became interesting for neural network researchers in the early 1960s. One of the first algorithms that constructs a separating hyperplane for linearly separable points was Rosenblatt's perceptron; see Rosenblatt [84]. It is an iterative online and mistake-driven algorithm which starts with an initial weight guess w for the hyperplane and adapts the weight at each time a training point is misclassified by the current weight. If the data are linearly separable, the procedure converges, and the number of mistakes (number of updates of w) does not exceed $(2R/\gamma)^2$, where $R := \min_{i=1,\dots,m} \|x_i\|$ and γ is the smallest distance between a training point and the hyperplane. For linearly separable points, there exist various hyperplanes separating them.

An *optimal* hyperplane for linearly separable points in the sense that the minimal distance of the points from the plane becomes maximal was constructed as so-called generalized portrait algorithm by Vapnik and Lerner [108]. This learning method is also known as *linear hard margin support vector classifier*. The method was generalized to nonseparable points by Cortes and Vapnik [26] which leads to *soft margin classifiers*. Finally, the step from linear to nonlinear classifiers via feature maps was taken by Boser et al. [12]. Their idea to combine a linear algorithm with a kernel approach inspired the further examination of specific kernels for applications.

However, the theory of kernels and their applications is older than SVMs. Aronzajn [5], systematically developed the theory of RKHSs in the 1940s though it was discovered that many results were independently obtained by Povzner [83]. The work of Parzen [78] brought the RKHS to the fore in statistical problems; see also Kailath [54]. Kernels in pattern recognition were already applied by Aizerman et al. [1]. Empirical risk minimization over RKHSs was considered by Wahba [112] in connection with splines and by Poggio and Giriosi [81] in relation with neural networks. Schölkopf et al. [89] realized that the *kernel trick* works not only for SVMs but for many other methods as principal component analysis in unsupervised learning.

The invention of SVMs has led to a gigantic amount of developments in learning theory and practice. The size of this paper would be not enough to list the references on this topic. Beyond various applications, also advanced generalization results, suitable choices of kernels, efficient numerical methods in particular for large data sets, relations to other sparse representation methods, multi-class classification, and multitask learning were addressed. The reader will find some references in the corresponding sections.

3 Mathematical Modeling and Applications

Linear Learning

This section starts with linear classification and regression which provide the easiest algorithms to understand some of the main building blocks that appear also in the

more sophisticated nonlinear support vector machines. Moreover, concerning the classification task, this seems to be the best approach to explain its *geometrical background*. The simplest function to feed a classifier with or to use as an approximation of some unknown function in regression tasks is a linear (multivariate) function

$$f(x) = f_w(x) := \langle w, x \rangle, \quad x \in \mathcal{X} \subset \mathbb{R}^d. \quad (2)$$

Often it is combined with some appropriate real number b , i.e., one considers the linear polynomial $f(x) + b = \langle w, x \rangle + b$. In the context of learning, w is called *weight vector* and b *offset, intercept* or *bias*.

Linear Support Vector Classification

Let us consider binary classification first and postpone multi-class classification to section “Multi-class Classification and Multitask Learning.” As binary classifier $F = F_{w,b} : \mathcal{X} \rightarrow \{-1, 1\}$, one can use

$$F(x) := \text{sgn}(f_w(x) + b) = \text{sgn}(\langle w, x \rangle + b)$$

with the agreement that $\text{sgn}(0) := 0$. The hyperplane

$$H(w, b) := \{x : \langle w, x \rangle + b = 0\}$$

has the normal vector $w/\|w\|$, and the distance of a point $\tilde{x} \in \mathbb{R}^d$ to the hyperplane is given by

$$\left| \left\langle \frac{w}{\|w\|}, \tilde{x} \right\rangle + \frac{b}{\|w\|} \right|$$

see Fig. 3 left. In particular, $|b|/\|w\|$ is the distance of the hyperplane from the origin.

The training set Z consists of two classes labeled by ± 1 with indices $I_+ := \{i : y_i = 1\}$ and $I_- := \{i : y_i = -1\}$. The training set is said to be *separable by the hyperplane* $H(w, b)$ if $\langle w, x_i \rangle + b > 0$ for $i \in I_+$ and $\langle w, x_i \rangle + b < 0$ for $i \in I_-$, i.e.,

$$y_i (\langle w, x_i \rangle + b) > 0.$$

The points in Z are called (linearly) *separable* if there exists a hyperplane separating them. In this case, their distance from a separating hyperplane is given by

$$y_i \left(\left\langle \frac{w}{\|w\|}, x_i \right\rangle + \frac{b}{\|w\|} \right), \quad i = 1, \dots, m.$$

The smallest distance of a point from the hyperplane

$$\gamma := \min_{i=1, \dots, m} y_i \left(\left\langle \frac{w}{\|w\|}, x_i \right\rangle + \frac{b}{\|w\|} \right) \quad (3)$$

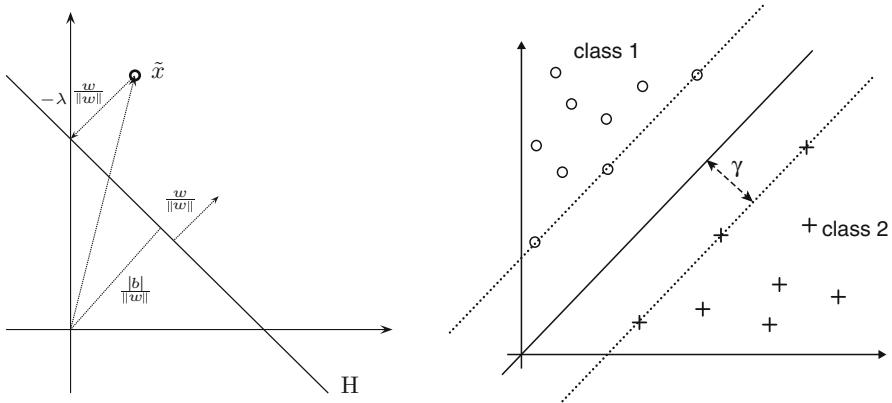

Fig. 3 Left: Hyperplane H with normal $w/\|w\|$ and distance $|b|/\|w\|$ from the origin. The distance of the point \tilde{x} from the hyperplane is the value λ fulfilling $\langle w, \tilde{x} - \lambda w/\|w\| \rangle + b = 0$, i.e., $\lambda = (\langle w, \tilde{x} \rangle + b)/\|w\|$. Right: Linearly separable training set together with a separating hyperplane and the corresponding margin γ

is called *margin*. Figure 3, right, shows a separating hyperplane of two classes together with its margin. Of course for a separable training set, there may exist various separating hyperplanes. One way to ensure a unique solution is to pose additional requirements on the hyperplane in form of minimizing a cost functional.

Hard Margin Classifier One obvious way is to choose those separating hyperplane which has the maximal distance from the data, i.e., a maximal margin. The corresponding classifiers are called *maximal margin classifiers* or *hard margin classifiers*. The hyperplane and the corresponding half-spaces do not change if the defining vectors is rescaled to $(c w, c b)$, $c > 0$. The so-called generalized portrait algorithm of Vapnik and Lerner [108], constructs a hyperplane that maximizes γ under the constraint $\|w\| = 1$. The same hyperplane can be obtained as follows: by (3), it holds

$$\gamma \|w\| = \min_{i=1,\dots,m} y_i (\langle w, x_i \rangle + b)$$

so that one can use the scaling

$$\gamma \|w\| = 1 \Leftrightarrow \gamma = \frac{1}{\|w\|}.$$

Now γ becomes maximal if and only if $\|w\|$ becomes minimal, and the scaling means that $y_i (\langle w, x_i \rangle + b) \geq 1$ for all $i = 1, \dots, m$. Therefore, the hard margin classifier aims to find parameters w and b solving the following quadratic optimization problem with linear constraints:

Linear SV hard margin classification (Primal problem)

$$\frac{1}{2} \|w\|^2 \rightarrow \min_{w,b} \quad \text{subject to} \quad y_i (\langle w, x_i \rangle + b) \geq 1, \quad i = 1, \dots, m.$$

If the training data are linearly separable, the problem has a unique solution. A brief introduction into quadratic programming methods is given in section “Quadratic Optimization.” To transform the problem into its dual form, consider the Lagrangian

$$L(w, b, \alpha) = \frac{1}{2} \|w\|^2 + \sum_{i=1}^m \alpha_i (1 - y_i (\langle w, x_i \rangle + b)), \quad \alpha_i \geq 0.$$

Since

$$\frac{\partial L}{\partial w} = w - \sum_{i=1}^m \alpha_i y_i x_i = 0 \quad \Leftrightarrow \quad w = \sum_{i=1}^m \alpha_i y_i x_i, \quad (4)$$

$$\frac{\partial L}{\partial b} = \sum_{i=1}^m \alpha_i y_i = 0 \quad (5)$$

the Lagrangian can be rewritten as

$$L(w, b, \alpha) = -\frac{1}{2} \sum_{i=1}^m \sum_{j=1}^m y_i \alpha_i y_j \alpha_j \langle x_i, x_j \rangle + \sum_{i=1}^m \alpha_i \quad (6)$$

and the dual problem becomes

Linear SV hard margin classification (Dual problem)

$$\frac{1}{2} \sum_{i=1}^m \sum_{j=1}^m y_i \alpha_i y_j \alpha_j \langle x_i, x_j \rangle - \sum_{i=1}^m \alpha_i \rightarrow \min_{\alpha} \quad \text{subject to} \quad \sum_{i=1}^m y_i \alpha_i = 0, \\ \alpha_i \geq 0, \quad i = 1, \dots, m.$$

Note that the dual maximization problem has been rewritten into a minimization problem by using that $\max \phi = -\min -\phi$. Let 1_m denote the vector with m coefficients 1, $\alpha := (\alpha_i)_{i=1}^m$, $y := (y_i)_{i=1}^m$, $\mathbf{Y} := \text{diag}(y_i)_{i=1}^m$ and

$$\mathbf{K} := (\langle x_i, x_j \rangle)_{i,j=1}^m. \quad (7)$$

Note that \mathbf{K} is symmetric and positive semi-definite. The dual problem can be rewritten in *matrix-vector form* as

Linear SV hard margin classification (Dual problem)

$$\frac{1}{2} \alpha^T \mathbf{Y} \mathbf{K} \mathbf{Y} \alpha - \langle 1_m, \alpha \rangle \rightarrow \min_{\alpha} \quad \text{subject to} \quad \langle y, \alpha \rangle = 0, \quad \alpha \geq 0.$$

Let α^* be the minimizer of this dual problem. The intercept b does not appear in the dual problem, and one has to determine its optimal value in another way. By the Kuhn-Tucker conditions, the equations

$$\alpha_i^* (y_i(\langle w^*, x_i \rangle + b^*) - 1) = 0, \quad i = 1, \dots, m$$

hold true, so that $\alpha_i^* > 0$ is only possible for those training data with $y_i(\langle w^*, x_i \rangle + b^*) = 1$. These are exactly the (few) points having margin distance γ from the hyperplane $H(w^*, b^*)$. Define

$$I_S := \{i : \alpha_i^* > 0\}, \quad S := \{x_i : i \in I_S\}. \quad (8)$$

The vectors from S are called *support vectors*. In general $|S| \ll m$ and by (4) the optimal weight w^* and the optimal function f_{w^*} have a *sparse representation* in terms of the support vectors

$$w^* = \sum_{i \in I_S} \alpha_i^* y_i x_i, \quad f_{w^*}(x) = \sum_{i \in I_S} \alpha_i^* y_i \langle x_i, x \rangle. \quad (9)$$

Moreover,

$$b^* = y_i - \langle w^*, x_i \rangle = y_i - f_{w^*}(x_i), \quad i \in I_S \quad (10)$$

and hence, using (5),

$$\begin{aligned} \|w^*\|^2 &= \sum_{i \in I_S} \alpha_i^* y_i \sum_{j \in I_S} \alpha_j^* y_j \langle x_i, x_j \rangle = \sum_{i \in I_S} \alpha_i^* y_i f_{w^*}(x_i) \\ &= \sum_{i \in I_S} \alpha_i^* (1 - y_i b^*) = \sum_{i \in I_S} \alpha_i^* \end{aligned}$$

so that

$$\gamma = 1/\|w\| = \left(\sum_{i \in I_S} \alpha_i^* \right)^{-1/2}.$$

Soft Margin Classifier If the training data are not linearly separable which is the case in most applications, the hard margin classifier is not applicable. The extension of hard margin classifiers to the nonseparable case was done by Cortes and Vapnik [26] by bringing additional *slack variables* and a parameter $C > 0$ into the constrained model:

Linear SV soft margin classification (Primal problem)

$$\frac{1}{2} \|w\|^2 + C \sum_{i=1}^m \xi_i \rightarrow \min_{w, b, \xi} \quad \text{subject to} \quad y_i (\langle w, x_i \rangle + b) \geq 1 - \xi_i, \\ \xi_i \geq 0, \quad i = 1, \dots, m.$$

For $C = \infty$, this is again the hard margin classifier model. As before, the *margin* is defined as $\gamma = 1/\|w^*\|$, where w^* is the solution of the above problem. If the slack variable fulfills $0 \leq \xi_i^* < 1$, then x_i is correctly classified, and in the case $y_i (\langle w^*, x_i \rangle + b^*) = 1 - \xi_i^*$ the distance of x_i from the hyperplane is $\gamma - \xi_i^*/\|w^*\|$. If $1 < \xi_i^*$, then one has a misclassification. By penalizing the sum of the slack variables, one tries to keep them small.

The above constrained minimization model can be rewritten as an unconstrained one by using a *margin-based loss function*. A function $L : \{-1, 1\} \times \mathbb{R} \rightarrow [0, \infty)$ is called *margin based* if there exists a representing function $l : \mathbb{R} \rightarrow [0, \infty)$ such that

$$L(y, t) = l(yt).$$

In soft margin classification the appropriate choice of a loss function is the *hinge loss function* l_h determined by

$$l_h(x) := \max\{0, 1 - x\}.$$

Then the *unconstrained* primal problem reads

Linear SV soft margin classification (Primal problem)

$$\frac{1}{2} \|w\|^2 + C \sum_{i=1}^m L_h(y_i, (\langle w, x_i \rangle + b)) \rightarrow \min_{w,b}.$$

The Lagrangian of the linear constrained problem has the form

$$L(w, b, \xi, \alpha) = \frac{1}{2} \|w\|^2 + C \sum_{i=1}^m \xi_i + \sum_{i=1}^m \alpha_i (1 - \xi_i - y_i (\langle w, x_i \rangle + b)) - \sum_{i=1}^m \beta_i \xi_i,$$

where $\alpha_i, \beta_i \geq 0$. Partial differentiation of the Lagrangian with respect to w and b results in (4), (5) and with respect to ξ in

$$\frac{\partial L}{\partial \xi} = C 1_m - \alpha - \beta = 0.$$

Using these relations, the Lagrangian can be rewritten in the same form as in (6), and the dual problem becomes in matrix-vector form

Linear SV soft margin classification (Dual problem)

$$\frac{1}{2} \alpha^T \mathbf{Y} \mathbf{K} \mathbf{Y} \alpha - \langle 1_m, \alpha \rangle \quad \text{subject to} \quad \langle y, \alpha \rangle = 0, \quad 0 \leq \alpha \leq C.$$

Let α^* be the minimizer of the dual problem. Then the optimal weight w^* and f_{w^*} are again given by (9) and depend only on the few support vectors defined by (8). By the Kuhn-Tucker conditions, the equations

$$\alpha_i^* (y_i (\langle w^*, x_i \rangle + b^*) - 1 + \xi_i^*) = 0 \quad \text{and}$$

$$\beta_i^* \xi_i^* = (C - \alpha_i^*) \xi_i^* = 0, \quad i = 1, \dots, m$$

hold true. For $0 < \alpha_i^* < C$, it follows that $\xi_i^* = 0$ and $y_i(\langle w^*, x_i \rangle + b^*) = 1$, i.e., the points x_i have margin distance $\gamma = 1/\|w^*\|$ from $H(w^*, b^*)$. Moreover,

$$b^* = y_i - \langle w^*, x_i \rangle, \quad i \in \tilde{I}_S := \{i : 0 < \alpha_i^* < C\}. \quad (11)$$

For $\alpha_i^* = C$, one concludes that $y_i(\langle w^*, x_i \rangle + b^*) = 1 - \xi_i^*$, i.e., x_i has distance $\gamma - \xi_i^*/\|w^*\|$ from the optimal hyperplane.

Linear Support Vector Regression

Of course one can also approximate unknown functions by linear (multivariate) polynomials of the form (2).

Hard Margin Regression The model for linear hard margin regression is given by

Linear SV hard margin regression (Primal problem)

$$\frac{1}{2} \|w\|^2 \rightarrow \min_{w,b} \quad \text{subject to} \quad \begin{aligned} \langle w, x_i \rangle + b - y_i &\leq \epsilon, \\ -\langle w, x_i \rangle - b + y_i &\leq \epsilon, \quad i = 1, \dots, m. \end{aligned}$$

The constraints make sure that the test data y_i lie within an ϵ distance from the value $f(x_i) + b$ of the approximating linear polynomial. The Lagrangian reads

$$\begin{aligned} L(w, b, \xi^\pm, \alpha^\pm, \beta^\pm) &= \frac{1}{2} \|w\|^2 + \sum_{i=1}^m \alpha_i^- (\langle w, x_i \rangle + b - y_i - \epsilon) \\ &\quad + \sum_{i=1}^m \alpha_i^+ (-\langle w, x_i \rangle - b + y_i - \epsilon), \end{aligned}$$

where $\alpha_i^\pm \geq 0$. Setting partial derivatives to zero leads to

$$\frac{\partial L}{\partial w} = w + \sum_{i=1}^m (\alpha_i^- - \alpha_i^+) x_i = 0 \quad \Leftrightarrow \quad w = \sum_{i=1}^m (\alpha_i^+ - \alpha_i^-) x_i, \quad (12)$$

$$\frac{\partial L}{\partial b} = \sum_{i=1}^m (\alpha_i^+ - \alpha_i^-) = 0. \quad (13)$$

Using these relations and setting

$$\alpha := \alpha^+ - \alpha^-,$$

the Lagrangian can be written as

$$L(w, b, \xi^\pm, \alpha^\pm, \beta^\pm) = -\frac{1}{2} \sum_{i=1}^m \sum_{j=1}^m \alpha_i \alpha_j \langle x_i, x_j \rangle - \epsilon \sum_{i=1}^m (\alpha_i^+ + \alpha_i^-) + \sum_{i=1}^m y_i \alpha_i$$

and the dual problem becomes in *matrix-vector form*

| |
|---|
| $\text{Linear SV hard margin regression (Dual problem)}$ $\frac{1}{2}(\alpha^+ - \alpha^-)^T \mathbf{K}(\alpha^+ - \alpha^-) + \epsilon \langle 1_m, \alpha^+ + \alpha^- \rangle - \langle y, \alpha^+ - \alpha^- \rangle \rightarrow \min_{\alpha^+, \alpha^-}$ <p style="margin-left: 20px;">subject to $\langle 1_m, \alpha^+ - \alpha^- \rangle = 0, \quad \alpha^\pm \geq 0.$</p> |
|---|

This is a quadratic optimization problem with linear constraints. Let $(\alpha^+)^*, (\alpha^-)^*$ be the solution of this problem and $\alpha^* = (\alpha^+)^* - (\alpha^-)^*$. Then, by (12), the optimal weight and the optimal function have in general a sparse representation in terms of the support vectors $x_i, i \in I_S$, namely,

$$w^* = \sum_{i \in I_S} \alpha_i^* x_i, \quad f_{w^*}(x) = \sum_{i \in I_S} \alpha_i^* \langle x_i, x \rangle, \quad I_S := \{i : \alpha_i^* \neq 0\}. \quad (14)$$

The corresponding Kuhn-Tucker conditions are

$$\begin{aligned} (\alpha_i^-)^* (\epsilon - \langle w^*, x_i \rangle - b^* + y_i) &= 0, \\ (\alpha_i^+)^* (\epsilon + \langle w^*, x_i \rangle + b^* - y_i) &= 0. \end{aligned} \quad (15)$$

If $(\alpha_i^-)^* > 0$ or $(\alpha_i^+)^* > 0$, then

$$b^* = y_i - \langle w^*, x_i \rangle + \epsilon, \quad b^* = y_i - \langle w^*, x_i \rangle - \epsilon,$$

respectively. Since both conditions cannot be fulfilled for the same index, it follows that $(\alpha_i^-)^* (\alpha_i^+)^* = 0$ and consequently, either $\alpha_i^* = (\alpha_i^+)^* \geq 0$ or $\alpha_i^* = -(\alpha_i^-)^* \leq 0$. Thus, one can obtain the intercept by

$$b^* = y_i - \langle w^*, x_i \rangle - \epsilon, \quad i \in I_S. \quad (16)$$

Soft Margin Regression Relaxing the constraints in the hard margin model leads to the following linear soft margin regression problem with $C > 0$:

| |
|--|
| $\text{Linear SV soft margin regression (Primal problem)}$ $\frac{1}{2} \ w\ ^2 + C \sum_{i=1}^m (\xi_i^+ + \xi_i^-) \rightarrow \min_{w, b, \xi_i^\pm}$ <p style="margin-left: 20px;">subject to $\langle w, x_i \rangle + b - y_i \leq \epsilon + \xi_i^-,$ $-\langle w, x_i \rangle - b + y_i \leq \epsilon + \xi_i^+,$ $\xi_i^+, \xi_i^- \geq 0.$</p> |
|--|

For $C = \infty$, this recovers the linear hard margin regression problem. The above constrained model can be rewritten as an unconstrained one by using a *distance-based loss function*. A function $L : \mathcal{Y} \times \mathbb{R} \rightarrow [0, \infty)$ is called *distance based* if there exists a representing function $l : \mathbb{R} \rightarrow [0, \infty)$ such that

$$L(y, t) = l(y - t).$$

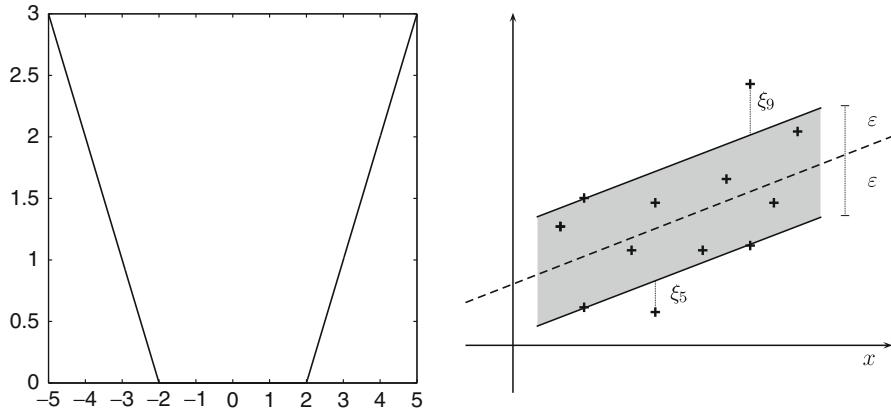

Fig. 4 Vapnik's ϵ -insensitive loss function for $\epsilon = 2$ (left). Example of linear SV soft margin regression (right)

In soft margin regression, the appropriate choice is Vapnik's *ϵ -insensitive loss function* defined by

$$l_\epsilon(x) := \max\{0, |x| - \epsilon\}.$$

The function l_ϵ is depicted in Fig. 4, left. Then the *unconstrained* primal model reads

Linear SV soft margin regression (Primal problem)

$$\frac{1}{2} \|w\|^2 + C \sum_{i=1}^m L_\epsilon(y_i, \langle w, x_i \rangle + b) \rightarrow \min_{w,b}.$$

The Lagrangian of the constrained problem is given by

$$\begin{aligned} L(w, b, \xi^\pm, \alpha^\pm, \beta^\pm) &= \frac{1}{2} \|w\|^2 + C \sum_{i=1}^m (\xi_i^+ + \xi_i^-) \\ &\quad + \sum_{i=1}^m \alpha_i^- (\langle w, x_i \rangle + b - y_i - \epsilon - \xi_i^-) \\ &\quad + \sum_{i=1}^m \alpha_i^+ (-\langle w, x_i \rangle - b + y_i - \epsilon - \xi_i^+) \\ &\quad - \sum_{i=1}^m \beta_i^+ \xi_i^+ - \sum_{i=1}^m \beta_i^- \xi_i^-, \end{aligned}$$

where $\alpha_i^\pm \geq 0$ and $\beta_i^\pm \geq 0$, $i = 1, \dots, m$. Setting the partial derivatives to zero leads to (12), (13) and

$$\frac{\partial L}{\partial \xi^+} = C \mathbf{1}_m - \alpha^+ - \beta^+ = 0, \quad \frac{\partial L}{\partial \xi^-} = C \mathbf{1}_m - \alpha^- - \beta^- = 0.$$

Using these relations the Lagrangian can be written exactly as in the hard margin problem, and the dual problem becomes in *matrix-vector form*

Linear SV soft margin regression (Dual problem)

$$\frac{1}{2}(\alpha^+ - \alpha^-)^T \mathbf{K}(\alpha^+ - \alpha^-) + \epsilon(\mathbf{1}_m, \alpha^+ + \alpha^-) - \langle y, \alpha^+ - \alpha^- \rangle \rightarrow \min_{\alpha^+, \alpha^-}$$

subject to $\langle \mathbf{1}_m, \alpha^+ - \alpha^- \rangle = 0, \quad 0 \leq \alpha^+, \alpha^- \leq C$

If $(\alpha^+)^*, (\alpha^-)^*$ are the solution of this problem and $\alpha^* = (\alpha^+)^* - (\alpha^-)^*$, then the optimal weight w^* and the optimal function f_{w^*} are given by (14). The corresponding Kuhn-Tucker conditions are

$$\begin{aligned} (\alpha_i^-)^* (\epsilon + (\xi_i^-)^* - \langle w^*, x_i \rangle - b^* + y_i) &= 0, \\ (\alpha_i^+)^* (\epsilon + (\xi_i^+)^* + \langle w^*, x_i \rangle + b^* - y_i) &= 0, \\ (C - (\alpha_i^+)^*)(\xi_i^+)^* &= 0, \quad (C - (\alpha_i^-)^*)(\xi_i^-)^* = 0, \quad i = 1, \dots, m. \end{aligned}$$

If $0 < (\alpha_i^+)^*$ or $0 < (\alpha_i^-)^*$, then

$$b^* = y_i - \langle w^*, x_i \rangle + \epsilon + \xi_i^+, \quad b^* = y_i - \langle w^*, x_i \rangle - \epsilon - \xi_i^-,$$

respectively. Both equations cannot be fulfilled at the same time so that one can conclude that either $\alpha_i^* = (\alpha_i^+)^* \geq 0$ or $\alpha_i^* = -(\alpha_i^-)^* \leq 0$. In case $\alpha_i^* = (\alpha_i^+)^* < C$, this results in the intercept

$$b^* = y_i - \langle w^*, x_i \rangle - \epsilon, \quad i \in \tilde{I}_S. \quad (17)$$

Linear Least Squares Classification and Regression

Instead of the hinge loss function for classification and the ϵ -insensitive loss function for regression, other loss functions can be used. Popular margin-based and distance-based loss functions are the *logistic loss* for classification and regression

$$l(yt) := \ln(1 + e^{-yt}) \quad \text{and} \quad l(y - t) := -\ln \frac{4e^{y-t}}{(1 + e^{y-t})^2},$$

respectively. In contrast to the loss functions in the previous subsections, logistic loss functions are differentiable in t so that often standard methods as gradient descent methods or Newton (like) methods can be applied for computing the minimizers of the corresponding problems. For details, see, e.g., the book of Mitchell [73] or of Hastie et al. [47]. Other loss functions for regression are the *pinball loss*, the *Huber function*, and the *p-th power absolute distance loss* $|y - t|^p$, $p > 0$. For $p = 2$, the latter is the *least squares loss*

$$l_{\text{lsq}}(y - t) = (y - t)^2.$$

Since $(y - t)^2 = (1 - yt)^2$ for $y \in \{-1, 1\}$, the least squares loss is also margin based, and one can handle least squares classification and regression using just the same model with $y \in \{-1, 1\}$ for classification and $y \in \mathbb{R}$ for regression. In the *unconstrained* form, one has to minimize

Linear LS classification/regression (Primal problem)

$$\frac{1}{2} \|w\|^2 + \frac{C}{2} \sum_{i=1}^m (\underbrace{\langle w, x_i \rangle + b - y_i}_L) \rightarrow \min_{w,b}.$$

This model was published as *ridge regression* by Hoerl and Kennard [49] and is a regularized version of the Gaussian model (1). Therefore, it can be considered as a special case of regularization theory introduced by Tikhonov and Arsenin [102]. The minimizer can be computed via a linear system of equations. To this end, rewrite the unconstrained problem in matrix-vector form

$$\frac{1}{2} \|w\|^2 + \frac{C}{2} \|\mathbf{X}^T w + b \mathbf{1}_m - y\|^2 \rightarrow \min_{w,b},$$

where

$$\mathbf{X} := (x_1 \dots x_m) = \begin{pmatrix} x_{1,1} & \dots & x_{m,1} \\ \vdots & & \vdots \\ x_{1,d} & \dots & x_{m,d} \end{pmatrix}.$$

Setting the gradient (with respect to w and b) to zero, one obtains

$$\begin{aligned} 0 &= \frac{1}{C} w + \mathbf{X} \mathbf{X}^T w + b \mathbf{X} \mathbf{1}_m - \mathbf{X} y, \\ 0 &= \mathbf{1}_m^T \mathbf{X}^T w - \mathbf{1}_m^T y + mb \quad\Leftrightarrow\quad b = \bar{y} - \langle w, \bar{x} \rangle, \end{aligned} \tag{18}$$

where $\bar{y} := \frac{1}{m} \sum_{i=1}^m y_i$ and $\bar{x} := \frac{1}{m} \sum_{i=1}^m x_i$. Hence b and w can be obtained by solving the linear system of equations

$$\begin{pmatrix} \mathbf{1}^T \bar{x} \\ \bar{x}^T \frac{1}{m} \mathbf{X} \mathbf{X}^T + \frac{1}{mC} I \end{pmatrix} \begin{pmatrix} b \\ w \end{pmatrix} = \begin{pmatrix} \bar{y} \\ \frac{1}{m} \mathbf{X} y \end{pmatrix}. \tag{19}$$

Instead of the above problem, one solves in general the “centered” problem

Linear LS classification/regression *in centered version* (Primal problem)

$$\frac{1}{2} \|\tilde{w}\|^2 + \frac{C}{2} \sum_{i=1}^m (\langle \tilde{w}, \tilde{x}_i \rangle + \tilde{b} - y_i)^2 \rightarrow \min_{\tilde{w}, \tilde{b}},$$

where $\tilde{x}_i := x_i - \bar{x}$, $i = 1, \dots, m$. The advantage is that $\tilde{\bar{x}} = 0_m$, where 0_m is the vector consisting of m zeros. Thus, (19) with \tilde{x}_i instead of x_i becomes a separable system, and one obtains immediately that $\tilde{b}^* = \bar{y}$ and that \tilde{w}^* follows by solving the linear system with positive definite, symmetric coefficient matrix

$$\left(\tilde{\mathbf{X}}\tilde{\mathbf{X}}^\top + \frac{1}{C}I \right) w = \tilde{\mathbf{X}}y.$$

This means that \tilde{w} is just the solution of the centered primal problem without intercept. Finally, one can check by the following argument that indeed $w^* = \tilde{w}^*$:

$$\begin{aligned} (\tilde{w}^*, \tilde{b}^*) &:= \operatorname{argmin}_{\tilde{w}, \tilde{b}} \left\{ \frac{1}{2} \|\tilde{w}\|^2 + \frac{C}{2} \sum_{i=1}^m (\langle \tilde{w}, \tilde{x}_i \rangle + \tilde{b} - y_i)^2 \right\}, \\ \tilde{w}^* &= \operatorname{argmin}_{\tilde{w}} \left\{ \frac{1}{2} \|\tilde{w}\|^2 + \frac{C}{2} \sum_{i=1}^m (\langle \tilde{w}, \tilde{x}_i \rangle + \bar{y} - y_i)^2 \right\} \\ &= \operatorname{argmin}_{\tilde{w}} \left\{ \frac{1}{2} \|\tilde{w}\|^2 + \frac{C}{2} \sum_{i=1}^m (\langle \tilde{w}, x_i \rangle + \bar{y} - \langle \tilde{w}, \bar{x} \rangle - y_i)^2 \right\} \end{aligned}$$

and with (18) on the other hand

$$\begin{aligned} (w^*, b^*) &:= \operatorname{argmin}_{w, b} \left\{ \frac{1}{2} \|w\|^2 + \frac{C}{2} \sum_{i=1}^m (\langle w, x_i \rangle + b - y_i)^2 \right\}, \\ w^* &= \operatorname{argmin}_w \left\{ \frac{1}{2} \|w\|^2 + \frac{C}{2} \sum_{i=1}^m (\langle w, x_i \rangle + \bar{y} - \langle w, \bar{x} \rangle - y_i)^2 \right\}. \end{aligned}$$

Note that $\mathbf{X}^\top \mathbf{X} = \mathbf{K} \in \mathbb{R}^{m,m}$, but this is not the coefficient matrix in (19). When turning to nonlinear methods in section ‘‘Nonlinear Learning,’’ it will be essential to work with $\mathbf{K} = \mathbf{X}^\top \mathbf{X}$ instead of \mathbf{XX}^\top . This can be achieved by switching to the dual setting. In the following, this dual approach is shown although it makes often not sense *for the linear setting* since the size of the matrix \mathbf{K} is in general larger than those of $\mathbf{XX}^\top \in \mathbb{R}^{d,d}$. First, one reformulates the primal problem into a constrained one:

| Linear LS classification/regression (Primal problem) |
|--|
| $\frac{1}{2} \ w\ ^2 + \frac{C}{2} \sum_{i=1}^m \xi_i^2 \rightarrow \min_{w, b, \xi} \quad \text{subject to} \quad \langle w, x_i \rangle + b - y_i = \xi_i, \quad i = 1, \dots, m.$ |

The Lagrangian reads

$$L(w, b, \xi, \alpha) = \frac{1}{2} \|w\|^2 + \frac{C}{2} \sum_{i=1}^m \xi_i^2 - \sum_{i=1}^m \alpha_i (\langle w, x_i \rangle + b - y_i - \xi_i)$$

and

$$\begin{aligned}\frac{\partial L}{\partial w} = w - \sum_{i=1}^m \alpha_i x_i &= 0 \quad \Leftrightarrow \quad w = \sum_{i=1}^m \alpha_i x_i, \\ \frac{\partial L}{\partial b} = \sum_{i=1}^m \alpha_i &= 0, \\ \frac{\partial L}{\partial \xi} = C \xi + \alpha &= 0.\end{aligned}$$

The equality constraint in the primal problem together with the above equalities leads to the following linear system of equations to determine the optimal α^* and b^* :

$$\left(\begin{array}{c|c} 0 & 1_m^\top \\ \hline 1_m & \mathbf{K} + \frac{1}{C} I \end{array} \right) \begin{pmatrix} b \\ \alpha \end{pmatrix} = \begin{pmatrix} 0 \\ y \end{pmatrix}. \quad (20)$$

The optimal weight and the corresponding optimal function read

$$w^* = \sum_{i=1}^m \alpha_i^* x_i, \quad f_{w^*}(x) = \sum_{i=1}^m \alpha_i^* \langle x_i, x \rangle. \quad (21)$$

In general there is no sparse representation with respect to the vectors x_i ; see also Theorem 8.36 in the book of Steinwart and Christmann [93]. Therefore, this method is not called a support vector method in this paper. Finally, note that the centered approach also helps to avoid the intercept in the dual approach. Since this is no longer true when turning to the nonlinear setting, the intercept is kept here.

Nonlinear Learning

A linear form of a decision or regression function may not be suitable for the task at hand. Figure 5 shows two examples, where a linear classifier is not appropriate.

A basic idea to handle such problems was proposed by Boser et al. [12] and consists of the following two steps which will be further explained in the rest of this subsection:

1. Mapping of the input data $X \subset \mathcal{X}$ into a *feature space* $\Phi(\mathcal{X}) \subset \ell_2(I)$, where I is a countable (possibly finite) index set, by a nonlinear *feature map*

$$\Phi : \mathcal{X} \rightarrow \ell_2(I).$$

2. Application of the linear classification/regression model to the feature set

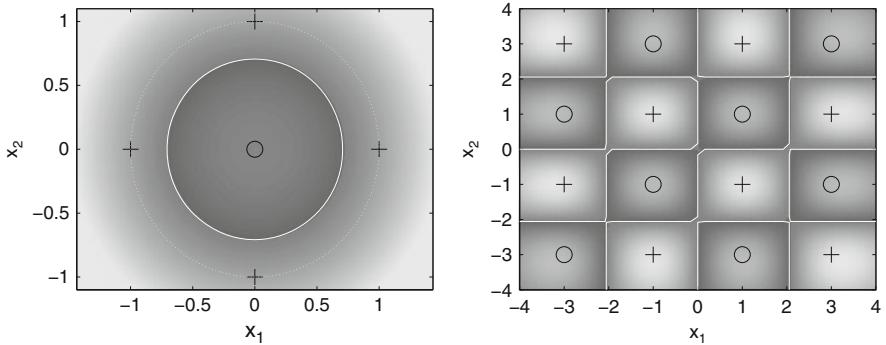

Fig. 5 Two sets, where linear classification is not appropriate

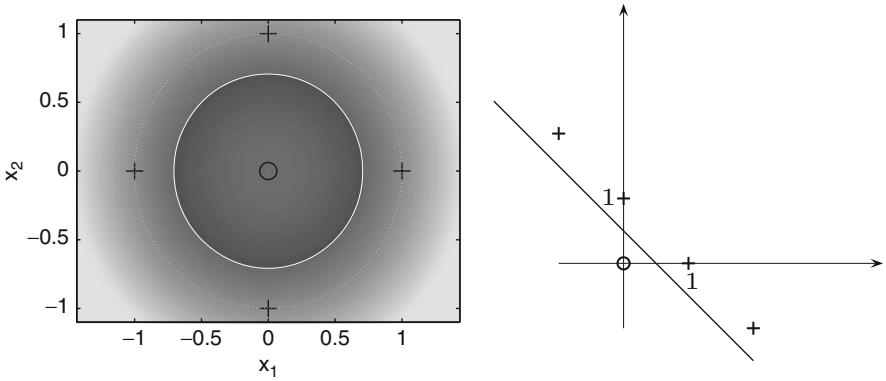

Fig. 6 Linearly nonseparable training data in the original space $\mathcal{X} \subset \mathbb{R}^2$ (left) and become separable in the feature space $\Phi(\mathcal{X})$, where $\Phi(x_1, x_2) := (x_1^2, x_2^2)$ (right)

$$\{(\Phi(x_1), y_1), \dots, (\Phi(x_m), y_m)\}.$$

This means that instead of a linear function (2), we are searching for a function of the form

$$f(x) = f_w(x) := \langle w, \Phi(x) \rangle_{\ell_2(I)} \quad (22)$$

now. This nonlinear function on \mathcal{X} becomes linear in the feature space $\Phi(\mathcal{X})$.

Figure 6 shows an example of a feature map. In this example, the set $\{(x_i, y_i) : i = 1, \dots, 5\}$ is not linearly separable while $\{(\Phi(x_i), y_i) : i = 1, \dots, 5\}$ is linearly separable. In practical applications, in contrast to this example, the feature map often maps into a higher dimensional, possibly also infinite dimensional space.

Together with the so-called kernel trick to avoid the direct work with the feature map Φ , this approach results in the successful *support vector machine* (SVM).

Kernel Trick

In general, one avoids to work directly with the feature map by dealing with the dual problem and applying the so-called kernel trick. For a feature map Φ , define a *kernel* $K : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ associated with Φ by

$$K(x, t) := \langle \Phi(x), \Phi(t) \rangle_{\ell_2(I)}. \quad (23)$$

More precisely, in practice one often follows the opposite way, namely, one starts with a suitable kernel which is known to have a representation of the form (23) without knowing Φ explicitly.

A frequently applied group of kernels are continuous, symmetric, positive (semi-) definite kernels like the Gaussian

$$K(x, t) = e^{-\|x-t\|^2/c^2}.$$

These kernels, which are also called *Mercer kernels*, will be considered in detail in section “Reproducing Kernel Hilbert Spaces.” By Mercer’s theorem, it can be shown that a Mercer kernel possesses a representation

$$K(x, t) = \sum_{j \in I} \sqrt{\lambda_j} \psi_j(x) \sqrt{\lambda_j} \psi_j(t), \quad x, t \in \mathcal{X}$$

with L_2 -orthonormal functions ψ_j and positive values λ_j , where the right-hand side converges uniformly. Note that the existence of such a representation is clear, but in general without knowing the functions ψ_j explicitly. The set $\{\varphi_j := \sqrt{\lambda_j} \psi_j : j \in I\}$ forms an orthonormal basis of a *reproducing kernel Hilbert space* (RKHS) \mathcal{H}_K . These spaces are considered in more detail in section “Reproducing Kernel Hilbert Spaces.” Then the feature map is defined by

$$\Phi(x) := (\varphi_j(x))_{j \in I} = \left(\sqrt{\lambda_j} \psi_j(x) \right)_{j \in I}.$$

Using the orthonormal basis, one knows that for any $f \in \mathcal{H}_K$ there exists a unique sequence $w = w_f := (w_j)_{j \in I} \in \ell_2(I)$ such that

$$f(x) = \sum_{j \in I} w_j \varphi_j(x) = \langle w, \Phi(x) \rangle, \quad \text{and} \quad w_j = \langle f, \varphi_j \rangle_{\mathcal{H}_K}, \quad (24)$$

where the convergence is uniformly. Conversely every sequence $w \in \ell_2(I)$ defines a function f_w lying in \mathcal{H}_K by (24). Moreover, Parseval’s equality says that

$$\|f_w\|_{\mathcal{H}_K} := \|w\|_{\ell_2(I)}. \quad (25)$$

For nonlinear classification and regression purposes, one can follow exactly the lines of section “Linear Learning” except that one has to work in $\Phi(\mathcal{X})$ instead of \mathcal{X} . Using (22) instead of (2) and

$$\mathbf{K} := (\langle \Phi(x_i), \Phi(x_j) \rangle_{\ell_2(I)})_{i,j=1}^m = (K(x_i, x_j))_{i,j=1}^m \quad (26)$$

instead of the kernel matrix $\mathbf{K} := (\langle x_i, x_j \rangle)_{i,j=1}^m$ in (7), the linear models from section “Linear Learning” can be rewritten as in the following subsections. Note again that \mathbf{K} is positive semi-definite.

Support Vector Classification

In the following, the linear classifiers are generalized to feature spaces.

Hard Margin Classifier The hard margin classification model is

SVM hard margin classification (Primal problem)

$$\frac{1}{2} \|w\|_{\ell_2(I)}^2 \rightarrow \min_{w,b} \quad \text{subject to} \quad y_i (\langle w, \Phi(x_i) \rangle_{\ell_2(I)} + b) \geq 1, \quad i = 1, \dots, m.$$

Interestingly, if Φ is associated with a Mercer kernel K , then $f(x) = \langle w, \Phi(x) \rangle_{\ell_2(I)}$ lies in the RKHS \mathcal{H}_K , and the model can be rewritten using (25) from the *point of view of RKHS* as

SVM hard margin classification in RKHS (Primal problem)

$$\frac{1}{2} \|f\|_{\mathcal{H}_K}^2 \rightarrow \min_{f \in \mathcal{H}_K} \quad \text{subject to} \quad y_i (f(x_i) + b) \geq 1, \quad i = 1, \dots, m.$$

The dual problem reads

SVM hard margin classification (Dual problem)

$$\frac{1}{2} \sum_{i=1}^m \sum_{j=1}^m y_i \alpha_i y_j \alpha_j \langle \Phi(x_i), \Phi(x_j) \rangle_{\ell_2(I)} - \sum_{i=1}^m \alpha_i \rightarrow \min_{\alpha} \quad \text{subject to} \quad \sum_{i=1}^m y_i \alpha_i = 0, \\ \alpha_i \geq 0, \quad i = 1, \dots, m.$$

and with \mathbf{K} defined by (26) the *matrix-vector form of the dual problem* looks as those for the linear hard margin classifier.

Let α^* be the minimizer of the dual problem. Then, by (9) together with the feature space modification, the optimal weight and the function f_{w^*} become

$$w^* = \sum_{i \in I_S} \alpha_i^* y_i \Phi(x_i), \quad f_{w^*}(x) = \sum_{i \in I_S} \alpha_i^* y_i \langle \Phi(x_i), \Phi(x) \rangle_{\ell_2(I)} = \sum_{i \in I_S} \alpha_i^* y_i K(x_i, x). \quad (27)$$

Thus, one can compute f_{w^*} knowing only the kernel and not the feature map itself. One property of a Mercer kernel used for learning purposes should be that it can be simply evaluated at points from $\mathcal{X} \times \mathcal{X}$. This is, for example, the case for the Gaussian. Finally, using (10) in the feature space, the intercept can be computed by

$$b^* = y_i - \langle w^*, \Phi(x_i) \rangle_{\ell_2(I)} = y_i - \sum_{j \in I_S} \alpha_j^* y_j K(x_j, x_i), \quad i \in I_S$$

and the margin $\gamma = 1/\|w^*\|_{\ell_2(I)}^2$ by using $\|w^*\|_{\ell_2(I)}^2 = (\alpha^*)^\top \mathbf{Y} \mathbf{K} \mathbf{Y} \alpha^*$.

Soft Margin Classifier The soft margin classification model in the feature space is

SVM soft margin classification (Primal problem)

$$\frac{1}{2} \|w\|_{\ell_2(I)}^2 + C \sum_{i=1}^m \xi_i \rightarrow \min_{w, b, \xi} \text{ subject to } y_i (\langle w, \Phi(x_i) \rangle_{\ell_2(I)} + b) \geq 1 - \xi_i,$$

$$i = 1, \dots, m$$

$$\xi_i \geq 0, \quad i = 1, \dots, m.$$

If Φ is associated with a Mercer kernel K , the corresponding unconstrained version reads in the RKHS

SVM soft margin classification in RKHS (Primal problem)

$$\frac{1}{2} \|f\|_{\mathcal{H}_K}^2 + C \sum_{i=1}^m L_h(y_i, f(x_i) + b) + \rightarrow \min_{f \in \mathcal{H}_K} .$$

With \mathbf{K} defined by (26), the *matrix-vector form of the dual problem* looks as those for the linear soft margin classifier. The function f_{w^*} reads as in (27), and, using (11), the intercept can be computed by

$$b^* = y_i - \langle w^*, \Phi(x_i) \rangle_{\ell_2(I)} = y_i - \sum_{j \in \tilde{I}_S} \alpha_j^* y_j K(x_j, x_i), \quad i \in \tilde{I}_S.$$

Support Vector Regression

In the following, the linear regression models are generalized to feature spaces.

Hard Margin Regression One obtains

SVM hard margin regression (Primal problem)

$$\frac{1}{2} \|w\|_{\ell_2(I)}^2 \rightarrow \min_{w, b} \text{ subject to } \begin{aligned} \langle w, \Phi(x_i) \rangle_{\ell_2(I)} + b - y_i &\leq \epsilon, \\ -\langle w, \Phi(x_i) \rangle_{\ell_2(I)} - b + y_i &\leq \epsilon, \end{aligned} \quad i = 1, \dots, m.$$

If Φ is associated with a Mercer kernel K , then $f(x) = \langle w, \Phi(x) \rangle_{\ell_2(I)}$ lies in the RKHS \mathcal{H}_K , and the model can be rewritten using (25) from the *point of view of RKHS* as

SVM hard margin regression in RKHS (Primal problem)

$$\frac{1}{2} \|f\|_{\mathcal{H}_K}^2 \rightarrow \min_{f \in \mathcal{H}_K} \text{ subject to } \begin{aligned} f(x_i) + b - y_i &\leq \epsilon, \\ -f(x_i) - b + y_i &\leq \epsilon, \end{aligned} \quad i = 1, \dots, m.$$

The dual problem reads in matrix-vector form as the dual problem for the linear SV hard margin regression except that we have to use the kernel matrix \mathbf{K}

defined by (26). Let $(\alpha^+)^*, (\alpha^-)^*$ be the solution of this dual problem and $\alpha^* = (\alpha^+)^* - (\alpha^-)^*$. Then one can compute the optimal function f_{w^*} using (14) with the corresponding feature space modification as

$$f_{w^*}(x) = \sum_{i \in I_{rs}} \alpha_i^* K(x_i, x). \quad (28)$$

One obtains sparse representations in terms of the support vectors. By (16), the intercept can be computed by

$$b^* = y_i - \sum_{j \in I_{rs}} \alpha_j^* K(x_j, x_i) - \epsilon, \quad i \in I_S.$$

Soft Margin Regression In the feature space, the soft margin regression model is

| |
|--|
| SVM soft margin regression (Primal problem) |
| $\frac{1}{2} \ w\ _{\ell_2(I)}^2 + C \sum_{i=1}^m (\xi_i^+ + \xi_i^-) \rightarrow \min_{w, b, \xi_i^\pm}$ s.t. $\langle w, \Phi(x_i) \rangle_{\ell_2(I)} + b - y_i \leq \epsilon + \xi_i^-,$ |
| $-\langle w, \Phi(x_i) \rangle_{\ell_2(I)} - b + y_i \leq \epsilon + \xi_i^+,$ |
| $\xi_i^+, \xi_i^- \geq 0.$ |

Having a feature map associated with a Mercer kernel K , the corresponding unconstrained problem can be written as the following minimization problem in the RKHS \mathcal{H}_K :

| |
|---|
| SVM soft margin regression in RKHS (Primal problem) |
| $\frac{1}{2} \ f\ _{\mathcal{H}_K}^2 + C \sum_{i=1}^m L_\epsilon(y_i, f(x_i) + b) \rightarrow \min_{f \in \mathcal{H}_K} .$ |

The dual problem looks as the dual problem for linear SV soft margin regression but with kernel (26). From the solution of the dual problem $(\alpha^+)^*, (\alpha^-)^*$, one can compute the optimal function f_{w^*} as in (28) and the optimal intercept using (17) as

$$b^* = y_i - \sum_{j \in I_{rs}} \alpha_j^* K(x_j, x_i) - \epsilon, \quad i \in \tilde{I}_S.$$

Figure 7, left, shows an SVM soft margin regression function for the data in Fig. 2.

Relations to Sparse Approximation in RKHSs, Interpolation by Radial Basis Functions, and Kriging

SVM regression is related to various tasks in approximation theory. Some of them will be sketched in the following.

Relation to Sparse Approximation in RKHSs Let \mathcal{H}_K be a RKHS with kernel K . Consider the problem of finding for an unknown function $\tilde{f} \in \mathcal{H}_K$ with given $\tilde{f}(x_i) = y_i, i = 1, \dots, m$ an approximating function of the form

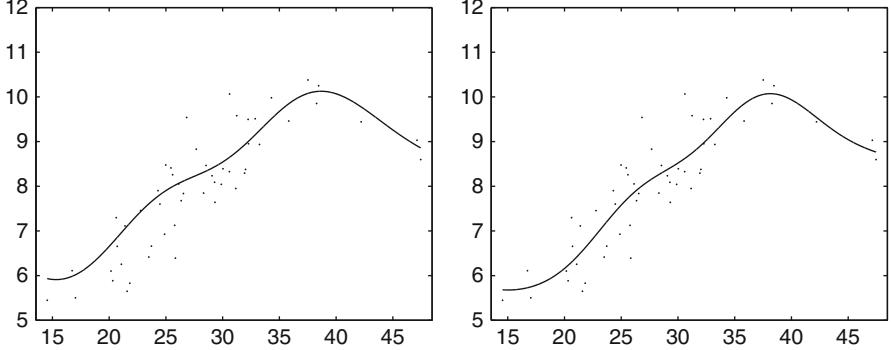

Fig. 7 SVM regression using the Gaussian with $c = 8$ for the data in Fig. 2. SVM soft margin regression curve with $C = 0.5$ and $\epsilon = 0.2$ (*left*). Least squares SVM regression curve with $C = 40$

$$f(x) := \sum_{i=1}^m \alpha_i K(x, x_i) \in \mathcal{H}_K \quad (29)$$

with only few summands. A starting point would be to minimize the \mathcal{H}_K -norm of the error and to penalize the so-called ℓ_0 -norm of α given by $\|\alpha\|_0 := |\{i : \alpha_i \neq 0\}|$ to enforce sparsity. Unfortunately, the complexity when solving such ℓ_0 -penalized problems increases exponentially with m . One remedy is to replace the ℓ_0 -norm by the ℓ_1 -norm, i.e., to deal with

$$\frac{1}{2} \|\tilde{f}(x) - \sum_{i=1}^m \alpha_i K(x, x_i)\|_{\mathcal{H}_K}^2 + \epsilon \|\alpha\|_1 \rightarrow \min_{\alpha}, \quad (30)$$

where $\epsilon > 0$. This problem and its relation to support vector regression were considered by Girosi [44] and Evgeniou et al. [37]. Using the relations in RKHS from section ‘‘Reproducing Kernel Hilbert Spaces,’’ in particular the reproducing property (H2), this problem becomes

$$\frac{1}{2} \alpha^\top \mathbf{K} \alpha - \sum_{i=1}^m \alpha_i y_i + \frac{1}{2} \|\tilde{f}\|_{\mathcal{H}_K}^2 + \epsilon \|\alpha\|_1 \rightarrow \min_{\alpha}, \quad (31)$$

where \mathbf{K} is defined by (26). With the splitting

$$\alpha_i = \alpha_i^+ - \alpha_i^-, \quad \alpha_i^\pm \geq 0, \quad \alpha_i^+ \alpha_i^- = 0, \quad i = 1, \dots, m$$

and consequently $|\alpha_i| = \alpha_i^+ + \alpha_i^-$, the sparse approximation model (30) has finally the form of the *dual problem of the SVM hard margin regression without intercept*:

SVM hard margin regression *without intercept* (Dual problem)

$$\frac{1}{2}(\alpha^+ - \alpha^-)^T \mathbf{K}(\alpha^+ - \alpha^-) + \epsilon \langle \mathbf{1}_m, \alpha^+ + \alpha^- \rangle - \langle \mathbf{y}, \alpha^+ - \alpha^- \rangle \rightarrow \min_{\alpha^+, \alpha^-}$$

subject to $\alpha^\pm \geq 0$.

Note that for $\epsilon > 0$ the additional constraints $\alpha_i^+ \alpha_i^- = 0$, $i = 1, \dots, m$ are automatically fulfilled by the minimizer since otherwise, the Kuhn-Tucker conditions (15) without intercept would imply the contradiction $f(x_i) = y_i + \epsilon = y_i - \epsilon$.

Relation to the Interpolation by Radial Basis Functions For $\epsilon = 0$, problem (30), resp. (31) becomes

$$F(\alpha) := \frac{1}{2} \alpha^T \mathbf{K} \alpha - \alpha^T \mathbf{y} \rightarrow \min_{\alpha}.$$

If \mathbf{K} is positive definite, the solution of this problem is given by the solution of

$$\nabla F(\alpha) = \mathbf{K}\alpha - \mathbf{y} = 0, \quad \Leftrightarrow \quad \mathbf{K}\alpha = \mathbf{y}$$

and the approximating function f reads

$$f(x) = \langle \mathbf{K}^{-1} \mathbf{y}, (K(x, x_i))_{i=1}^m \rangle. \quad (32)$$

This is just the solution of the *interpolation problem* to find f of the form (29) such that $f(x_i) = y_i$ for all $i = 1, \dots, m$. If the kernel K of the positive definite matrix arises from a radial basis function $\kappa(x) = k(\|x - t\|^2)$, i.e., $K(x, t) = \kappa(x - t)$ as, e.g., from a Gaussian or an inverse multiquadric described in section “Reproducing Kernel Hilbert Spaces,” this interpolation problem is called *interpolation by radial basis function*.

If the kernel K arises from a conditionally positive definite radial function κ of order v , e.g., from a thin plate spline, the matrix \mathbf{K} is in general not positive semi-definite. In this case, it is useful to replace the function f in (29) by

$$f(x) := \sum_{i=1}^m \alpha_i K(x, x_i) + \sum_{k=1}^n \beta_k p_k(x),$$

where n is the dimension of the polynomial space $\Pi_{v-1}(\mathbb{R}^d)$ and $\{p_k : k = 1, \dots, n\}$ is a basis of $\Pi_{v-1}(\mathbb{R}^d)$. The additional degrees of freedom in the interpolation problem $f(x_i) = y_i$, $i = 1, \dots, m$ are compensated by adding the new conditions

$$\sum_{i=1}^m \alpha_i p_k(x_i) = 0, \quad k = 1, \dots, n.$$

This leads to the final problem of finding $\alpha := (\alpha_i)_{i=1}^m$ and $\beta := (\beta_k)_{k=1}^n$ such that

$$\begin{pmatrix} \mathbf{K} & \mathbf{P} \\ \mathbf{P}^\top & \mathbf{0} \end{pmatrix} \begin{pmatrix} \alpha \\ \beta \end{pmatrix} = \begin{pmatrix} y \\ 0 \end{pmatrix}, \quad \mathbf{P} := (p_k(x_i))_{i,k=1}^{m,n}. \quad (33)$$

If the points $\{x_i : i = 1, \dots, m\}$, $m \geq \dim(\Pi_{v-1}(\mathbb{R}^d))$ are $\Pi_{v-1}(\mathbb{R}^d)$ -unisolvant, i.e., the zero polynomial is the only polynomial from $\Pi_{v-1}(\mathbb{R}^d)$ that vanishes on all of them, then the linear system of equations (33) has a unique solution. To verify that the coefficient matrix in (33) is indeed invertible, consider the corresponding homogeneous system. Then the second system of equations $\mathbf{P}^\top \alpha = 0$ means that α satisfies (39). Multiplying the first system of equations by α^\top gives $0 = \alpha^\top \mathbf{K} \alpha + (\mathbf{P}^\top \alpha)^\top \beta = \alpha^\top \mathbf{K} \alpha$. By the definition of conditionally positive definite functions of order v , this is only possible if $\alpha = 0$. But then $\mathbf{P} \beta = 0$. Since the points $\{x_i : i = 1, \dots, m\}$ are $\Pi_{v-1}(\mathbb{R}^d)$ -unisolvant, this implies that $\beta = 0$.

The interpolation by radial basis functions having (conditionally) positive definite kernels was examined, including fast evaluation techniques for the interpolating function f , by many authors; for an overview see, e.g., the books of Buhmann 2003 [18], Wendland [114], and Fasshauer 2007 [39].

Relation to Kriging The interpolation results can be derived in another way by so-called kriging. Kriging is a group of geostatistical techniques to interpolate the unknown value of a random field from observations of its value at nearby locations. Based on the pioneering work of Krige [59] on the plotter of the distance-weighted average gold grades at the Witwatersrand reef in South Africa, the French mathematician Matheron [70] developed its theoretical foundations. Let $S(x)$ denote a random field such that the expectation value fulfills $E(S(X)) = 0$ which is the setting in the so-called simple kriging. Let $K(x_i, x_j) := \text{Cov}(S(x_i), S(x_j))$ and $\mathbf{K} := (K(x_i, x_j))_{i,j=1}^m$. The aim is to approximate the value $S(x_0)$ from observations $S(x_i) = y_i$, $i = 1, \dots, m$ by the kriging estimator

$$\hat{S}(x_0) = \sum_{i=1}^m \omega_i(x_0) S(x_i)$$

in such a way that the variance of the error is minimal, i.e.,

$$\begin{aligned} \text{Var}(\hat{S} - S) &= \text{Var}(\hat{S}) + \text{Var}(S) - 2\text{Cov}(S, \hat{S}) \\ &= \sum_{i=1}^m \sum_{j=1}^m \omega_i(x_0) \omega_j(\hat{x}) K(x_i, x_j) \\ &\quad - 2 \sum_{i=1}^m \omega_i(x_0) K(x_0, x_i) + \text{Var}(S) \rightarrow \min_{\omega(x_0)}. \end{aligned}$$

Setting the gradient to zero, the minimizer $\omega^* = (\omega_1^*(x_0), \dots, \omega_m^*(x_0))^T$ is given by the solution of the following linear system of equations:

$$\mathbf{K}\omega = (K(x_0, x_i))_{i=1}^m.$$

In case \mathbf{K} is invertible, we get

$$S(x_0) = \langle y, \mathbf{K}^{-1}(K(x_0, x_i))_{i=1}^m \rangle = \langle \mathbf{K}^{-1}y, (K(x_0, x_i))_{i=1}^m \rangle.$$

Supposing the same values $K(x_i, x_j)$ as in the interpolation task, this is exactly the same value as $f(x_0)$ from the radial basis interpolation problem (32).

Least Squares Classification and Regression

Also in the feature space, least squares classification and regression can be treated by the same model. So-called Least Squares Support Vector Classifiers were introduced by Suykens and Vandewalle [199] while least squares regression was also considered within *regularization network* approaches, e.g., by Evgeniou et al. [37] and Wahba [112]. The least squares model in the feature space is

LS classification/regression in feature space (Primal problem)

$$\frac{1}{2} \|w\|_{\ell_2(I)}^2 + \frac{C}{2} \sum_{i=1}^m (\langle w, \Phi(x_i) \rangle_{\ell_2(I)} + b - y_i)^2 \rightarrow \min_{w,b}.$$

and becomes in the case that the feature map is related with a Mercer kernel K a problem in a RKHS \mathcal{H}_K :

LS classification/regression in RKHS (Primal problem)

$$\frac{1}{2} \|f\|_{\mathcal{H}_K}^2 + \frac{C}{2} \sum_{i=1}^m (f(x_i) + b - y_i)^2 \rightarrow \min_{w,b}.$$

Setting gradients to zero, one can try to solve this primal problem via a linear system of equations (19) with $\mathbf{X} := (\Phi(x_1) \dots \Phi(x_m))$. However, one has to compute with $\mathbf{X}\mathbf{X}^T$ here which is only possible if the feature space is finite dimensional. In contrast, the dual approach leads to the linear system of equations (20) which involves only the kernel matrix $\mathbf{K} = \mathbf{X}^T \mathbf{X}$ from (26). Knowing the dual variable α^* , the optimal function f_{w^*} can be computed using (21) with the feature space modification as

$$f_{w^*}(x) = \sum_{i=1}^m \alpha_i^* \langle \Phi(x_i), \Phi(x) \rangle \sum_{i=1}^m \alpha_i^* K(x_i, x).$$

In general there is no sparse representation with respect to the vectors x_i . For more information on least squares kernel methods, the reader may consult the book of Suykens et al. [98]. Figure 7, right, shows a least squares SVM function for the data in Fig. 2.

Other Models

There are numerous models related to the classification and regression models of the previous subsections. A simple classification model which uses only the hinge loss function without penalizing the weight was proposed by Bennet and Mangasarian [7]:

$$\sum_{i=1}^m L_h(y_i, \langle w, x_i \rangle + b) \rightarrow \min_{w,b}.$$

This approach is called *robust linear programming* (RLP) and requires only linear programming methods. Note that the authors weighted the training errors by $1/n_{\pm}$, where $n_{\pm} := |\{i; y_i = \pm 1\}|$. The *linear SV soft margin classifier* adds just the penalizer $\frac{\lambda}{2} \|w\|_2^2$ with $\lambda = 1/C$, $0 < C < \infty$ to the RLP term which leads to quadratic programming. Alternatively, one can add instead the ℓ_2 -norm the ℓ_1 -norm of the weight as it was done by Bradley and Mangasarian [16]:

$$\sum_{i=1}^m L_h(y_i, \langle w, x_i \rangle + b) + \lambda \|w\|_1 \rightarrow \min_{w,b}.$$

As in (30), the ℓ_1 penalizer enforces the sparsity of the solution vector w^* . Note that the sparsity of w^* itself and not a sparse representation of w^* as linear combination of the support vectors x_i is announced here. The ℓ_1 -penalizer was introduced in the statistical context of linear regression in conjunction with the least squares loss function by Tibshirani [101] and is called “LASSO” (Least Absolute Shrinkage and Selection Operator):

$$\sum_{i=1}^m L_{\text{lsq}}(y_i, \langle w, x_i \rangle + b) + \lambda \|w\|_1 \rightarrow \min_{w,b}$$

As emphasized in section “Support Vector Regression,” the ℓ_1 -norm is more or less a replacement for the ℓ_0 -norm to make problems computable. Other substitutes of the ℓ_0 -norm are possible, e.g., $\|w\|_{\ell_0} \approx \sum_{j=1}^d (1 - e^{v|w_j|})$, $v > 0$ which gives

$$\sum_{i=1}^m L_h(y_i, \langle w, x_i \rangle + b) + \lambda \sum_{j=1}^d (1 - e^{v|w_j|}) \rightarrow \min_{w,b}.$$

This is a nonconvex model and was proposed by Bradley and Mangasarian [16] and by Weston et al. [115] as FSV (*Features Selection concaveVe*). Numerical solution methods via *successive linearization algorithms* and *difference of convex functions* algorithms by Tao and An [100] were applied.

Further, one can couple several penalizers and generalize the models to the feature space to obtain nonlinear classifiers as it was done, e.g., by Neumann et

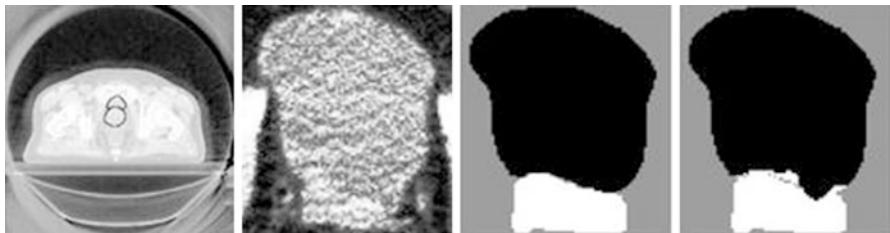

Fig. 8 From left to right: (i) Sample CT slice from a three-dimensional scan of the data set with contours of bladder and prostate. (ii) A zoom within the region of interest shows that the organs are very difficult to distinguish visually. (iii) Manual classification by an expert as “accepted truth.” (iv) A classification result: The images are filtered by a three-dimensional steerable pyramid filter bank with 16 angular orientations and four decomposition levels. Then local histograms are built for the filter responses with ten bins per channel. Including the original grey values, this results in 650 features per image voxel which are used for classification by the “ ℓ_2 - ℓ_0 -SV” machine

al. [75]. Figure 8 shows an example for the binary classification of specific organs in CT scans with a so-called “ ℓ_2 - ℓ_0 -SV” machine taken from the above paper, where more information can be found. In particular, a χ^2 kernel was used here.

Multi-class Classification and Multitask Learning

So far only binary classification was considered. Assume now that one wants to learn $K > 2$ classes. Figure 9 shows a typical example of 12 classes for the classification of Mammals; see Amit et al. [2].

Some attempts to extend the binary case to multi-classes were achieved by adding constraints for every class; see Weston and Watkins [116] and Vapnik [105]. In case of many classes, this approach often results in quadratic problems which are hard to solve and difficult to store. In the following, two general approaches to handle multiple classes are presented, namely, with:

- (i) Vector-valued binary class labeling,
- (ii) K class labeling.

The dominating approach for solving multi-class problems using SVMs is based on reducing a single multi-class problem to multiple binary problems. For instance, a common method is to build a set of binary classifiers, where each classifier distinguishes between one of the labels and the rest. This so-called *one-versus-all* classifier cannot capture correlations between different classes since it breaks the multi-class problem into independent binary problems. More general, one can assign to each class a *vector-valued binary class label* $(y^{(1)}, \dots, y^{(K)})^\top \in \{-1, 1\}^K$ and use a classifier based on

$$F(x) := (\text{sgn}(\langle w^{(k)}, x \rangle + b^{(k)}))_{k=1}^K.$$

Fig. 9 Classification of mammal images: 12 from 72 classes of animals which were used for classification in Amit et al. [2]. Typically these classes share common characteristics as in the different rows above (deers, canines, felines, rodents), e.g., the texture or shape

For example, in the one-versus-all method, the classes can be labeled by $\{(-1 + 2\delta_{r,k})_{k=1}^K : r = 1, \dots, K\}$, i.e., $\kappa = K$, and the assignment of x to a class can be made according to the shortest Hamming distance of $F(x)$ from these class labels. In the one-versus-all example, there was $\kappa = K$. More sophisticated methods use values $\kappa > K$ and error-correcting output codes as Dietterich and Bakiri [32]. Note that 2^κ different labels are in general possible with binary vectors of length κ which is an upper bound for the number of classes that could be learned. In the learning process, one can obtain $w^{(k)} \in \mathbb{R}^m$ and $b^{(k)} \in \mathbb{R}$ by solving, e.g.,

$$\frac{1}{2} \sum_{k=1}^{\kappa} \|w^{(k)}\|^2 + \sum_{k=1}^{\kappa} C_k \sum_{i=1}^m L(y_i, \langle w^{(k)}, x_i \rangle + b^{(k)}) \rightarrow \min_{w^{(k)}, b^{(k)}}, \quad (34)$$

where L is some loss function. Note that this problem can be decoupled with respect to k . Let $W := (w^{(1)} \dots w^{(\kappa)}) \in \mathbb{R}^{d \times \kappa}$ be the weight matrix. Then the first sum in (34)

coincides with the squared *Frobenius norm* of W defined by

$$\|W\|_F^2 := \sum_{k=1}^{\kappa} \sum_{i=1}^d (w_i^{(k)})^2.$$

Let us consider the second labeling approach. Here one assumes that each class label is an integer from $\mathcal{Y} := \{1, \dots, K\}$. As before, one aims to learn weight vectors $w^{(k)}$, $k = 1, \dots, K$ (the intercept is neglected for simplicity here). The classifier is given by

$$F_W(x) := \operatorname{argmax}_{k=1,\dots,K} \langle w^{(k)}, x \rangle.$$

A training sample (x_i, y_i) is correctly classified by this classifier if

$$\langle w^{(y_i)}, x_i \rangle \geq \langle w^{(k)}, x_i \rangle + 1, \quad \forall k = 1, \dots, K, k \neq y_i.$$

Without adding 1 at the left-hand side of the inequality, correct classification is still attained if there is strong inequality for $k \neq y_i$. This motivates to learn the weight vectors by solving the minimization problem

$$\begin{aligned} \frac{1}{2} \|W\|_F^2 \rightarrow \min_W \text{ subject to } & \langle w^{(y_i)}, x_i \rangle + \delta_{y_i, k} - \langle w^{(k)}, x_i \rangle \geq 1, \\ & \forall k = 1, \dots, K \text{ and } i = 1, \dots, m. \end{aligned}$$

After introducing slack variables to relax the constraints, one gets

$$\begin{aligned} \frac{1}{2} \|W\|_F^2 + C \sum_{i=1}^m \xi_i \rightarrow \min_{W, \xi_i} \text{ subject to } & \langle w^{(y_i)}, x_i \rangle + \delta_{y_i, k} - \langle w^{(k)}, x_i \rangle \geq 1 - \xi_i, \\ & \forall k = 1, \dots, K \text{ and } i = 1, \dots, m. \end{aligned}$$

This can be rewritten as the following unconstrained problem:

$$\frac{1}{2} \|W\|_F^2 + C \sum_{i=1}^m l_h \left(\langle w^{(y_i)}, x_i \rangle + \max_k (\langle w^{(k)}, x_i \rangle - \delta_{y_i, k}) \right) \rightarrow \min_W.$$

In this functional the learning tasks are coupled in the loss function.

In general the aim of *multitask learning* is to learn data that are common across multiple related supervised learning tasks, i.e., to facilitate “cooperative” learning. Recently, multitask learning has received attention in various applications; see the paper of Caruana [21]. Learning of vector-valued functions in RKHSs was considered, e.g., by Micchelli and Pontil [72]. Inspired by the “sparseness” models in section “Other Models” which focus on the sparsity of the weight vector w , one can ask for similar approaches for a weight matrix W . As a counterpart of the ℓ_0 -norm of a weight vector, there can serve a low rank of the weight matrix. But

as in ℓ_0 -penalized minimization problems, such problems are computationally not manageable. A remedy is to replace the low-rank condition by demanding a small *trace norm* or *nuclear norm* of W defined by

$$\|W\|_* := \sum_j \sigma_j,$$

where σ_j are the singular values of W . Then a minimization problem to learn the weight matrix reads, for example, as

$$\frac{1}{2} \|W\|_* + C \sum_{k=1}^K \sum_{i=1}^m L(y_i, \langle w^{(k)}, x_i \rangle), \rightarrow \min_W$$

where L is mainly the least squares loss function. Such models were considered by Amit et al. [2], Obozinski et al. [76], and Pong et al. [82]. Other approaches use the norm

$$\|W\|_{2,1} := \sum_{j=1}^d \left\| \left(w_j^{(k)} \right)_{k=1}^K \right\|$$

which favors a small number of nonzero rows in W instead of the trace norm; see Argyriou et al. [4] and Obozinski et al. [76]. Another interesting model was proposed by Argyriou et al. [4] and learns in addition to a weight matrix an orthogonal matrix $U \in \mathcal{O}$ by minimizing

$$\|W\|_{2,1} + C \sum_{k=1}^K \sum_{i=1}^m L(y_i, \langle w^{(k)}, Ux_i \rangle). \rightarrow \min_{W, U \in \mathcal{O}}.$$

The numerical solution of multitask problems which are convex but non-smooth requires sophisticated techniques. The trace norm minimization problem can be, for example, reformulated as a semi-definite program (SDP), and then existing SDP solvers can be used as long as the size of the problem is moderate; see the papers of Fazel et al. [40] and Srebro et al. [91]. A smooth, but nonconvex reformulation of the problem and a subsequent solution by a conjugate gradient or alternating minimization method was proposed, e.g., by Weimer et al. [113]. Accelerated proximal gradient methods (multistep methods) and Bregman iterative methods were applied in the papers of Lu et al. [66], Ma et al. [67], Cai et al. [20], and Toh and Yun [103]. A new primal-dual reformulation of the problem in conjunction with a gradient projection method to solve the reduced dual problem was given by Pong et al. [82].

Applications of SVMs

SVMs have been applied to many real-world problems. Some applications were already sketched in the previous subsections. Very often SVMs are used in connection with other techniques, in particular feature extraction/selection methods to specify the input domain.

A non-exhaustive list of SVM applications includes *text categorization* (see Joachims [53] and Leopold and Kinderman [64]), *hand-written character recognition* (see LeCun et al. [62]), *texture and image classification* (see Chapelle et al. [23]), *protein homology detection* (see Jaakkola and Haussler [51]), *gene expression* (see Brown et al. [17]), *medical diagnostics* (see Strauss et al. [96]), and *pedestrian and face detection* (see Osuna et al. [77], Viola and Jones [110]).

This subsection describes only two applications of SVM classification and shows how the necessary design choices can be made. In particular, one has to choose an appropriate SVM kernel for the given application. Default options are Gaussians or polynomial kernels, and the corresponding SVMs often already outperform other classification methods. Even for such parameterized families of kernels, one has to specify the parameters like the standard deviation of the Gaussian or the degree of the polynomial. In the Gaussian case, a good choice of the standard deviation in the classification problem is the distance between closest points within different classes. In the absence of reliable criteria, one could use a validation set or cross-validation to determine useful parameters. Various applications require more elaborate kernels which implicitly describe the feature space.

Handwritten Digit Recognition The problem of handwritten digit recognition was the first real-world task on which SVMs were successfully tested. The results are reported in detail in the book of Vapnik [105]. This SVM application was so interesting because other algorithms incorporating prior knowledge on the USPS database have been designed. The fact that SVMs perform better than these specific systems without using prior detailed information is remarkable; see [62].

Different SVM models have been tested on two databases:

- United States Postal Service (USPS): 7,291 training and 2,007 test patterns of the numbers 0, . . . , 9, represented by 16×16 gray level matrices; see Fig. 10.
- National Institute of Standard and Technology (NIST): 60,000 training and 10,000 test patterns, represented by 20×20 gray-level matrices.

In the following, the results for the USPS database are considered.

For constructing the decision rules, SVMs with polynomial and Gaussian kernels were used:

$$K(x, t) := (\langle x, t \rangle / 256)^n, \quad K(x, t) := e^{-\|x-t\|^2 / (256\sigma^2)}.$$

Fig. 10 Examples of patterns from the USPS database; see [105]

The overall machine consists of 10 classifiers, each one separating one class from the rest (one-versus-all classifier). Then the 10-class classification was done by choosing the class with the largest output number.

All types of SVMs demonstrated approximately the same performance shown in the following tables, cf. [105]. The tables contain the parameters for the hard margin machines, the corresponding performance, and the average (over one classifier) number of support vectors. Moreover, it was observed that the different types of SVMs use approximately the same set of support vectors.

| Degree n | 1 | 2 | 3 | 4 | 5 | 6 |
|--------------|-----|-----|-----|-----|-----|-----|
| Error | 8.9 | 4.7 | 4.0 | 4.2 | 4.5 | 4.5 |
| Number of SV | 282 | 237 | 274 | 321 | 374 | 422 |

Results for SVM classification with polynomial kernels

| σ | 4.0 | 1.5 | 0.3 | 0.25 | 0.2 | 0.1 |
|--------------|-----|-----|-----|------|-----|-----|
| Error | 5.3 | 4.9 | 4.2 | 4.3 | 4.5 | 4.6 |
| Number of SV | 266 | 237 | 274 | 321 | 374 | 422 |

Results for SVM classification with Gaussian kernels

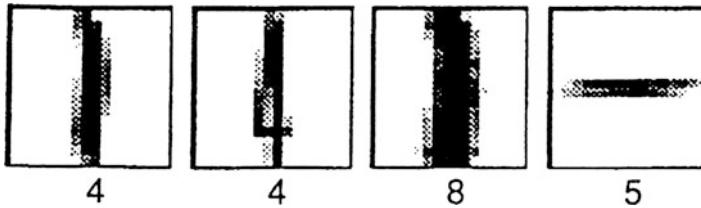

Fig. 11 Labeled USPS examples of training errors for the SVM with second degree polynomial kernel; see [105]

Finally, it is worth to mention that the *training data* are not *linearly* separable; $\approx 5\%$ of these data were misclassified by a linear learning machine. For a degree 2 polynomial kernel, only the 4 examples in Fig. 11 were misclassified. For polynomials of degree 3, the training data are separable. The number of support vectors increases only slowly with the degree of the polynomial.

Color Image Recognition Image recognition is another area where SVMs were successfully applied. Chapelle et al. [23] have reported their SVM classification results for color image recognition. The database was a subset (Corel14) of the Corel Stock Photo Collection consisting of 1,400 photos associated with 14 categories. Each category was split into 2/3 for training and 1/3 for testing. Again the one-versus-all classifier was applied.

The images were not used themselves as inputs, but each image was associated to its color histogram. Since each color is a point in a three-dimensional vector space and the number of bins per color was fixed at 16, the dimension of such a histogram (and thus of the feature space) is $d = 16^3$. Note that low-level features like histograms have the advantage that they are invariant with respect to many operations and allow the comparison of images of different sizes. Of course, local high-level image features like edges are not captured by low-level features. Chapelle and co-workers [23] have used both the RGB (red, green, blue) and the HSV/HSB (hue, saturation, value/hue, saturation, brightness) histogram representation. Note that HSV arranges the geometry of RGB in an attempt to be more perceptually relevant. As kernels they have used

$$K(x, t) := e^{-\text{dist}(x, t)/\sigma^2},$$

where dist denotes a measure of similarity in the feature space which has to be determined. For histograms, the χ^2 function

$$\text{dist}(x, t) := \sum_{i=1}^d \frac{(x_i - t_i)^2}{x_i + t_i}$$

is accepted as an appropriate distance measure. It is not clear if the corresponding kernel is a Mercer kernel. For the distances $\text{dist}_p(x, t) := \|x - t\|_p^p$, $p = 1, 2$ this is the case.

As can be seen in the following table, the SVM with the χ^2 and the ℓ_1 distance perform similarly and significantly better than the SVM with the squared ℓ_2 distance. Therefore, the Gaussian kernel is not the best choice here. RGB- and HSV-based methods perform similarly.

| | Linear | Degree 2 poly | χ^2 | ℓ_1 | Gaussian |
|-----|--------|---------------|----------|----------|----------|
| RGB | 42.1 | 33.6 | 28.8 | 14.7 | 14.7 |
| HSV | 36.3 | 35.3 | 30.5 | 14.5 | 14.7 |

Error rates (percent) using different SVM kernels

For comparison, Chapelle and co-workers conducted some experiments of color image histogram (HSV-based) classifications with the K -nearest neighbor algorithm with χ^2 and ℓ_2 . Here $K = 1$ gives the best result presented in the following table:

| χ^2 | ℓ_2 |
|----------|----------|
| 26.5 | 47.7 |

Error rates (percent) with k -nearest neighbor algorithm

The χ^2 -based SVM is roughly twice as good as the χ^2 -based k -nearest neighbor technique.

4 Survey of Mathematical Analysis of Methods

Reproducing Kernel Hilbert Spaces

General theory For simplicity, let $\mathcal{X} \subset \mathbb{R}^d$ be a compact set throughout this subsection. Moreover, only spaces of real-valued functions are considered. Let $C(\mathcal{X})$ denote the set of continuous functions on \mathcal{X} . Together with the norm

$$\|f\|_{C(\mathcal{X})} = \sup\{|f(x)| : x \in \mathcal{X}\}$$

this becomes a Banach space. Further, let $L_2(\mathcal{X})$ be the Hilbert space of (equivalence classes) quadratic integrable, real-valued functions on \mathcal{X} with inner product and norm given by

$$\langle f, g \rangle_{L_2} := \int_{\mathcal{X}} f(x)g(x) dx, \quad \|f\|_{L_2} = \left(\int_{\mathcal{X}} f(x)^2 dx \right)^{1/2}.$$

Since \mathcal{X} is compact, the space $C(\mathcal{X})$ is continuously embedded into $L_2(\mathcal{X})$ which means that $\|f\|_{L_2(\mathcal{X})} \leq C \|f\|_{C(\mathcal{X})}$ for all $f \in C(\mathcal{X})$. A function $K : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$

is *symmetric*, if $K(x, t) = K(t, x)$ for all $x, t \in \mathcal{X}$. With a symmetric function $K \in L_2(\mathcal{X} \times \mathcal{X})$, one can associate an integral operator $T_K : L_2(\mathcal{X}) \rightarrow L_2(\mathcal{X})$ by

$$T_K f(t) := \int_{\mathcal{X}} K(x, t) f(x) dx.$$

This operator is a compact and self-adjoint operator, and K is called its *kernel*. The following spectral theorem holds true for compact, self-adjoint operators, i.e., in particular for T_K .

Theorem 1 (Spectral theorem for compact, self-adjoint operators). *Let T be a compact, self-adjoint operator on the Hilbert space \mathcal{H} . Then there exists a countable (possibly finite) orthonormal system $\{\psi_i : i \in I\}$ and a zero sequence $(\lambda_i)_{i \in I}$, $\lambda_i \in \mathbb{R} \setminus \{0\}$ such that*

$$\mathcal{H} = \ker T \oplus \overline{\text{span}\{\psi_i : i \in I\}}$$

and

$$Tf = \sum_{j \in I} \lambda_j \langle f, \psi_j \rangle_{\mathcal{H}} \psi_j \quad \forall f \in \mathcal{H}. \quad (35)$$

The numbers λ_j are the nonzero eigenvalues of T and ψ_j are the corresponding eigenfunctions. If T is a positive operator, i.e.,

$$\langle Tf, f \rangle_{\mathcal{H}} = \int_{\mathcal{X}} \int_{\mathcal{X}} K(x, t) f(x) f(t) dx dt \geq 0 \quad \forall f \in \mathcal{H},$$

then the values λ_j are positive.

Consider the special operator T_K for a symmetric kernel $K \in L_2(\mathcal{X} \times \mathcal{X})$. Using the L_2 -orthonormal eigenfunctions $\{\psi_i : i \in I\}$ of T_K , one can also expand the kernel itself as

$$K(x, t) = \sum_{j \in I} \lambda_j \psi_j(x) \psi_j(t),$$

where the sum converges as those in (35) in general only in $L_2(\mathcal{X} \times \mathcal{X})$. One can tighten the statement if K is continuous and symmetric. Then $T_K : C(\mathcal{X}) \rightarrow C(\mathcal{X})$ is a compact operator on the Pre-Hilbert spaces $C(\mathcal{X})$ equipped with the L_2 -norm into itself, and the functions ψ_j are continuous. If $f \in C(\mathcal{X})$, then the right-hand side in (35) converges absolutely and uniformly. To prove such a convergence result also for the kernel expansion, one needs moreover that the operator T_K is positive. Unfortunately, it is not true that a positive kernel K implies a positive operator T_K . There is another criterion which will be introduced in the following. A matrix

$\mathbf{K} \in \mathbb{R}^{m,m}$ is called *positive semi-definite* if

$$\alpha^T \mathbf{K} \alpha \geq 0 \quad \forall \alpha \in \mathbb{R}^m$$

and *positive definite* if strong inequality holds true for all $\alpha \neq 0$. A symmetric kernel $K : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ is *positive (semi)-definite* if the matrix $\mathbf{K} := (K(x_i, x_j))_{i,j=1}^m$ is positive (semi)-definite for all finite sets $\{x_1, \dots, x_m\} \subset \mathcal{X}$. Now a symmetric kernel $K \in C(\mathcal{X} \times \mathcal{X})$ is positive semi-definite if and only if the corresponding integral operator T_K is positive.

Theorem 2 (Mercer's theorem). *Let $K \in C(\mathcal{X} \times \mathcal{X})$ be a continuous, symmetric, and positive semi-definite function with corresponding integral operator T_K . Then K can be expanded into an absolutely and uniformly convergent series in terms of T_K 's orthonormal eigenfunctions ψ_j and the associated eigenvalues $\lambda_j > 0$ as follows:*

$$K(x, t) = \sum_{j \in I} \lambda_j \psi_j(x) \psi_j(t). \quad (36)$$

Moreover, if K is positive definite, then $\{\psi_i : i \in I\}$ form an orthonormal basis of $L_2(\mathcal{X})$.

A continuous, symmetric, positive semi-definite kernel is called a *Mercer kernel*. Mercer kernels are closely related to so-called reproducing kernel Hilbert spaces.

Let \mathcal{H} be a real Hilbert space of functions $f : \mathcal{X} \rightarrow \mathbb{R}$. A function $K : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ is called a *reproducing kernel* of \mathcal{H} if

- (H1) $K_t := K(\cdot, t) \in \mathcal{H} \quad \forall t \in \mathcal{X}$,
- (H2) $f(t) = \langle f, K_t \rangle_{\mathcal{H}} \quad \forall f \in \mathcal{H} \text{ and } \forall t \in \mathcal{X}$ (Reproducing Property).

In particular, property (H2) implies for $f := \sum_{i=1}^m \alpha_i K_{x_i}$ and $g := \sum_{j=1}^n \beta_j K_{x_j}$ that

$$\langle f, g \rangle_{\mathcal{H}} := \sum_{i=1}^m \sum_{j=1}^n \alpha_i \beta_j K(x_i, t_j), \quad \|f\|_{\mathcal{H}}^2 = \sum_{i=1}^m \sum_{j=1}^m \alpha_i \alpha_j K(x_i, t_j) = \alpha^T \mathbf{K} \alpha, \quad (37)$$

where $\alpha = (\alpha_1, \dots, \alpha_m)^T$ and $\mathbf{K} := (K(x_i, x_j))_{i,j=1}^m$. If such a kernel exists for \mathcal{H} , then it is uniquely determined. A Hilbert space which exhibits a reproducing kernel is called *reproducing kernel Hilbert space* (RKHS); write \mathcal{H}_K to emphasize the relation with the kernel. In \mathcal{H}_K , the set of all finite linear combinations of K_t , $t \in \mathcal{X}$ is dense, i.e.,

$$\mathcal{H}_K = \overline{\text{span} \{K_t : t \in \mathcal{X}\}}. \quad (38)$$

Moreover, the kernel K of a RKHS must be a symmetric, positive semi-definite function; see Wendland [114]. Finally, based on the Riesz representation theorem, another characterization of RKHSs can be given. It can be shown that a Hilbert space \mathcal{H} is a RKHS if and only if the point evaluation functionals $\delta_x : \mathcal{H} \rightarrow \mathbb{R}$ determined by $\delta_x f := f(x)$ are continuous on \mathcal{H} , i.e.,

$$|f(x)| \leq C \|f\|_{\mathcal{H}} \quad \forall f \in \mathcal{H}.$$

Conversely, by the following theorem, any Mercer kernel gives rise to a RKHS.

Theorem 3. *Let $K \in C(\mathcal{X} \times \mathcal{X})$ be a continuous, symmetric, and positive semi-definite function. Then there exists a unique Hilbert space \mathcal{H}_K of functions on \mathcal{X} which is a RKHS with kernel K . The space \mathcal{H}_K consists of continuous functions on \mathcal{X} , and the embedding operator $\iota_K : \mathcal{H}_K(\mathcal{X}) \rightarrow C(\mathcal{X}) (\rightarrow L_2(\mathcal{X}))$ is continuous.*

Proof. 1. First, one constructs a Hilbert space which fulfills (H1) and (H2). By (H1), the space \mathcal{H}_K has to contain all functions K_t , $t \in \mathcal{X}$ and since the space is linear also their finite linear combinations. Therefore, define

$$\mathcal{H}_0 := \text{span}\{K_t : t \in \mathcal{X}\}.$$

According to (37), this space can be equipped with the inner product and corresponding norm

$$\langle f, g \rangle_{\mathcal{H}_0} := \sum_{i=1}^m \sum_{j=1}^n \alpha_i \beta_j K(x_i, t_j), \quad \|f\|_{\mathcal{H}_0}^2 = \alpha^T \mathbf{K} \alpha.$$

It can easily be checked that this is indeed an inner product. In particular $\|f\|_{\mathcal{H}_0} = 0$ for some $f = \sum_{i=1}^m \alpha_i K_{x_i}$ implies that $f(t) = \sum_{i=1}^m \alpha_i K(t, x_i) = 0$ for all $t \in \mathcal{X}$ by the following argument: set $x_{m+1} := t$. By the positive semi-definiteness of K it follows for any $\epsilon \in \mathbb{R}$ that

$$(\alpha^T, \epsilon) (K(x_i, x_j))_{i,j=1}^{m+1} \begin{pmatrix} \alpha \\ \epsilon \end{pmatrix} = \alpha^T \mathbf{K} \alpha + 2\epsilon \sum_{i=1}^m \alpha_i K(x_i, t) + \epsilon^2 K(t, t) \geq 0.$$

With $\alpha^T \mathbf{K} \alpha = \|f\|_{\mathcal{H}_0} = 0$, this can be rewritten as

$$\epsilon (2f(t) + \epsilon K(t, t)) \geq 0.$$

Since K is positive semi-definite, it holds $K(t, t) \geq 0$. Assume that $f(t) < 0$. Then choosing $0 < \epsilon < -2f(t)/K(t, t)$ if $K(t, t) > 0$ and $0 < \epsilon$ if $K(t, t) = 0$ leads to a contradiction. Similarly, assuming that $f(t) > 0$ and choosing $-2f(t)/K(t, t) < \epsilon < 0$ if $K(t, t) > 0$ and $\epsilon < 0$ if $K(t, t) = 0$ gives a contradiction. Thus $f(t) = 0$.

Now one defines \mathcal{H}_K to be the completion of \mathcal{H}_0 with the associated norm. This space has the reproducing property (H2) and is therefore a RKHS with kernel K .

2. To prove that \mathcal{H}_K is unique, assume that there exists another Hilbert space \mathcal{H} of functions on \mathcal{X} with kernel K . By (H1) and (38), it is clear that \mathcal{H}_0 is a dense subset of \mathcal{H} . By (H2) it follows that $\langle f, g \rangle_{\mathcal{H}} = \langle f, g \rangle_{\mathcal{H}_K}$ for all $f, g \in H_0$. Since both \mathcal{H} and \mathcal{H}_K are completions of \mathcal{H}_0 , the uniqueness follows.
3. Finally, one concludes by the Schwarz inequality that

$$|f(t)| = |\langle f, K_t \rangle_{\mathcal{H}_K}| \leq \|f\|_{\mathcal{H}_K} \|K_t\|_{\mathcal{H}_K} = \|f\|_{\mathcal{H}_K} \sqrt{K(t, t)}$$

so that f is continuous since K is continuous. Moreover, $\|f\|_{C(\mathcal{X})} \leq C \|f\|_{\mathcal{H}_K}$ with $C := \max_{t \in \mathcal{X}} \sqrt{K(t, t)}$ which means that the embedding ι_K is continuous. \square

Since the completion of \mathcal{H}_0 is rather abstract, another characterization of \mathcal{H}_K based on Mercer's theorem is useful. Let $\{\psi_i : i \in I\}$ be the L_2 -orthonormal eigenfunctions of T_K with corresponding eigenvalues $\lambda_j > 0$ from the Mercer theorem. Then it follows by Schwarz's inequality and Mercer's theorem for $w := (w_i)_{i \in I} \in \ell_2(I)$ that

$$\sum_{i \in I} |w_i \sqrt{\lambda_i} \psi_i(x)| \leq \|w\|_{\ell_2} \left(\sum_{i \in I} \lambda_i \psi_i^2(x) \right)^{1/2} = \|w\|_{\ell_2} \sqrt{K(x, x)}$$

so that the series $\sum_{i \in I} w_i \sqrt{\lambda_i} \psi_i(x)$ converges absolutely and uniformly for all $(w_i)_{i \in I} \in \ell_2(I)$. Now another characterization of \mathcal{H}_K can be given.

Corollary 1. *Let $K \in C(\mathcal{X} \times \mathcal{X})$ be a continuous, symmetric, and positive semi-definite kernel with expansion (36). Then the Hilbert space*

$$\mathcal{H} := \left\{ \sum_{i \in I} w_i \sqrt{\lambda_i} \psi_i : (w_i)_{i \in I} \in \ell_2(I) \right\}$$

with inner product

$$\langle f, g \rangle_{\mathcal{H}} := \sum_{i \in I} w_i \omega_i = \sum_{j=1}^{\infty} \frac{1}{\lambda_j} \langle f, \psi_j \rangle_{L_2} \langle g, \psi_j \rangle_{L_2}$$

for $f := \sum_{i \in I} w_i \sqrt{\lambda_i} \psi_i$ and $g := \sum_{j \in I} w_j \sqrt{\lambda_j} \psi_j$ is the RKHS with kernel K , i.e., $\mathcal{H} = \mathcal{H}_K$. The system $\{\varphi_i := \sqrt{\lambda_i} \psi_i : i \in I\}$ is an orthonormal basis of \mathcal{H} .

If K is positive definite, then \mathcal{H} can be also characterized by

$$\mathcal{H} = \left\{ f \in L_2(\mathcal{X}) : \sum_{j=1}^{\infty} \frac{1}{\lambda_j} |\langle f, \psi_j \rangle_{L_2}|^2 < \infty \right\}$$

Proof. By the above definition of the inner product, the set $\{\sqrt{\lambda_i} \psi_i : i \in I\}$ is an orthonormal basis of \mathcal{H} . The second equality in the definition of the inner product follows by the orthonormality of the ψ_i in L_2 .

It remains to show that K fulfills (H1) and (H2). Concerning (H1), it holds $K_t = \sum_{i \in I} \sqrt{\lambda_i} \psi_i(t) \sqrt{\lambda_i} \psi_i$, and since

$$\sum_{i \in I} (\sqrt{\lambda_i} \psi_i(t))^2 = K(t, t) < \infty,$$

it follows that $K_t \in \mathcal{H}$. Using the orthonormal basis property, one can conclude with respect to (H2) that

$$\langle f, K_t \rangle_{\mathcal{H}} = \left\langle \sum_{j \in I} w_j \sqrt{\lambda_j} \psi_j, \sum_{i \in I} \sqrt{\lambda_i} \psi_i(t) \sqrt{\lambda_i} \psi_i \right\rangle_{\mathcal{H}} = \sum_{i \in I} w_i \sqrt{\lambda_i} \psi_i(t) = f(t).$$

□

For more information on RKHS, see the book of Berlinet and Thomas-Agnan [8].

Kernels The choice of appropriate kernels for SVMs depend on the application. Default options are Gaussians or polynomial kernels which are described together with some more examples of Mercer kernels below:

1. Let $\mathcal{X} := \{x \in \mathbb{R}^d : \|x\| \leq R\}$ with radius $R > 0$. Then the *dot product kernels*

$$K(x, t) := \sum_{j=0}^{\infty} a_j (x \cdot t)^j, \quad a_j \geq 0, \quad \sum_{j=1}^{\infty} a_j R^{2j} < \infty$$

are Mercer kernels on \mathcal{X} . A proof that these kernels are indeed positive semi-definite is given in the book of Cucker and Zhou [29]. A special case appears if \mathcal{X} contains the coordinate vectors e_j , $j = 1, \dots, d$ and the kernel is $K(x, t) = 1 + x \cdot t$. Note that even in one dimension $d = 1$, this kernel is not positive definite. Here the corresponding RKHS \mathcal{H}_K is the space of linear functions and $\{1, x_1, \dots, x_d\}$ forms an orthonormal basis of \mathcal{H}_K .

The special dot product $K(x, t) := (c + x \cdot t)^n$, $c \geq 0$, $n \in \mathbb{N}$, also known as *polynomial kernel* was introduced in statistical learning theory by Vapnik 1998 [105]. More general dot products were described, e.g., by Smola, Schölkopf and Müller [89]. See also all-subset kernels and ANOVA kernels in [88].

2. Next, consider *translation invariant kernels*

$$K(x, t) := \kappa(x - t),$$

where $\kappa : \mathbb{R}^d \rightarrow \mathbb{R}$ is a continuous function which has to be even, that is, $\kappa(-x) = \kappa(x)$ for all $x \in \mathbb{R}^d$ to ensure that K is symmetric. Let us see if K is a Mercer kernel on \mathbb{R}^d and hence on any subset \mathcal{X} of \mathbb{R}^d . First, one knows from Bochner's theorem that K is positive semi-definite if and only if it is the Fourier transform of a finite nonnegative Borel measure on \mathbb{R}^d . Let $\kappa \in L_1(\mathbb{R}^d)$. Then, K is positive definite if and only if κ is bounded and its Fourier transform is nonnegative and non-vanishing.

A special example on \mathbb{R} ($d = 1$) is the *spline kernel* K generated by the “hat function” $\kappa(x) := \max\{0, 1 - |x|/2\}$. Its Fourier transform is $\hat{\kappa}(\omega) = 2(\sin \omega/\omega)^2 \geq 0$. Multivariate examples of this form can be constructed by using, e.g., box splines. Spline kernels and corresponding RKHSs were discussed, e.g., by Wahba [112].

3. A widely used class of translation invariant kernels are *kernels associated with radial functions*. A function $\kappa : \mathbb{R}^d \rightarrow \mathbb{R}$ is said to be *radial* if there exists a function $k : [0, \infty) \rightarrow \mathbb{R}$ such that $\kappa(x) = k(\|x\|^2)$ for all $x \in \mathbb{R}^d$. For radial kernels define

$$K(x, t) := k(\|x - t\|^2).$$

A result of Schoenberg [85] says that K is positive semi-definite on \mathbb{R}^d if and only if the function k is completely monotone on $[0, \infty)$. Recall that k is *completely monotone* on $(0, \infty)$ if $k \in C^\infty(0, \infty)$ and

$$(-1)^l k^{(l)}(r) \geq 0 \quad \forall l \in \mathbb{N}_0 \text{ and } \forall r > 0.$$

The function k is called completely monotone on $[0, \infty)$ if it is in addition in $C[0, \infty)$.

It holds that K is positive definite if and only if *one* of the following conditions is fulfilled

- (i) $k(\sqrt{\cdot})$ is completely monotone on $[0, \infty)$ and not constant,
- (ii) There exists a finite nonnegative Borel measure ν on $[0, \infty)$ that is not concentrated at zero such that

$$k(r) = \int_0^\infty e^{-r^2 t} d\nu(t).$$

The proofs of these results on radial kernels are contained, e.g., in the book of Wendland [114].

For $c > 0$, the kernels K arising from the following radial functions κ are positive definite:

$$\begin{aligned}\kappa(x) &:= e^{-\|x\|^2/c^2} \quad \text{Gaussian,} \\ \kappa(x) &:= (c^2 + \|x\|^2)^{-s}, \quad s > 0 \quad \text{inverse multiquadric,}\end{aligned}$$

where the positive definiteness of the Gaussian follows from (i) and those of the inverse multiquadric from (ii) with

$$k(r) = \frac{1}{\Gamma(s)} \int_0^\infty t^{s-1} e^{-c^2 t} e^{-r^2 t} dt.$$

Positive definite kernels arising from Wendland's radial basis functions with compact support (see Wendland [114]) were applied in SVM classification by Strauss and Steidl [95].

Finally, the following techniques for creating Mercer kernels are remarkable.

Theorem 4. *Let $K_j \in C(\mathcal{X} \times \mathcal{X})$, $j = 1, 2$ be Mercer kernels and p a polynomial with positive coefficients. Then the following functions are also Mercer kernels:*

- (i) $K(x, t) := K_1(x, t) + K_2(x, t)$,
- (ii) $K(x, t) := K_1(x, t)K_2(x, t)$,
- (iii) $K(x, t) := p(K_1(x, t))$,
- (iv) $K(x, t) := e^{K_1(x, t)}$.

Beyond the above Mercer kernels other kernels like kernels for text and structured data (strings, trees), diffusion kernels on graphs or kernel incorporating generative information were used in practice; see the book of Shawe-Taylor and Cristianini [88].

Conditionally positive semi-definite radial functions. In connection with radial basis functions, so-called conditionally positive semi-definite functions $\kappa(x) := k(\|x\|^2)$ were applied for approximation tasks. Let $\Pi_{v-1}(\mathbb{R}^d)$ denote the space of polynomials on \mathbb{R}^d of degree $< v$. This space has dimension $\dim(\Pi_{v-1}(\mathbb{R}^d)) = \binom{d+v-1}{v}$. A continuous radial function $\kappa : \mathbb{R}^d \rightarrow \mathbb{R}$ is *conditionally positive semi-definite of order v* if for all $m \in \mathbb{N}$, all pairwise distinct points $x_1, \dots, x_m \in \mathbb{R}^d$, and all $\alpha \in \mathbb{R}^m \setminus \{0\}$ satisfying

$$\sum_{i=1}^m \alpha_i p(x_i) = 0 \quad \forall p \in \Pi_{v-1}(\mathbb{R}^d) \tag{39}$$

the relation

$$\alpha^T \mathbf{K} \alpha \geq 0, \quad \mathbf{K} := (\kappa(x_i - x_j))_{i,j=1}^m$$

holds true for all $\alpha \in \mathbb{R}^m$. If equality is attained only for $\alpha = 0$, the function κ is said to be *conditionally positive definite of order v* .

The following result is due to Micchelli [71]: For $k \in C[0, \infty) \cap C^\infty(0, \infty)$, the function $\kappa(x) := k(\|x\|^2)$ is conditionally positive semi-definite of order v if and only if $(-1)^v k^{(v)}$ is completely monotone on $(0, \infty)$. If k is not a polynomial of degree at most v , then κ is conditionally positive definite of order v .

Using this result, one can show that the following functions are conditionally positive definite of order v :

$$\kappa(x) := (-1)^{\lceil s \rceil} (c^2 + \|x\|^2)^s, \quad s > 0, s \notin \mathbb{N}, \quad v = \lceil s \rceil \quad \text{multiquadric,}$$

$$\kappa(x) := (-1)^{\lceil s/2 \rceil} \|x\|^s, \quad s > 0, s \notin 2\mathbb{N}, \quad v = \lceil s/2 \rceil,$$

$$\kappa(x) := (-1)^{k+1} \|x\|^{2k} \log \|x\|, \quad k \in \mathbb{N}, \quad v = k+1 \quad \text{thin plate spline.}$$

A relation of a combination of thin plate splines and polynomials to the reproducing kernels of certain RKHSs can be found in Wahba [112].

Quadratic Optimization

This subsection collects the basic material from optimization theory to understand the related parts in the previous Sect. 3, in particular the relation between primal and dual problems in quadratic programming. More on this topic can be found in any book on optimization theory, e.g., in the books of Mangasarian [68] or Spellucci [90].

A (nonlinear) optimization problem in \mathbb{R}^d has the general form

| |
|--|
| Primal problem (P) |
| $\theta(x) \rightarrow \min_x \quad \text{subject to} \quad g(x) \leq 0, h(x) = 0$ |

where $\theta : \mathbb{R}^d \rightarrow \mathbb{R}$ is a real-valued function and $g : \mathbb{R}^d \rightarrow \mathbb{R}^m$, $h : \mathbb{R}^d \rightarrow \mathbb{R}^p$ are vector-valued functions. In general, only the case $p < d$ is of interest since otherwise one is confronted with the solution of a (nonlinear) system of equations. The region

$$\mathcal{G} := \{x \in \mathbb{R}^d : g(x) \leq 0, h(x) = 0\},$$

where the *objective function* θ is defined and where all constraints are satisfied, is called *feasible region*. There are classes of problems (P) which are well examined as convex optimization problems and in particular special classes of convex problems, namely, linear and quadratic problems. Problem (P) is called *convex*, if θ is a convex function and \mathcal{G} is a convex region. Recall, that $x^* \in \mathcal{G}$ is a *local minimizer* of θ in \mathcal{G} if there exists a neighborhood $\mathcal{U}(x^*)$ of x^* such that $\theta(x^*) \leq \theta(x)$ for all $x \in \mathcal{U}(x^*) \cap \mathcal{G}$. For convex problems, any local minimizer x^* of θ in \mathcal{G} is also a *global minimizer* of θ in \mathcal{G} and therefore a solution of the minimization problem.

This subsection deals mainly with the following setting which gives rise to a convex optimization problem:

- (C1) θ convex and differentiable,
- (C2) $g_i, i = 1, \dots, m$ convex and differentiable,
- (C3) $h_j, j = 1, \dots, p$ affine linear.

Important classes of problems fulfilling (C1)–(C3) are *quadratic programs*, where the objective function is quadratic and the constraints are (affine) linear and *linear programs*, where the objective function is also linear. The constrained optimization problems considered in Sect. 3 are of this kind.

The function $L : \mathbb{R}^d \times \mathbb{R}_+^m \times \mathbb{R}^p \rightarrow \mathbb{R}$ defined by

$$L(x, \alpha, \beta) := \theta(x) + \sum_{i=1}^m \alpha_i g_i(x) + \sum_{j=1}^p \beta_j h_j(x)$$

is called the *Lagrangian* associated with (P), and the coefficients α_i and β_j are called *Lagrange multipliers*. Recall that $(x^*, \lambda^*) \in \Omega \times \Xi$, $\Omega \subset \mathbb{R}^d$, $\Xi \subset \mathbb{R}^n$ is called a *saddle point* of a function $\Phi : \Omega \times \Xi \rightarrow \mathbb{R}$ if

$$\Phi(x^*, \lambda) \leq \Phi(x^*, \lambda^*) \leq \Phi(x, \lambda^*) \quad \forall (x, \lambda) \in \Omega \times \Xi.$$

There is the following close relation between saddle point problems and min-max problems:

Lemma 1. *Let $\Phi : \Omega \times \Xi \rightarrow \mathbb{R}$. Then the inequality*

$$\max_{\lambda \in \Xi} \min_{x \in \Omega} \Phi(x, \lambda) \leq \min_{x \in \Omega} \max_{\lambda \in \Xi} \Phi(x, \lambda)$$

holds true supposed that all extreme points exist. Moreover, in this case, the equality

$$\max_{\lambda \in \Xi} \min_{x \in \Omega} \Phi(x, \lambda) = \Phi(x^*, \lambda^*) = \min_{x \in \Omega} \max_{\lambda \in \Xi} \Phi(x, \lambda)$$

is fulfilled if and only if (x^, λ^*) is a saddle point of Φ .*

The solution of (P) is related to the saddle points of its associated Lagrangian as detailed in the following theorem.

Theorem 5. *If $(x^*, (\alpha^*, \beta^*)) \in \mathbb{R}^d \times (\mathbb{R}_+^m \times \mathbb{R}^p)$ is a saddle point of the Lagrangian associated with the minimization problem (P), i.e.,*

$$L(x^*, \alpha, \beta) \leq L(x^*, \alpha^*, \beta^*) \leq L(x, \alpha^*, \beta^*) \quad \forall x \in \mathbb{R}^d, \forall (\alpha, \beta) \in \mathbb{R}_+^m \times \mathbb{R}^p,$$

then x^* is a solution of (P). Assume that the functions θ, g, h satisfy the conditions (C1)–(C3) and that g fulfills in addition the following Slater condition:

there exists $x_0 \in \Omega$ such that $g(x_0) > 0$ and $h(x_0) = 0$.

Then, if x^* is a solution of (P), there exist $\alpha^* \in \mathbb{R}_+^m$ and $\beta^* \in \mathbb{R}^p$ such that $(x^*, (\alpha^*, \beta^*))$ is a saddle point of the associated Lagrangian.

By the next theorem, the minimizers of (P) can be also described via the following conditions on the Lagrangian: there exist $x^* \in \mathcal{G}$, $\alpha^* \in \mathbb{R}_+^m$ and $\beta^* \in \mathbb{R}^p$ such that

$$\begin{aligned} \text{(KKT1)} \quad & \nabla_x L(x^*, \alpha^*, \beta^*) = 0, \\ \text{(KKT2)} \quad & (\alpha^*)^\top g(x^*) = 0, \quad \alpha^* \geq 0. \end{aligned}$$

These conditions were independently established by Karush and Kuhn and Tucker [60] and are mainly called *Kuhn-Tucker conditions*.

Theorem 6. Let θ, g and h fulfill (C1)–(C3). If x^* satisfies (KKT1)–(KKT2), then x^* is a solution of (P). Assume that g fulfills in addition the Slater condition. Then, if x^* is a solution of (P), it also fulfills (KKT1)–(KKT2).

If there are *only equality constraints* in (P), then a solution is determined by

$$\nabla_x L(x^*, \beta^*) = 0, \quad h(x^*) = 0.$$

For the rest of this subsection, assume that (C1)–(C3) and the Slater condition hold true. Let a solution x^* of (P) exist. Then, by Lemma 1 and Theorem 5, there exist α^* and β^* such that

$$L(x^*, \alpha^*, \beta^*) = \max_{\alpha \in \mathbb{R}_+^m, \beta} \min_x L(x, \alpha, \beta).$$

Therefore, one can try to find x^* as follows: for any fixed $(\alpha, \beta) \in \mathbb{R}_+^m \times \mathbb{R}^p$, compute

$$\hat{x}(\alpha, \beta) := \operatorname{argmin}_x L(x, \alpha, \beta). \tag{40}$$

If θ is uniformly convex, i.e., there exists $\gamma > 0$ such that

$$\mu\theta(x) + (1-\mu)\theta(y) \geq \theta(\mu x + (1-\mu)y) + \mu(1-\mu)\gamma\|x-y\|^2 \quad \forall x, y \in \mathbb{R}^d, \mu \in [0, 1],$$

then $\hat{x}(\alpha, \beta)$ can be obtained as the unique solution of

$$\nabla_x L(x, \alpha, \beta) = 0.$$

This can be substituted into L which results in $\psi(\alpha, \beta) := L(\hat{x}(\alpha, \beta), \alpha, \beta)$ and α^* and β^* are the solution of

$$\psi(\alpha, \beta) \rightarrow \max_{\alpha, \beta} \quad \text{subject to} \quad \alpha \geq 0.$$

This problem, which is called the *dual problem* of (P) can often be more easily solved than the original problem since one has only simple inequality constraints. However, this approach is only possible if (40) can easily be solved. Then, finally $x^* = \hat{x}(\alpha^*, \beta^*)$.

The objective functions in the primal problems in Sect. 3 are not strictly convex (and consequently also not uniformly convex) since there does not appear the intercept b in these functions. So let us formulate the dual problem with $\psi(x, \alpha, \beta) := L(x, \alpha, \beta)$ as follows:

Dual problem (D)

$$\psi(x, \alpha, \beta) \rightarrow \max_{x, \alpha, \beta} \quad \text{subject to} \quad \nabla_x L(x, \alpha, \beta) = 0, \quad \alpha \geq 0.$$

The solutions of the primal and dual problem, i.e., their minimum and maximum, respectively, coincide according to the following theorem of Wolfe [117].

Theorem 7. *Let θ , g and h fulfill (C1)–(C3) and the Slater condition. Let x^* be a minimizer of (P). Then there exist α^*, β^* such that x^*, α^*, β^* solves the dual problem and*

$$\theta(x^*) = \psi(x^*, \alpha^*, \beta^*).$$

Duality theory can be handled in a more sophisticated way using tools from Perturbation Theory in Convex Analysis; see, e.g., the book of Bonnans and Shapiro [11]. Let us briefly mention the general idea. Let $v : \mathbb{R}^m \rightarrow (-\infty, \infty]$ be an extended function, where only extended functions $\not\equiv \infty$ are considered in the following. The *Fenchel conjugate* of v is defined by

$$v^*(\alpha) := \sup_{p \in \mathbb{R}^m} \{\langle \alpha, p \rangle - v(p)\}$$

and the *biconjugate* of v by $v^{**} := (v^*)^*$. In general, the inequality $v^{**}(x) \leq v(x)$ holds true and becomes an equality if and only if v is convex and lower semicontinuous. (Later the inequality is indicated by the fact that one minimizes the primal and maximizes the dual problem.) For convex, lower semicontinuous functions $\theta : \mathbb{R}^d \rightarrow (-\infty, \infty]$, $\gamma : \mathbb{R}^m \rightarrow (-\infty, \infty]$ and $g : \mathbb{R}^d \rightarrow \mathbb{R}^m$ one considers the primal problems

$$(P_u) \quad v(u) = \inf_{x \in \mathbb{R}^d} \{\theta(x) + \gamma(g(x) + u)\},$$

$$(P) \quad v(0) = \inf_{x \in \mathbb{R}^d} \{\theta(x) + \gamma(g(x))\}$$

where $u \in \mathbb{R}^m$ is the “perturbation.” With $L(x, \alpha) := \theta(x) + \langle g(x), \alpha \rangle$, the dual problem reads

$$(D_u) \quad v^{**}(u) = \sup_{\alpha \in \mathbb{R}^m} \{\langle \alpha, u \rangle - \gamma^*(\alpha) + \inf_{x \in \mathbb{R}^d} L(x, \alpha)\},$$

$$(D) \quad v^{**}(0) = \sup_{\alpha \in \mathbb{R}^m} \{-\gamma^*(\alpha) + \inf_{x \in \mathbb{R}^d} L(x, \alpha)\}.$$

For the special setting with the indicator function

$$\gamma(y) = \iota_{\mathbb{R}_+^m}(y) := \begin{cases} 0 & \text{if } y \leq 0, \\ \infty & \text{otherwise} \end{cases}$$

the primal problem (P) is equivalent to

$$\theta(x) \rightarrow \min_x \quad \text{subject to} \quad g(x) \leq 0$$

and since $\gamma^* = \iota_{\mathbb{R}_+^m}$ the dual problem (D) becomes

$$\sup_{\alpha \in \mathbb{R}^m} \inf_{x \in \mathbb{R}^d} L(x, \alpha) \quad \text{subject to} \quad \alpha \geq 0.$$

Again, if θ and g are convex and differentiable and θ is uniformly convex, then the unique solution $\hat{x}(\alpha)$ of $\nabla_x L(x, \alpha) = 0$ is the solution of the infimum problem, and the dual problem becomes $\sup_{\alpha \in \mathbb{R}^m} L(\hat{x}(\alpha), \alpha)$ subject to $\alpha \geq 0$.

Results from Generalization Theory

There exists a huge amount of results on the generalization abilities of statistical learning methods and in particular of support vector machines. The following subsection can only give a rough impression on the general tasks considered in this field from a simplified mathematical point of view that ignores technicalities, e.g., the definition of the correct measure and function spaces and what measurable in the related context means. Most of the material is borrowed from the book of Steinwart and Christmann [93], where the reader can find a sound mathematical treatment of the topic.

To start with, remember that the aim in Sect. 3 was to find a function $f : \mathcal{X} \rightarrow \mathbb{R}$ from samples $Z := \{(x_i, y_i) : i = 1, \dots, m\}$ such that $f(x)$ is a good prediction of y at x for $(x, y) \in \mathcal{X} \times \mathcal{Y}$. Let P denote an unknown probability distribution on $\mathcal{X} \times \mathcal{Y}$. Then a general assumption is that the data used in training and testing are identically independent distributed (iid) according to P . The *loss function* or *cost function* $L : \mathcal{X} \times \mathcal{Y} \times \mathbb{R} \rightarrow [0, \infty)$ describes the cost of the discrepancy between the

prediction $f(x)$ and the observation y at x . The choice of the loss function depends on the specific learning goal. In the models of this paper, the loss functions depend on x only via $f(x)$ such that one can simply write $L(y, f(x))$. In Sect. 3, the hinge loss function and the least squares loss function were used for classification tasks. Originally, one was interested in the 0/1 classification loss $L_{0/1} : \mathcal{Y} \times \mathbb{R} \rightarrow \{0, 1\}$ defined by

$$L_{0/1}(y, t) := \begin{cases} 0 & \text{if } y = \text{sgn}(t), \\ 1 & \text{otherwise.} \end{cases}$$

To the loss function, there is associated a *risk* which is the expected loss of f :

$$R_{L,P}(f) := \int_{\mathcal{X} \times \mathcal{Y}} L(x, y, f(x)) dP(x, y) = \int_{\mathcal{X}} \int_{\mathcal{Y}} L(x, y, f(x)) dP(y|x) dP_{\mathcal{X}}.$$

For example, the 0/1 loss function has the risk

$$R_{L_{0/1},P}(f) = P((x, y) \in \mathcal{X} \times \mathcal{Y} : \text{sgn} f(x) \neq y).$$

A function f is considered to be “better” the smaller the risk is. Therefore, one is interested in the *minimal risk* or *Bayes risk* defined by

$$R_{L,P}^* := \inf_{f:\mathcal{X} \rightarrow \mathbb{R}} R_{L,P}(f), \quad (41)$$

where the infimum is taken over all possible (measurable) functions. However, since the distribution P is unknown, it is impossible to find a minimizer of $R_{L,P}$. In learning tasks one can exploit finite training sets Z of iid data. A learning method on $\mathcal{X} \times \mathcal{Y}$ maps every data set $Z \in (\mathcal{X} \times \mathcal{Y})^m$ to a function $f_Z : \mathcal{X} \rightarrow \mathbb{R}$. A learning methods should produce for sufficiently large training sets Z nearly optimal decision functions f_Z with high probability. A measurable learning method is called *L-risk consistent* for P if

$$\lim_{m \rightarrow \infty} P^m(Z \in (\mathcal{X} \times \mathcal{Y})^m : R_{L,P}(f_Z) \leq R_{L,P}^* + \varepsilon) = 1 \quad \forall \varepsilon > 0$$

and *universally L-risk consistent*, if it is L-risk consistent for all distributions P on $\mathcal{X} \times \mathcal{Y}$. The first learning method that was proved to be universally consistent was the so-called nearest neighbor method; see Stone [94]. Many uniformly consistent classification and regression methods are presented in the books of Devroye et al. [30] and Györfi [46]. Consistency does not address the *speed of convergence*, i.e., convergence rates. Unfortunately, the *no-free-lunch theorem* of Devroye [31], says that for every learning method there exists a distribution P for which the learning methods cannot produce a “good” decision function in the above sense with an a priori fixed speed of convergence. To obtain uniform convergence rates, one has to pose additional requirements on P .

Instead of the risk one can deal with the *empirical risk* defined by

$$R_{L,Z}(f) := \frac{1}{m} \sum_{i=1}^m L(x_i, y_i, f(x_i)).$$

Then the law of large numbers shows that $R_{L,Z}(f)$ becomes a “good” approximation of $R_{L,P}(f)$ for a fixed f if m is “large enough.” However finding the minimizer of

$$\inf_{f:\mathcal{X} \rightarrow \mathbb{R}} R_{L,Z}(f) \quad (42)$$

does in general not lead to a good approximation of $R_{L,P}^*$. For example, the function which classifies all $x_i \in X$ correctly and is zero elsewhere is a minimizer of the above functional (42) but gives in general a poor approximation of the optimal decision function according to (41). This is an example of so-called overfitting, where the learning method approximates the training data too closely and has poor generalization/prediction properties. One common way to cope with this phenomenon is to choose a smaller set \mathcal{F} of functions, e.g., subsets of continuous functions, which should have good approximation properties. In the SVMs treated in Sect. 3, this set \mathcal{F} was a RKHS \mathcal{H}_K . Then one considers the *empirical risk minimization* (ERM)

$$\inf_{f \in \mathcal{F}} R_{L,Z}(f). \quad (43)$$

Let a minimizer f_Z of (43) be somehow “computed.” (In this subsection, the question of the existence and uniqueness of a minimizer of the various functionals is not addressed.) Then one is of course interested in the error $R_{L,P}(f_Z) - R_{L,P}^*$. Using the infinite-sample counterpart of the ERM

$$R_{L,P,\mathcal{F}}^* := \inf_{f \in \mathcal{F}} R_{L,P}(f)$$

this error can be splitted as

$$R_{L,P}(f_Z) - R_{L,P}^* = \underbrace{R_{L,P}(f_Z) - R_{L,P,\mathcal{F}}^*}_{\text{sample error}} + \underbrace{R_{L,P,\mathcal{F}}^* - R_{L,P}^*}_{\text{approximation error}}.$$

The first error, called *sample error*, is a probabilistic one since it depends on random samples, while the second error, called *approximation error*, is a deterministic one. Finding a good balance between both errors is sometimes called *bias-variance problem*, where the bias is related to the approximation error and the variance to the sampling error.

Concerning the approximation error, it turns out that for RKHS $\mathcal{F} = \mathcal{H}_K$ on compact metric spaces \mathcal{X} which are dense in $C(\mathcal{X})$ and continuous, P-integrable, so-called Nemitski losses, this error becomes zero; see Corollary 5.29 in Steinwart and Christmann [93]. In particular, this is true for RKHS with the Gaussian kernel and the loss functions considered in Sect. 3. For relations between the approximation error, interpolation spaces, and K-functionals, see the book of Cucker and Zhou [29] and the references therein.

Concerning the sample error, there is a huge amount of results, and this paper can only cover some basic directions. For a survey on recent developments in the statistical analysis of classification methods, see Boucheron et al. [14]. Based on Hoeffding's inequality, the first of such relations goes back to Vapnik and Chervonenkis [107]. See also the books of Tsyplkin [104], Vapnik [105], Anthony and Bartlett [3], and Vidyasagar [109]. To get an impression how such estimates look like, two of them from Proposition 6.18 and 6.22 of the book of Steinwart and Christmann [93] are presented in the following. If \mathcal{F} is finite and $L(x, y, f(x)) \leq B$, then it holds for all $m \geq 1$ that

$$P^m \left(Z \in (\mathcal{X} \times \mathcal{Y})^m : R_{L,P}(f_Z) - R_{L,P,\mathcal{F}}^* \geq B \sqrt{\frac{2\tau + 2 \ln(2|\mathcal{F}|)}{m}} \right) \leq e^{-\tau} \forall \tau > 0.$$

If the function class \mathcal{F} is infinite, in particular not countable, one needs some bounds on the “complexity” of \mathcal{F} . The most classical of such a “complexity” measure is the *VC dimension* (see Vapnik and Chervonenkis [107]) applied in connection with the 0/1 loss function. Another possibility is the use of *covering numbers* or its counterpart *entropy numbers* going back to Kolmogorov and Tikhomirov [57]. The ε -covering number of a metric set T with metric d is the size of the smallest ε -net of T , i.e.,

$$N(T, d, \varepsilon) := \inf \left\{ n \geq 1 : \exists s_1, \dots, s_n \in T \text{ such that } T \subset \bigcup_{i=1}^n B_d(s_i, \varepsilon) \right\},$$

where $B_d(s, \varepsilon)$ is the closed ball with center s and radius ε . For the estimation of covering numbers see Edmunds and Triebel [35] and Pinkus [79]. Then, for compact $\mathcal{F} \subset L_\infty(X)$, one has basically to replace $|\mathcal{F}|$ in the above relation by its covering number:

$$\begin{aligned} P^m \left(Z \in (\mathcal{X} \times \mathcal{Y})^m : R_{L,P}(f_Z) - R_{L,P,\mathcal{F}}^* \right. \\ \left. \geq B \sqrt{\frac{2\tau + 2 \ln(2N(\mathcal{F}, \|\cdot\|_\infty, \varepsilon))}{m}} + 4\varepsilon|L|_{M,1} \right) \leq e^{-\tau} \end{aligned}$$

for all $\tau > 0$ and for all $\varepsilon > 0$, where ones assumes in addition that $\|f\|_\infty \leq M$, $f \in \mathcal{F}$ and that L is locally Lipschitz continuous with constant $|L|_{M,1}$ here.

Next let us turn to the SVM setting, where an additional term comes along with the loss function, namely, one is interested in minimizers of

$$\inf_{f \in \mathcal{H}_K} \{R_{L,Z}(f) + \lambda \|f\|_{\mathcal{H}_K}^2\}, \quad \lambda > 0$$

with a regularization term $\lambda \|f\|_{\mathcal{H}_K}^2$ that penalizes functions f with large RKHS norms. The techniques developed for ERM analysis can be extended to the SVM setting.

First let us mention that under some assumptions on the loss function, which are fulfilled for the setting in Sect. 3, a unique minimizer $f_{Z,\lambda}$ exists and has the form

$$f_{Z,\lambda} = \sum_{i=1}^m \alpha_i K(x_i, \cdot).$$

This was established in the *representer theorem* by Kimeldorf and Wahba [56] for special continuous loss functions and generalized, e.g., in Schölkopf et al. [86]. There also exist a representer-like theorems for the minimizer $f_{P,\lambda}$ of the infinite-sample setting

$$\inf_{f \in \mathcal{H}_K} \{R_{L,P}(f) + \lambda \|f\|_{\mathcal{H}_K}^2\}$$

(see Steinwart [92], de Vito [111], and Dinuzzo et al. [33]). One can show for the infinite-sample setting that the error

$$A(\lambda) := \inf_{f \in \mathcal{H}_K} \{R_{L,P}(f) + \lambda \|f\|_{\mathcal{H}_K}^2\} - R_{L,P,\mathcal{H}_K}^*$$

tends to zero as λ goes to zero and that $\lim_{\lambda \rightarrow 0} R_{L,P}(f_{P,\lambda}) = R_{L,P,\mathcal{H}_K}^*$. Let us come to the essential question how close $R_{P,\lambda}(f_{Z,\lambda})$ is to $R_{L,P}^*$. Recall that $R_{L,P}^* = R_{L,P,\mathcal{H}_K}^*$ for the above mentioned RKHS. An ERM analysis like estimation has, for example, the form

$$\begin{aligned} P^m \left(Z \in (\mathcal{X} \times \mathcal{Y})^m : R_{L,P}(f_{Z,\lambda}) + \lambda \|f_{Z,\lambda}\|_{\mathcal{H}_K}^2 - R_{L,P,\mathcal{H}_K}^* \right. \\ \geq A(\lambda) + (\lambda^{-1/2} |L|_{\lambda^{-1/2},1} + 1) \\ \left. \sqrt{\frac{2\tau + 2 \ln(2N(B_{\mathcal{H}_K}, \|\cdot\|_\infty, \lambda^{1/2}\varepsilon))}{m}} + 4\varepsilon |L|_{\lambda^{-1/2},1} \right) \leq e^{-\tau}, \end{aligned}$$

for $\tau > 0$, where one assumes that the continuous kernel fulfills $\|K\|_\infty \leq 1$, $L(x, y, 0) \leq 1$ and $B_{\mathcal{H}}$ is the closed unit ball in \mathcal{H} (see Theorem 6.25 in Steinwart

and Christmann [93] and also Cucker and Smale [28] and Bousquet and Elisseeff [15]). For a certain decay of the covering number $\ln(2N(B_{\mathcal{H}_K}, \|\cdot\|_\infty, \varepsilon))$ in ε and a RKHS for which the approximation error becomes zero, one can then conclude that for zero sequences $(\lambda_m)_{m \geq 1}$ with an additional suitable decay property related to the decay of the covering number, the relation $R_{L,P}(f_{Z,\lambda_m}) \rightarrow R_{L,P}^*$ holds true in probability.

The above relations can be further specified for classification and regression tasks with special loss functions. With respect to classification, one can find, for example, upper bounds for the risk in terms of the margin or the number of support vectors. For the 0/1 loss function, the reader may consult, e.g., the book of Cristianini and Shawe-Taylor [27]. For the hinge loss function and the soft margin SVM with $C = 1/(2\lambda m)$, it holds, for example, that

$$\frac{|I_S|}{m} \geq 2\lambda \|f_{Z,\lambda}\|_{\mathcal{H}_K}^2 + R_{L,Z}(f_{Z,\lambda})$$

(see Proposition 8.27 in Steinwart and Christmann [93]). For a suitable zero sequence $(\lambda_m)_{m \geq 1}$ and a RKHS with zero approximation error, the following relation is satisfied:

$$\lim_{m \rightarrow \infty} P^m \left(Z \in (\mathcal{X} \times \mathcal{Y})^m : \frac{|\{i : \alpha_i^*(Z) > 0\}|}{m} \geq R_{L,P}^* - \varepsilon \right) = 1, \quad \varepsilon > 0.$$

Finally, let us address the setting, where the risk function defining the learning task is hard to handle numerically. One example is the risk function associated with the 0/1 loss function. This function is neither continuous nor convex. One remedy is to replace such unpleasant loss functions L by a convex *surrogate* L_{sur} where one has to ensure that the minimizer f_Z in (43) for the surrogate loss fulfills $R_{L,P}(f_Z) \approx R_{L,P}^*$. For the hinge function as surrogate of the 0/1 loss function, Zhang [119], has proved that

$$R_{L_{0/1},P}(f) - R_{L_{0/1},P}^* \leq R_{L_h,P}(f) - R_{L_h,P}^*$$

for all measurable functions f . Thus, if $R_{L_h,P}(f_Z) - R_{L_h,P}^*$ is small, this follows for the original risk function, too. For a systematical treatment of surrogate loss functions, the reader may consult Chapter 3 in the book of Steinwart and Christmann [93] which was partially inspired by the work of Barlett et al. [6].

5 Numerical Methods

This section concentrates on the support vector machines in Sect. 3. Numerical methods for the other models were always sketched when they were introduced. Support vector machines require finally the minimization of a quadratic functional subject to linear constraints (QP). These minimization problems involve a symmetric, fully populated kernel matrix having the size m of the training set.

Hence, this matrix has in general $m(m + 1)/2$ distinct nonzero coefficients one has to work with. Therefore, one has to distinguish between small- to moderate-sized problems, where such a matrix can be stored into the RAM of the computer, and large-sized problems, say, with more than a million training data.

For quadratic programming with *small to moderate data sizes*, there exist various meanwhile standard algorithms. They are implemented in commercial software packages like CPLEX or MOSEK (see also the MATLAB optimization toolbox or in freeware packages like MINOS and LOQO). Among them, the *primal-dual interior point algorithms* belong to the most reliable and accurate techniques. The main idea of interior point methods is to solve the primal and dual problems simultaneously by enforcing the Kuhn-Tucker conditions to iteratively find a feasible solution. The duality gap, i.e., the difference between the minimum of the primal problem and the maximum of the dual problem, is used to determine the quality of the current set of variables and to check whether the stopping criteria are fulfilled. For QP algorithms including recent algorithms for solving large QPs, the reader may consult the new book of Zdenek [118].

The problem of learning *large data sets* was mainly addressed based on so-called “working set” methods. The idea is the following: if one knew in advance which constraints were active, it would be possible to cancel all of the inactive constraints which simplifies the problem.

The simplest method in this direction is known as *chunking*. It starts with an arbitrary subset (“chunk” = working set) of the data and trains the SVM using an optimizer on this subset. The algorithm then keeps the support vectors and deletes the others. Next, the M points (M algorithm parameter) from the remaining part of the data, where the “current SVM” makes the largest errors, are added to these support vectors to form a new chunk. This procedure is iterated. In general, the working set grows until in the last iteration the machine is trained on the set of support vectors representing the active constraints. Chunking techniques in SVMs were already used by Vapnik [106] and were improved and generalized in various papers.

Currently, more advanced “working set” methods, namely, *decomposition algorithms*, are one of the major tools to train SVMs. These methods select in each iteration a small *fixed size* subset of variables as working set, and a QP problem is solved with respect to this set (see, e.g., Osuna et al. [77]). A special type of decomposition methods is the *sequential minimal optimization* (SMO) which uses only *working sets of two variables*. This method was introduced by Platt [80] for classification; see Flake and Lawrence [42] for regression. The main advantage of these extreme small working sets is that the partial QP problems can be solved analytically. For the soft margin SVM in the dual form from Sect. 3 (with a variable exchange $\alpha \mapsto \mathbf{Y}\alpha$)

$$\frac{1}{2} \alpha^T \mathbf{K} \alpha - \langle \mathbf{y}, \alpha \rangle \quad \text{subject to} \quad \langle \mathbf{1}_m, \alpha \rangle = 0, \quad 0 \leq \mathbf{y}\alpha \leq \mathbf{C}.$$

the SMO algorithm looks as follows:

| SMO-type decomposition methods |
|---|
| 1. Fix $\alpha^{(1)}$ as initial feasible solution and set $k := 1$. |
| 2. If $\alpha^{(k)}$ solves the dual problem up to a desired precision, stop. Otherwise, select a working set $B := \{i, j\} \subset \{1, \dots, m\}$. Define $N := \{1, \dots, m\} \setminus B$ and $\alpha_B^{(k)}$ and $\alpha_N^{(k)}$ as sub-vectors of $\alpha^{(k)}$ corresponding to B and N , resp. |
| 3. Solve the following subproblem with fixed $\alpha_N^{(k)}$ for α_B : |
| $\frac{1}{2} \left(\alpha_B^T (\alpha_N^{(k)})^T \right) \begin{pmatrix} K_{BB} & K_{BN} \\ K_{NB} & K_{NN} \end{pmatrix} \begin{pmatrix} \alpha_B \\ \alpha_N^{(k)} \end{pmatrix} - (y_B^T y_N^T) \begin{pmatrix} \alpha_B \\ \alpha_N^{(k)} \end{pmatrix}$ $= \frac{1}{2} (\alpha_i \alpha_j) \begin{pmatrix} K_{ii} & K_{ij} \\ K_{ij} & K_{jj} \end{pmatrix} \begin{pmatrix} \alpha_i \\ \alpha_j \end{pmatrix} - (\alpha_i \alpha_j) (K_{BN} \alpha_N^{(k)} - y_B) + \text{constant} \rightarrow$ \min_{α_B} |
| subject to $\alpha_i + \alpha_j = -1_{m-2}^T \alpha_N^{(k)}$, $0 \leq y_i \alpha_i, y_j \alpha_j \leq C$. |
| Set $\alpha_B^{(k+1)}$ to be the minimizer. |
| 4. Set $\alpha_N^{(k+1)} := \alpha_N^{(k)}$, $k \mapsto k + 1$ and goto Step 2. |

The analytical solution in Step 3 is given as follows: for simplicity, set $\beta := -1_{m-2}^T \alpha_N^{(k)}$ and $(c_i c_j)^T := K_{BN} \alpha_N^{(k)} - y_B$. Substituting $\alpha_j = \beta - \alpha_i$ from the first constraint into the objective function, one gets

$$\frac{1}{2} \alpha_i^2 (K_{ii} - 2K_{ij} + K_{jj}) + \alpha_i (\beta K_{ij} - \beta K_{jj} - c_i + c_j) + \text{constant} \rightarrow \min_{\alpha_i}.$$

If \mathbf{K} is positive definite, it holds that $K_{ii} - 2K_{ij} + K_{jj} > 0$, and the above function has a unique finite global minimizer $\alpha_{i,g}$. One has to take care about the second constraint. This constraint requires that $\alpha_i \in [L, U]$, where L and U are defined by

$$(L, U) := \begin{cases} (\max(0, \beta - C), \min(C, \beta)) & \text{if } y_i = 1, y_j = 1, \\ (\max(0, \beta), \min(C, \beta + C)) & \text{if } y_i = 1, y_j = -1, \\ (\max(-C, \beta - C), \min(0, \beta)) & \text{if } y_i = -1, y_j = 1, \\ (\max(-C, \beta), \min(0, \beta + C)) & \text{if } y_i = -1, y_j = -1. \end{cases}$$

Hence the minimizer in Step 3 is given by $(\alpha_i^*, \beta - \alpha_i^*)$, where

$$\alpha_i := \begin{cases} \alpha_{ig} & \text{if } \alpha_{ig} \in [L, U], \\ L & \text{if } \alpha_{ig} < L, \\ U & \text{if } \alpha_{ig} > U. \end{cases}$$

It remains to determine the *selection of the working set*. (The determination of the stopping criteria is beyond the scope of this paper.) Indeed, current decomposition methods vary mainly according to different working set selections. The SVM^{light} algorithm of Joachims [52], was originally based on a rule for the selection the working set of Zoutendijk [120]. Moreover, this algorithm uses a *shrinking* technique to speed up the computational time. Shrinking is based on the idea that if a variable $\alpha_i^{(k)}$ remains equal to zero or C for many iteration steps, then it will probably not change anymore. The variable can be removed from the optimization problem such that a more efficient overall optimization is obtained. Another shrinking implementation is used in the software package LIBSVM of Chang and Lin [22]. A modification of Joachims' algorithm for regression called "SVMTorch" was given by Collobert and Bengio [25]. An often addressed working set selection due to Keerthi et al. [55] is the so-called *maximal violating pair* strategy. A more general way of choosing the two-element working set, namely, by choosing a *constant factor violating pair*, was given, including a convergence proof, by Chen et al. [24]. For convergence results, see also the paper of Lin [65]. The *maximal violating pair* strategy relies on first-order (i.e., gradient) information of the objective function. Now for QP, second-order information directly relates to the decrease of the objective function. The paper of Fan et al. [38] proposes a promising working set selection based on second-order information.

For an overview of SVM solvers for large data sets, the reader may also consult the books of Huang et al. [50] and Bottou et al. [13] and the paper of Mangasarian and Musicant [69] with the references therein. An extensive list of SVM software including logistic loss functions and least squares loss functions can be found on the webpages www.kernel-machines.org and www.support-vector-machines.org.

6 Conclusion

The invention of SVMs in the 1990s led to an explosion of applications and theoretical results. This paper can only give a very basic introduction into the meanwhile classical techniques in this field. It is restricted to supervised learning although SVMs have also a large impact on semi- and unsupervised learning.

Some new developments are sketched as *multitask learning* where, in contrast to single-task learning, only limited work was involved until now and novel techniques taken from convex analysis come into the play.

An issue that is not addressed in this paper is the *robustness* of SVMs. There is some ongoing research on connections between stability, learning, and prediction of ERM methods (see, e.g., the papers of Elisseeff et al. [36] and Mukherjee et al. [74]).

Another field that has recently attained attention is the use of kernels as *diffusion kernels* on graphs (see Kondor and J. Lafferty [58] and also the book of Shawe-Taylor and Cristianini [88]).

Abstract

The use of total variation as a regularization term in imaging problems was motivated by its ability to recover the image discontinuities. This is on the basis of his numerous applications to denoising, optical flow, stereo imaging and 3D surface reconstruction, segmentation, or interpolation, to mention some of them. On one hand, we review here the main theoretical arguments that have been given to support this idea. On the other hand, we review the main numerical approaches to solve different models where total variation appears. We describe both the main iterative schemes and the global optimization methods based on the use of max-flow algorithms. Then we review the use of anisotropic total variation models to solve different geometric problems and its use in finding a convex formulation of some non-convex total variation problems. Finally we study the total variation formulation of image restoration.

1 Introduction

The total variation model in image processing was introduced in the context of image restoration [55] and image segmentation, related to the study of the Mumford–Shah segmentation functional [34]. Being more related to our purposes here, let us consider the case of image denoising and restoration.

We assume that the degradation of the image occurs during image acquisition and can be modeled by a linear and translation invariant blur and additive noise:

$$f = h * u + n, \quad (1)$$

where $u : \mathbb{R}^2 \rightarrow \mathbb{R}$ denotes the ideal undistorted image, $h : \mathbb{R}^2 \rightarrow \mathbb{R}$ is a blurring kernel, f is the observed image which is represented as a function $f : \mathbb{R}^2 \rightarrow \mathbb{R}$, and n is an additive white noise with zero mean and standard deviation σ . In practice, the noise can be considered as Gaussian.

A particular and important case contained in the above formulation is the denoising problem which corresponds to the case where $h = \delta$, so that Eq. (1) is written as

$$f = u + n, \quad (2)$$

where n is an additive Gaussian white noise of zero mean and variance σ^2 .

The problem of recovering u from f is ill-posed. Several methods have been proposed to recover u . Most of them can be classified as regularization methods

which may take into account statistical properties (Wiener filters), information theoretic properties [35], a priori geometric models [55], or the functional analytic behavior of the image given in terms of its wavelet coefficients (see [48] and references therein).

The typical strategy to solve this ill-conditioning is regularization [56]. In the linear case the solution of (1) is estimated by minimizing a functional

$$J_\gamma(u) = \| Hu - f \|_2^2 + \gamma \| Qu \|_2^2, \quad (3)$$

which yields the estimate

$$u_\gamma = (H^t H + \gamma Q^t Q)^{-1} H^t f, \quad (4)$$

where $Hu = h * u$, and Q is a regularization operator. Observe that to obtain u_γ we have to solve a system of linear equations. The role of Q is, on one hand, to move the small eigenvalues of H away from zero while leaving the large eigenvalues unchanged, and, on the other hand, to incorporate the a priori (smoothness) knowledge that we have on u .

If we treat u and n as random vectors and we select $\gamma = 1$ and $Q = R_s^{-1/2} R_n^{1/2}$ with R_s and R_n the image and noise covariance matrices, then (4) corresponds to the Wiener filter that minimizes the mean square error between the original and restored images.

One of the first regularization methods consisted in choosing between all possible solutions of (1) the one which minimized the Sobolev (semi) norm of u

$$\int_{\mathbb{R}^2} |Du|^2 dx, \quad (5)$$

which corresponds to the case $Qu = Du$. In the Fourier domain the solution of (3) given by (4) is $\hat{u} = \frac{\hat{h}}{|\hat{h}|^2 + 4\gamma\pi^2|\xi|^2} \hat{f}$. From the above formula we see that high frequencies of f (hence, the noise) are attenuated by the smoothness constraint.

This formulation was an important step, but the results were not satisfactory, mainly due to the inability of the previous functional to resolve discontinuities (edges) and oscillatory textured patterns. The smoothness required by the finiteness of the Dirichlet integral (5) constraint is too restrictive. Indeed, functions in $W^{1,2}(\mathbb{R}^2)$ (i.e., functions $u \in L^2(\mathbb{R}^2)$ such that $Du \in L^2(\mathbb{R}^2)$) cannot have discontinuities along rectifiable curves. These observations motivated the introduction of Total Variation in image restoration problems by L. Rudin, S. Osher, and E. Fatemi in their work [55]. The a priori hypothesis is that functions of bounded variation (the *BV* model) [9] are a reasonable functional model for many problems in image processing, in particular, for restoration problems [55]. Typically, functions of bounded variation have discontinuities along rectifiable curves, being continuous in some sense (in the measure theoretic sense) away from discontinuities [9]. The discontinuities could be identified with edges. The ability of total variation regularization

to recover edges is one of the main features which advocates for the use of this model, but its ability to describe textures is less clear, even if some textures can be recovered, up to a certain scale of oscillation. An interesting experimental discussion of the adequacy of the BV -model to describe real images can be found in [41].

In order to work with images, we assume that they are defined in a bounded domain $\Omega \subseteq \mathbb{R}^2$ which we assume to be the interval $[0, N]^2$. As in most of the works, in order to simplify this problem, we shall assume that the functions h and u are periodic of period N in each direction. That amounts to neglecting some boundary effects. Therefore, we shall assume that h, u are functions defined in Ω and, to fix ideas, we assume that $h, u \in L^2(\Omega)$. Our problem is to recover as much as possible of u , from our knowledge of the blurring kernel h , the statistics of the noise n , and the observed image f .

On the basis of the BV model, Rudin–Osher–Fatemi [55] proposed to solve the following constrained minimization problem:

$$\begin{aligned} & \text{Minimize} \quad \int_{\Omega} |Du| \\ & \text{subject to} \quad \int_{\Omega} |h * u(x) - f(x)|^2 dx \leq \sigma^2 |\Omega|. \end{aligned} \tag{6}$$

Notice that the image acquisition model (1) is only incorporated through a global constraint. Assuming that $h * 1 = 1$ (energy preservation), the additional constraint that $\int_{\Omega} h * u dx = \int_{\Omega} f(x)$ is automatically satisfied by its minima [28]. In practice, the above problem is solved via the following unconstrained minimization problem:

$$\text{Minimize} \quad \int_{\Omega} |Du| + \frac{1}{2\lambda} \int_{\Omega} |h * u - f|^2 dx \tag{7}$$

where the parameter λ is positive. Recall that we may interpret λ as a penalization parameter which controls the trade-off between the goodness of fit of the constraint and the smoothness term given by the Total Variation. In this formulation, a methodology is required for a correct choice of λ . The connections between (6) and (7) were studied by A. Chambolle and P.L. Lions in [28] where they proved that both problems are equivalent for some positive value of the Lagrange multiplier λ .

In the denoising case, the unconstrained variational formulation (7) with $h = \delta$ is

$$\text{Minimize} \quad \int_{\Omega} |Du| + \frac{1}{2\lambda} \int_{\Omega} |u - f|^2 dx, \tag{8}$$

and it has been the object of much theoretical and numerical research (see [10, 56] for a survey). Even if this model represented a theoretical and practical progress in the denoising problem due to the introduction of BV functions as image models, the experimental analysis readily showed its main drawbacks. Between them, let us mention the staircasing effect (when denoising a smooth ramp plus noise, the staircase is an admissible result), the pixelization of the image at smooth regions,

and the loss of fine textured regions, to mention some of them. This can be summarized with the simple observation that the residuals $f - u$, where u represents the solution of (8), do not look like noise. This has motivated the development of nonlocal filters [17] for denoising, the use of a stochastic optimization technique to estimate u [47], or the consideration of the image acquisition model as a set of local constraints [3, 38] to be discussed below.

Let us finally mention that, following the analysis of Y. Meyer in [48], the solution u of (8) permits to obtain a decomposition of the data f as a sum of two components $u + v$ where u contains the geometric sketch of f while v is supposed to contain its noise and textured parts. As Meyer observed, the L^2 norm of the residual $v := f - u$ in (8) is not the right one to obtain a decomposition of f in terms of geometry plus texture and he proposed to measure the size of the textured part v in terms of a dual BV norm showing that some models of texture have indeed a small dual BV norm.

In spite of its limitations, the total variation model has become one of the basic image models and has been adapted to many tasks: optical flow, stereo imaging and 3D surface reconstruction, segmentation, interpolation, or the study of $u + v$ models to mention a few cases. On the other hand, when compared to other robust regularization terms, it combines simplicity and geometric character and makes it possible a rigorous analysis. The theoretical analysis of the behavior of solutions of (8) has been the object of several works [6, 13, 14, 20, 48, 50] and will be summarized in Sects. 3 and 4.

Recall that one of the main reasons to introduce the Total Variation as a regularization term in imaging problems was its ability to recover discontinuities in the solution. This intuition has been confirmed by the experimental evidence and has been the motivation for the study of the local regularity properties of (8) in [20, 23]. After recalling in Sect. 2 some basic notions and results in the theory of bounded variation functions, we prove in section “The Discontinuities of Solutions of the TV Denoising Problem” that the set of jumps (in the BV sense) of the solution of (8) is contained in the set of jumps of the datum f [20]. In other words, model (8) does not create any new discontinuity besides the existing ones. As a refinement of the above statement, the local Hölder regularity of the solutions of (8) is studied in section “Hölder Regularity Results.” This has to be combined with results describing which discontinuities are preserved. No general statement in this sense exists, but many examples are described in the papers [5, 10, 13, 14]. The preservation of a jump discontinuity depends on the curvature of the level line at the given point, the size of the jump, and the regularization parameter λ . This is illustrated in the example given in Sect. 4. The examples support the idea that total variation is not perfect but may be a reasonable regularization term in order to restore discontinuities.

Being considered as a basic model, the numerical analysis of the total variation model has been the object of intensive research. Many numerical approaches have been proposed in order to give fast, efficient methods which are also versatile to cover the whole range of applications. In Sect. 5 we review some basic iterative methods introduced to solve the Euler–Lagrange equations of (8). In particular, we review in section “Chambolle’s Algorithm” the dual approach introduced by A.

Chambolle in [25]. In section “Primal-Dual Approaches” we review the primal-dual scheme of Zhu and Chan [57]. Both of them are between the most popular schemes by now. In Sect. 6 we discuss global optimization methods based on graph-cut techniques adapted to solve a quantized version of (8). Those methods have also become very popular due to its efficiency and versatility in applications and are an active area of research, as it can be seen in the references. Then, in section “Global Solutions of Geometric Problems” we review the applications of anisotropic TV problems to find the global solution of geometric problems. Similar anisotropic TV formulations appear as convexifications of nonlinear energies for disparity computation in stereo imaging, or related problems [30, 52], and they are reviewed in section “A Convex Formulation of Continuous Multilabel Problems.”

In Sect. 8 we review the application of Total Variation in image restoration (6), describing the approach where the image acquisition model is introduced as a set of local constraints [3, 38, 54].

We could not close this chapter without reviewing in Sect. 9 a recent algorithm introduced by C. Louchet and L. Moisan [47] which uses a Bayesian approach leading to an estimate of u as the expected value of the posterior distribution of u given the data f . This estimate requires to compute an integral in a high dimensional space and the authors use a Monte-Carlo method with Markov Chain (MCMC) [47]. In this context, the minimization of the discrete version of (8) corresponds to a Maximum a Posterior (MAP) estimate of u .

2 Notation and Preliminaries on BV Functions

Definition and Basic Properties

Let Ω be an open subset of \mathbb{R}^N . Let $u \in L_{\text{loc}}^1(\Omega)$. Recall that the distributional gradient of u is defined by

$$\int_{\Omega} \sigma \cdot Du = - \int_{\Omega} u(x) \operatorname{div} \sigma(x) dx \quad \forall C_c^{\infty}(\Omega, \mathbb{R}^N),$$

where $C_c^{\infty}(\Omega; \mathbb{R}^N)$ denotes the vector fields with values in \mathbb{R}^N which are infinitely differentiable and have compact support in Ω . The total variation of u in Ω is defined by

$$V(u, \Omega) := \sup \left\{ \int_{\Omega} u \operatorname{div} \sigma dx : \sigma \in C_c^{\infty}(\Omega; \mathbb{R}^N), |\sigma(x)| \leq 1 \quad \forall x \in \Omega \right\}, \quad (9)$$

where for a vector $v = (v_1, \dots, v_N) \in \mathbb{R}^N$ we set $|v|^2 := \sum_{i=1}^N v_i^2$. Following the usual notation, we will denote $V(u, \Omega)$ by $|Du|(\Omega)$ or by $\int_{\Omega} |Du|$.

Definition 1. Let $u \in L^1(\Omega)$. We say that u is a function of bounded variation in Ω if $V(u, \Omega) < \infty$. The vector space of functions of bounded variation in Ω will be denoted by $\text{BV}(\Omega)$.

Using Riesz representation Theorem [9], the above definition can be rephrased by saying that u is a function of bounded variation in Ω if the gradient Du in the sense of distributions is a (vector valued) Radon measure with finite total variation $V(u, \Omega)$.

Recall that $\text{BV}(\Omega)$ is a Banach space when endowed with the norm $\|u\| := \int_{\Omega} |u| dx + |Du|(\Omega)$. Recall also that the map $u \rightarrow |Du|(\Omega)$ is $L^1_{\text{loc}}(\Omega)$ -lower semicontinuous, as a sup (9) of continuous linear forms [9].

Sets of Finite Perimeter: The Co-area Formula

Definition 2. A measurable set $E \subseteq \Omega$ is said to be of finite perimeter in Ω if $\chi_E \in \text{BV}(\Omega)$. The perimeter of E in Ω is defined as $P(E, \Omega) := |D\chi_E|(\Omega)$. If $\Omega = \mathbb{R}^N$, we denote the perimeter of E in \mathbb{R}^N by $P(E)$.

The following inequality holds for any two sets $A, B \subseteq \Omega$:

$$P(A \cup B, \Omega) + P(A \cap B, \Omega) \leq P(A, \Omega) + P(B, \Omega). \quad (10)$$

Theorem 1. Let $u \in \text{BV}(\Omega)$. Then for a.e. $t \in \mathbb{R}$ the set $\{u > t\}$ is of finite perimeter in Ω and one has

$$\int_{\Omega} |Du| = \int_{-\infty}^{\infty} P(\{u > t\}, \Omega) dt.$$

In other words, the total variation of u amounts to the sum of the perimeters of its upper level sets.

An analogous formula with the lower level sets is also true. For a proof we refer to [9].

The Structure of the Derivative of a BV Function

Let us denote by \mathcal{L}^N and \mathcal{H}^{N-1} , respectively, the N -dimensional Lebesgue measure and the $(N - 1)$ -dimensional Hausdorff measure in \mathbb{R}^N (see [9] for precise definitions).

Let $u \in [L^1_{\text{loc}}(\Omega)]^m$ ($m \geq 1$). We say that u has an approximate limit at $x \in \Omega$ if there exists $\xi \in \mathbb{R}^m$ such that

$$\lim_{\rho \downarrow 0} \frac{1}{|B(x, \rho)|} \int_{B(x, \rho)} |u(y) - \xi| dy = 0. \quad (11)$$

The set of points where this does not hold is called the approximate discontinuity set of u , and is denoted by S_u . Using Lebesgue's differentiation theorem, one can show that the approximate limit $\tilde{\xi}$ exists at \mathcal{L}^N -a.e. $x \in \Omega$, and is equal to $u(x)$, in particular, $|S_u| = 0$. If $x \in \Omega \setminus S_u$, the vector $\tilde{\xi}$ is uniquely determined by (11) and we denote it by $\tilde{u}(x)$.

We say that u is approximately continuous at x if $x \notin S_u$ and $\tilde{u}(x) = u(x)$, that is, if x is a Lebesgue point of u (with respect to the Lebesgue measure).

Let $u \in [L_{\text{loc}}^1(\Omega)]^m$ and $x \in \Omega \setminus S_u$; we say that u is approximately differentiable at x if there exists an $m \times N$ matrix L such that

$$\lim_{\rho \downarrow 0} \frac{1}{|B(x, \rho)|} \int_{B(x, \rho)} \frac{|u(y) - \tilde{u}(x) - L(y - x)|}{\rho} dy = 0. \quad (12)$$

In that case, the matrix L is uniquely determined by (12) and is called the approximate differential of u at x .

For $u \in \text{BV}(\Omega)$, the gradient Du is a N -dimensional Radon measure that decomposes into its absolutely continuous and singular parts $Du = D^a u + D^s u$. Then $D^a u = \nabla u dx$ where ∇u is the Radon–Nikodym derivative of the measure Du with respect to the Lebesgue measure in \mathbb{R}^N . The function u is approximately differentiable \mathcal{L}^N -a.e. in Ω and the approximate differential coincides with $\nabla u(x)$ \mathcal{L}^N -a.e. The singular part $D^s u$ can be also split into two parts: the *jump* part $D^j u$ and the *Cantor* part $D^c u$.

We say that $x \in \Omega$ is an *approximate jump point* of u if there exist $u^+(x) \neq u^-(x) \in \mathbb{R}$ and $|v_u(x)| = 1$ such that

$$\lim_{\rho \downarrow 0} \frac{1}{|B_\rho^+(x, v_u(x))|} \int_{B_\rho^+(x, v_u(x))} |u(y) - u^+(x)| dy = 0$$

$$\lim_{\rho \downarrow 0} \frac{1}{|B_\rho^-(x, v_u(x))|} \int_{B_\rho^-(x, v_u(x))} |u(y) - u^-(x)| dy = 0,$$

where $B_\rho^+(x, v_u(x)) = \{y \in B(x, \rho) : \langle y - x, v_u(x) \rangle > 0\}$ and $B_\rho^-(x, v_u(x)) = \{y \in B(x, \rho) : \langle y - x, v_u(x) \rangle < 0\}$. We denote by J_u the set of approximate jump points of u . If $u \in \text{BV}(\Omega)$, the set S_u is countably \mathcal{H}^{N-1} rectifiable, J_u is a Borel subset of S_u , and $\mathcal{H}^{N-1}(S_u \setminus J_u) = 0$ [9]. In particular, we have that \mathcal{H}^{N-1} -a.e. $x \in \Omega$ is either a point of approximate continuity of \tilde{u} or a jump point with two limits in the above sense. Finally, we have

$$D^j u = D^s u|_{J_u} = (u^+ - u^-)v_u \mathcal{H}^{N-1}|_{J_u} \quad \text{and} \quad D^c u = D^s u|_{(\Omega \setminus S_u)}.$$

For a comprehensive treatment of functions of bounded variation we refer to [9].

3 The Regularity of Solutions of the TV Denoising Problem

The Discontinuities of Solutions of the TV Denoising Problem

Given a function $f \in L^2(\Omega)$ and $\lambda > 0$ we consider the minimum problem

$$\min_{u \in BV(\Omega)} \int_{\Omega} |Du| + \frac{1}{2\lambda} \int_{\Omega} (u - f)^2 dx. \quad (13)$$

Notice that problem (13) always admits a unique solution u_λ , since the energy functional is strictly convex.

As we mentioned in Sect. 1, one of the main reasons to introduce the Total Variation as a regularization term in imaging problems was its ability to recover the discontinuities in the solution. This section together with section ‘‘Hölder Regularity Results’’ and Sect. 4 is devoted to analyze this assertion. In this section we prove that the set of jumps of u_λ (in the BV sense) is contained in the set of jumps of f , whenever f has bounded variation. Thus, model (13) does not create any new discontinuity besides the existing ones. Section ‘‘Hölder Regularity Results’’ is devoted to review a local Hölder regularity result of [23]: the local Hölder regularity of the data is inherited by the solution. This has to be combined with results describing which discontinuities are preserved. In Sect. 4 we give an example of explicit solution of (13) which shows that the preservation of a jump discontinuity depends on the curvature of the level line at the given point, the size of the jump, and the regularization parameter λ . Other examples are given in the papers [2, 5, 10, 13, 14]. The examples support the idea that total variation may be a reasonable regularization term in order to restore discontinuities.

Let us recall the following observation, which is proved in [5, 18, 24].

Proposition 1. *Let u_λ be the (unique) solution of (13). Then, for any $t \in \mathbb{R}$, $\{u_\lambda > t\}$ (respectively, $\{u_\lambda \geq t\}$) is the minimal (resp., maximal) solution of the minimal surface problem*

$$\min_{E \subseteq \Omega} P(E, \Omega) + \frac{1}{\lambda} \int_E (t - f(x)) dx \quad (14)$$

(whose solution is defined in the class of finite-perimeter sets, hence up to a Lebesgue-negligible set). In particular, for all $t \in \mathbb{R}$ but a countable set, $\{u_\lambda = t\}$ has zero measure and the solution of (14) is unique up to a negligible set.

A proof that $\{u_\lambda > t\}$ and $\{u_\lambda \geq t\}$ both solve (14) is found in [24, Prop. 2.2]. A complete proof of this proposition, which we do not give here, follows from the co-area formula, which shows that, up to a renormalization, for any $u \in BV(\Omega) \cap L^2(\Omega)$,

$$\int_{\Omega} |Du| + \frac{1}{2\lambda} \int_{\Omega} (u - f)^2 dx = \int_{\mathbb{R}} \left(P(\{u > t\}, \Omega) + \frac{1}{\lambda} \int_{\{u>t\}} (t - f) dx \right) dt,$$

and from the following comparison result for solutions of (14) which is proved in [5, Lemma 4]:

Lemma 1. *Let $f, g \in L^1(\Omega)$ and E and F be respectively minimizers of*

$$\min_E P(E, \Omega) - \int_E f(x) dx \text{ and } \min_F P(F, \Omega) - \int_F g(x) dx.$$

Then, if $f < g$ a.e., $|E \setminus F| = 0$ (in other words, $E \subseteq F$ up to a negligible set).

Proof. Observe that we have

$$P(E, \Omega) - \int_E f(x) dx \leq P(E \cap F, \Omega) - \int_{E \cap F} f(x) dx$$

$$P(F, \Omega) - \int_F g(x) dx \leq P(E \cup F, \Omega) - \int_{E \cup F} g(x) dx.$$

Adding both inequalities and using that for two sets of finite perimeter we have (10) $P(E \cap F, \Omega) + P(E \cup F, \Omega) \leq P(E, \Omega) + P(F, \Omega)$, we obtain that

$$\int_{E \setminus F} (g(x) - f(x)) dx \leq 0.$$

Since $g(x) - f(x) > 0$ a.e., this implies that $E \setminus F$ is a null set. \square

The proof of this last lemma is easily generalized to other situations (Dirichlet boundary conditions, anisotropic and/or nonlocal perimeters; see [5] and also [2] for a similar general statement). Eventually, we mention that the result of Proposition 1 remains true if the term $(u(x) - f(x))^2 / (2\lambda)$ in (13) is replaced with a term of the form $\Psi(x, u(x))$, with Ψ of class C^1 and strictly convex in the second variable, and replacing $(t - f(x))/\lambda$ with $\partial_u \Psi(x, t)$ in (14).

From Proposition 1 and the regularity theory for surfaces of prescribed curvature (see for instance [8]), we obtain the following regularity result (see also [2]).

Corollary 1. *Let $f \in L^p(\Omega)$, with $p > N$. Then, for all $t \in \mathbb{R}$ the super-level set $E_t := \{u_\lambda > t\}$ (respectively, $\{u_\lambda \geq t\}$) has boundary of class $C^{1,\alpha}$, for all $\alpha < (p - N)/p$, out of a closed singular set Σ of Hausdorff dimension at most $N - 8$. Moreover, if $p = \infty$, the boundary of E_t is of class $W^{2,q}$ out of Σ , for all $q < \infty$, and is of class $C^{1,1}$ if $N = 2$.*

We now show that the jump set of u_λ is always contained in the jump set of f . Before stating this result let us recall two simple lemmas.

Lemma 2. *Let U be an open set in \mathbb{R}^N and $v \in W^{2,p}(U)$, $p \geq 1$. We have that*

$$\operatorname{div} \left(\frac{\nabla v}{\sqrt{1 + |\nabla v|^2}} \right) (y) = \operatorname{Trace} (A(\nabla v(y)) D^2 v(y)) \quad \text{a.e. in } U,$$

where $A(\xi) = \frac{1}{(1+|\xi|^2)^{\frac{1}{2}}} \left(\delta_{ij} - \frac{\xi_i \xi_j}{(1+|\xi|^2)} \right)_{i,j=1}^N$, $\xi \in \mathbb{R}^N$.

The proof follows simply by taking $\varphi \in C_0^\infty(U)$, integrating by parts in U , and regularizing v with a smoothing kernel.

Lemma 3. *Let U be an open set in \mathbb{R}^N and $v \in W^{2,1}(U)$. Assume that u has a minimum at $y_0 \in U$ and*

$$\begin{aligned} & \lim_{\rho \rightarrow 0^+} \frac{1}{B_\rho(y_0)} \\ & \int_{B_\rho(y_0)} \frac{|u(y) - u(y_0) - \nabla u(y_0) \cdot (y - y_0) - \frac{1}{2} \langle D^2 v(y_0)(y - y_0), y - y_0 \rangle|}{\rho^2} dy = 0. \end{aligned} \tag{15}$$

Then $D^2 v(y_0) \geq 0$.

If A is a symmetric matrix and we write $A \geq 0$ (respectively, $A \leq 0$) we mean that A is positive (resp., negative) semidefinite.

The result follows by proving that \mathcal{H}^{N-1} -a.e. for ξ in S^{N-1} (the unit sphere in \mathbb{R}^N) we have $\langle D^2 v(y_0)\xi, \xi \rangle \geq 0$.

Recall that if $v \in W^{2,1}(U)$, then (15) holds a.e. on U [58, Theorem 3.4.2].

Theorem 2. *Let $f \in \operatorname{BV}(\Omega) \cap L^\infty(\Omega)$. Then, for all $\lambda > 0$,*

$$J_{u_\lambda} \subseteq J_f \tag{16}$$

(up to a set of zero \mathcal{H}^{N-1} -measure).

Before giving the proof let us explain its main idea which is quite simple. Notice that, by (14), formally the Euler–Lagrange equation satisfied by ∂E_t is

$$\kappa_{E_t} + \frac{1}{\lambda}(t - f) = 0 \quad \text{on } \partial E_t,$$

where κ_{E_t} is the sum of the principal curvatures at the points of ∂E_t . Thus if $x \in J_{u_\lambda} \setminus J_f$, then we may find two values $t_1 < t_2$ such that $x \in \partial E_{t_1} \cap \partial E_{t_2} \setminus J_f$. Notice that $E_{t_2} \subseteq E_{t_1}$ and the boundaries of both sets have a contact at x . Of the two, the smallest level set is the highest and has smaller mean curvature. This contradicts its contact at x .

Proof. Let us first recall some consequences of Corollary 1. Let $E_t := \{u_\lambda > t\}$, $t \in \mathbb{R}$, and let Σ_t be its singular set given by Corollary 1. Since $f \in L^\infty(\Omega)$, around each point $x \in \partial E_t \setminus \Sigma_t$, $t \in \mathbb{R}$, ∂E_t is locally the graph of a function in $W^{2,p}$ for all $p \in [1, \infty)$ (hence $C^{1,\alpha}$ for any $\alpha \in (0, 1)$). Moreover, if $\mathcal{N} := \bigcup_{t \in \mathbb{Q}} \Sigma_t$, then $\mathcal{H}^{N-1}(\mathcal{N}) = 0$.

Let us prove that $\mathcal{H}^{N-1}(J_{u_\lambda} \setminus J_f) = 0$. Observe that we may write [9]

$$J_{u_\lambda} = \bigcup_{t_1, t_2 \in \mathbb{Q}, t_1 < t_2} \partial E_{t_1} \cap \partial E_{t_2}.$$

Thus it suffices to prove that for all $t_1, t_2 \in \mathbb{Q}$, $t_1 < t_2$, we have

$$\mathcal{H}^{N-1}(\partial E_{t_1} \cap \partial E_{t_2} \setminus (\mathcal{N} \cup J_f)) = 0. \quad (17)$$

Let us denote by B'_R the ball of radius $R > 0$ in \mathbb{R}^{N-1} centered at 0. Let $C_R := B'_R \times (-R, R)$. Let us fix $t_1, t_2 \in \mathbb{Q}$, $t_1 < t_2$. Given $x \in \partial E_{t_1} \cap \partial E_{t_2} \setminus \mathcal{N}$, by Corollary 1, we know that there is some $R > 0$ such that, after a change of coordinates that aligns the x_N -axis with the normal to $\partial E_{t_1} \cap \partial E_{t_2}$ at x , we may write the set $\partial E_{t_i} \cap C_R$ as the graph of a function $v_i \in W^{2,p}(B'_R)$, $\forall p \in [1, \infty)$, $x = (0, v_i(0)) \in C_R \subseteq \Omega$, $\nabla v_i(0) = 0$, $i \in \{1, 2\}$. Without loss of generality, we assume that $v_i > 0$ in B'_R , and that E_{t_i} is the supergraph of v_i , $i = 1, 2$. From $t_1 < t_2$ and Lemma 1, it follows $E_{t_2} \subseteq E_{t_1}$, which gives in turn $v_2 \geq v_1$ in B'_R .

Notice that, since ∂E_{t_i} is of finite \mathcal{H}^{N-1} measure, we may cover $\partial E_{t_1} \cap \partial E_{t_2} \setminus \mathcal{N}$ by a countable set of such cylinders. Thus, it suffices to prove that

$$\mathcal{H}^{N-1}((\partial E_{t_1} \cap \partial E_{t_2} \cap C_R) \setminus (\mathcal{N} \cup J_f)) = 0. \quad (18)$$

holds for any such cylinder C_R as constructed in the last paragraph.

Let us denote the points $x \in C_R$ as $x = (y, z) \in B'_R \times (-R, R)$. Then (18) will follow if we prove that

$$\mathcal{H}^{N-1}(\mathcal{M}_R) = 0, \quad (19)$$

where

$$\mathcal{M}_R := \{y \in B'_R : v_1(y) = v_2(y)\} \setminus \{y \in B'_R : (y, v_1(y)) \in J_f\}.$$

Recall that, by Theorem 3.108 in [9], \mathcal{H}^{N-1} -a.e. in $y \in B'_R$, the function $f(y, \cdot) \in \text{BV}((-R, R))$ and the jumps of $f(y, \cdot)$ are the points z such that

$(y, z) \in J_f$. Recall that v_i is a local minimizer of

$$\min_v \mathcal{E}_i(v) := \int_{B'_R} \sqrt{1 + |\nabla v|^2} dy - \frac{1}{\lambda} \int_{B'_R} \int_0^{v(y)} (t_i - f(y, z)) dz dy.$$

By taking a positive smooth test function $\psi(y)$ of compact support in B'_R , and computing $\lim_{\epsilon \rightarrow 0+} \frac{1}{\epsilon} (\mathcal{E}_i(v + \epsilon \psi) - \mathcal{E}_i(v)) \geq 0$, we deduce that

$$\operatorname{div} \frac{\nabla v_i(y)}{\sqrt{1 + |\nabla v_i(y)|^2}} + \frac{1}{\lambda} (t_i - f(y, v_i(y)) + 0) \leq 0, \quad \mathcal{H}^{N-1}\text{-a.e. in } B'_R. \quad (20)$$

In a similar way, we have

$$\operatorname{div} \frac{\nabla v_i(y)}{\sqrt{1 + |\nabla v_i(y)|^2}} + \frac{1}{\lambda} (t_i - f(y, v_i(y)) - 0) \geq 0, \quad \mathcal{H}^{N-1}\text{-a.e. in } B'_R. \quad (21)$$

Finally we observe that since $v_1, v_2 \in W^{2,p}(B'_R)$ for any $p \in [1, \infty)$ and $v_2 \geq v_1$ in B'_R , by Lemma 3 we have that $D^2(v_1 - v_2)(y) \leq 0$ \mathcal{H}^{N-1} -a.e. on $\{y \in B'_R : v_1(y) = v_2(y)\}$.

Thus, if $\mathcal{H}^{N-1}(\mathcal{M}_R) > 0$, then there is a point $\bar{y} \in \mathcal{M}_R$ such that $\nabla v_1(\bar{y}) = \nabla v_2(\bar{y})$, $D^2(v_1 - v_2)(\bar{y}) \leq 0$, $f(\bar{y}, \cdot)$ is continuous at $v_1(\bar{y}) = v_2(\bar{y})$, and both Eqs. (20) and (21) hold at \bar{y} . As a consequence, using Lemma 2 and subtracting the two equations, we obtain

$$0 \geq \operatorname{trace}(A(\nabla v_1(\bar{y})) D^2 v_1(\bar{y})) - \operatorname{trace}(A(\nabla v_2(\bar{y})) D^2 v_2(\bar{y})) = \frac{t_2 - t_1}{\lambda} > 0,$$

This contradiction proves (19). \square

Hölder Regularity Results

Let us review the local regularity result proved in [23]: if the datum f is locally Hölder continuous with exponent $\beta \in [0, 1]$ in some region $\Omega' \subset \Omega$, then a local minimizer u of (13) is also locally Hölder continuous in Ω' with the same exponent.

Recall that a function $u \in \operatorname{BV}(\Omega)$ is a local minimizer of (13) if for any $v \in \operatorname{BV}(\Omega)$ such that $u - v$ has support in a compact subset $K \subset \Omega$, we have

$$\int_K |Du| + \frac{1}{2} \int_K |u(x) - f(x)|^2 dx \leq \int_K |Dv| + \frac{1}{2} \int_K |v(x) - f(x)|^2 dx \quad (22)$$

It follows that u satisfies the equation [18]

$$-\operatorname{div} z + u = f \quad (23)$$

with $z \in L^\infty(\Omega, \mathbb{R}^N)$ with $\|z\|_\infty \leq 1$, and $z \cdot Du = |Du|$ [10].

As in section “The Discontinuities of Solutions of the TV Denoising Problem” [20], the analysis of the regularity of the local minimizers of u is based on the following observation: for any $t \in \mathbb{R}$, the level sets $\{u > t\}$ (resp., $\{u \geq t\}$) are solutions (the minimal and maximal, indeed) of the prescribed curvature problem (14) which is defined in the class of finite-perimeter sets and hence up to a Lebesgue-negligible set. The local regularity of u can be described in terms of the distance of any two of its level sets. This is the main idea in [20] which can be refined to obtain the Hölder regularity of solutions of (14). As we argued in section “The Discontinuities of Solutions of the TV Denoising Problem,” outside the jump discontinuities of f (modulo an \mathcal{H}^{N-1} -null set), any two level sets at different heights cannot touch and hence the function u is continuous there. To be able to assert a Hölder type regularity property for u one needs to prove a local estimate of the distance of the boundaries of two level sets. This can be done here under the assumption of local Hölder regularity for f [23].

Theorem 3. *Let $N \leq 7$ and let u be a solution of (23). Assume that f is in $C^{0,\beta}$ locally in some open set $A \subseteq \Omega$, for some $\beta \in [0, 1]$. Then u is also $C^{0,\beta}$ locally in A .*

The Lipschitz case corresponds to $\beta = 1$.

One can also state a global regularity result for solutions of the Neumann problem when $\Omega \subset \mathbb{R}^N$ is a convex domain. Let $f : \overline{\Omega} \rightarrow \mathbb{R}$ be a uniformly continuous function, with modulus of continuity $\omega_f : [0, +\infty) \rightarrow [0, +\infty)$, that is, $|f(x) - f(y)| \leq \omega_f(|x - y|)$ for all $x, y \in \Omega$. We consider the solution u of (23) with homogeneous Neumann boundary condition, that is, such that (22) for any compact set $K \subset \overline{\Omega}$ and any $v \in \text{BV}(\Omega)$ such that $v = u$ out of K . This solution is unique, as can be shown adapting the proof of [18, Cor. C.2.] (see also [10] for the required adaptations to deal with the boundary condition), which deals with the case $\Omega = \mathbb{R}^N$.

Then, the following result holds true [23]:

Theorem 4. *Assume $N \leq 7$. Then, the function u is uniformly continuous in Ω , with modulus $\omega_u \leq \omega_f$.*

Again, it is quite likely here that the assumption $N \leq 7$ is not necessary for this result.

4 Some Explicit Solutions

Recall that a convex body in \mathbb{R}^N is a compact convex subset of \mathbb{R}^N . We say that a convex body is nontrivial if it has nonempty interior.

We want to exhibit the explicit solution of (13) when $f = \chi_C$ and C is a nontrivial convex body in \mathbb{R}^N . This will show that the preservation of a jump

discontinuity depends on the curvature of ∂C at the given point, the size of the jump, and the regularization parameter λ .

Let $u_{\lambda,C}$ be the unique solution of the problem:

$$\min_{u \in \text{BV}(\mathbb{R}^N)} \int_{\mathbb{R}^N} |Du| + \frac{1}{2\lambda} \int_{\mathbb{R}^N} (u - \chi_C)^2 dx. \quad (24)$$

The following result was proved in [5].

Proposition 2. *We have that $0 \leq u_{\lambda,C} \leq 1$, $u_{\lambda,C} = 0$ in $\mathbb{R}^N \setminus C$, and $u_{\lambda,C}$ is concave in $\{u_{\lambda,C} > 0\}$.*

The proof of $0 \leq u_{\lambda,C} \leq 1$ follows from a weak version of the maximum principle [5]. Thanks to the convexity of C , by comparison with the characteristic function of hyperplanes, one can show that $u_{\lambda,C} = 0$ out of C [5]. To prove that $u_{\lambda,C}$ is concave in $\{u_{\lambda,C} > 0\}$ one considers first the case where C is of class $C^{1,1}$ and $\lambda > 0$ is small enough. Then one proves that $u_{\lambda,C}$ is concave by approximating $u_{\lambda,C}$ by the solution u_ϵ of

$$\begin{aligned} u - \lambda \operatorname{div} \left(\frac{\nabla u}{\sqrt{\epsilon^2 + |\nabla u|^2}} \right) &\quad \text{in } C \\ \frac{\nabla u}{\sqrt{\epsilon^2 + |\nabla u|^2}} \cdot v^C &= 0 \quad \text{in } \partial C, \end{aligned} \quad (25)$$

as $\epsilon \rightarrow 0+$, using Korevaar's concavity Theorem [46]. Then one considers the case where C is of class $C^{1,1}$ and we take any $\lambda > 0$. In this case, the concavity of $u_{\lambda,C}$ in $\{u_{\lambda,C} > 0\}$ is derived after proving Theorems 5 and 6 below. The final step proceeds by approximating a general convex body C by convex bodies of class $C^{1,1}$ [4].

Moreover, since $u_{\lambda,C} = 0$ out of C , the upper level set $\{u_{\lambda,C} > s\} \subseteq C$ for any $s \in (0, 1]$. Then, as in Proposition 1, one can prove that for any $s \in (0, 1]$ the level set $\{u_{\lambda,C} > s\}$ is a solution of

$$(P)_\mu \quad \min_{E \subseteq C} P(E) - \mu|E|. \quad (26)$$

for the value of $\mu = \lambda^{-1}(1-s)$. When taking $\lambda \in (0, +\infty)$ and $s \in (0, 1]$ we are able to cover the whole range of $\mu \in [0, \infty)$ [5]. By Lemma 1 we know that if $\mu < \mu'$ and $C_\mu, C_{\mu'}$ are minimizers of $(P)_\mu, (P)_{\mu'}$, respectively, then $C_\mu \subseteq C_{\mu'}$. This implies that the solution of $(P)_\mu$ is unique for any value $\mu \in (0, \infty)$ up to a countable exceptional set. Thus the sets C_μ can be identified with level sets of $u_{\lambda,C}$ for some $\lambda > 0$ and, therefore, we obtain its uniqueness from the concavity of $u_{\lambda,C}$. One can prove [4, 5, 21]:

Theorem 5. *There is a value $\mu^* > 0$ such that*

$$\begin{cases} \text{if } \mu < \mu^*, C_\mu = \emptyset, \\ \text{if } \mu > \mu^*, C_\mu \text{ is unique (and convex),} \\ \text{if } \mu = \mu^*, \text{ there are two solutions } \emptyset \text{ and } C_{\mu^*}, \end{cases}$$

where C_{μ^*} is the unique Cheeger set of C . Moreover for any $\lambda < \|\chi_C\|_*$ we have $\mu^* := \frac{1 - \|u_{\lambda,C}\|_\infty}{\lambda}$ and $C_\mu := \{u_{\lambda,C} > 1 - \mu\lambda\}$ for any $\mu > \mu^*$, where

$$\|\chi_C\|_* := \max \left\{ \int_{\mathbb{R}^N} u \chi_C \, dx : u \in \text{BV}(\mathbb{R}^N), \int_{\mathbb{R}^N} |Du| \leq 1 \right\}.$$

The set C_{μ^*} coincides with the level set $\{u_{\lambda,C} = \|u_{\lambda,C}\|_\infty\}$ and is of class $C^{1,1}$.

We call a Cheeger set in a nonempty open bounded subset Ω of \mathbb{R}^N any set $G \subseteq \Omega$ which minimizes

$$\mathcal{C}_\Omega := \min_{F \subseteq \Omega} \frac{P(F)}{|F|}. \quad (27)$$

The Theorem contains the assertion that there is a unique Cheeger set in any nonempty convex body of \mathbb{R}^N and $\mu^* = \mathcal{C}_\Omega$. This result was proved in [21] for uniformly convex bodies of class C^2 , and in [4] in the general case. Notice that the solution of (24) gives a practical algorithm to compute the Cheeger set of C .

Theorem 6. *Let C be a nontrivial convex body in \mathbb{R}^N . Let*

$$H_C(x) := \begin{cases} -\inf\{\mu : x \in C_\mu\} & \text{if } x \in C \\ 0 & \text{if } x \in \mathbb{R}^N \setminus C. \end{cases}$$

Then $u_{\lambda,C}(x) := (1 + \lambda H_C(x))^+ \chi_C$.

If $N = 2$ and $\mu > \mu^*$, the set C_μ coincides with the union of all balls of radius $1/\mu$ contained in C [6]. Thus its boundary outside ∂C is made by arcs of circle which are tangent to ∂C . In particular, if C is a square, then the Cheeger set corresponds to the arcs of circle with radius $R > 0$ such that $\frac{P(C_{\mu^*})}{|C_{\mu^*}|} = \frac{1}{R}$. We can see that the corners of C are rounded and the discontinuity disappears as soon as $\lambda > 0$ (see the left part of Fig. 1). This is a general fact at points of ∂C where its mean curvature is infinite.

Remark 1. By adapting the proof of Proposition 4 in [5] one can prove the following result. If Ω is a bounded subset of \mathbb{R}^N with Lipschitz continuous boundary, and $u \in \text{BV}(\Omega) \cap L^2(\Omega)$ is the solution of the variational problem

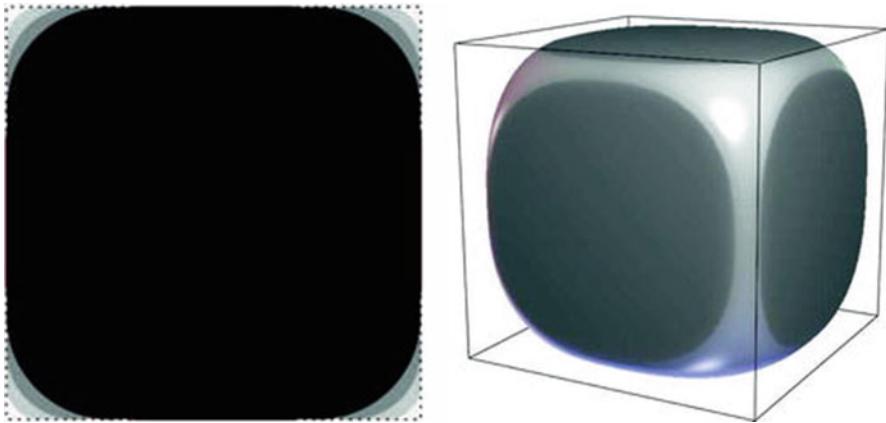

Fig. 1 *Left:* The denoising of a square. *Right:* The Cheeger set of a cube

$$\min_{u \in \text{BV}(\Omega) \cap L^2(\Omega)} \left\{ \int_{\Omega} |Du| + \frac{1}{2\lambda} \int_{\Omega} (u - 1)^2 dx + \int_{\partial\Omega} |u| d\mathcal{H}^{N-1} \right\}, \quad (28)$$

then $0 \leq u \leq 1$ and for any $s \in (0, 1]$ the upper level set $\{u \geq s\}$ is a solution of

$$\min_{F \subseteq \Omega} P(F) - \lambda^{-1}(1-s)|F|. \quad (29)$$

If $\lambda > 0$ is big enough, indeed greater than $1/\|\chi_{\Omega}\|_*$, then the level set $\{u = \|u\|_{\infty}\}$ is the maximal Cheeger set of Ω . In particular, the maximal Cheeger set can be computed by solving (28), and for that we can use the algorithm in [25] described in section ‘‘Chambolle’s Algorithm.’’ In the right side of Fig. 1 we display the Cheeger set of a cube.

Other explicit solutions corresponding to the union of convex sets can be found in [2, 13]. In particular, Allard [2] describes the solution corresponding to the union of two disks in the plane and also the case of two squares with parallel sides touching by a vertex. Some explicit solutions for functions whose level sets are a finite number of convex sets in \mathbb{R}^2 can be found in [14].

5 Numerical Algorithms: Iterative Methods

Notation

Let us fix our main notations. We denote by X the Euclidean space $\mathbb{R}^{N \times N}$. The Euclidean scalar product and the norm in X will be denoted by $\langle \cdot, \cdot \rangle_X$ and $\|\cdot\|_X$,

respectively. Then the image $u \in X$ is the vector $u = (u_{i,j})_{i,j=1}^N$, and the vector field ξ is the map $\xi : \{1, \dots, N\} \times \{1, \dots, N\} \rightarrow \mathbb{R}^2$. To define the discrete total variation, we define a discrete gradient operator. If $u \in X$, the discrete gradient is a vector in $Y = X \times X$ given by

$$\nabla u := (\nabla_x u, \nabla_y u),$$

where

$$(\nabla_x u)_{i,j} = \begin{cases} u_{i+1,j} - u_{i,j} & \text{if } i < N \\ 0 & \text{if } i = N, \end{cases} \quad (30)$$

$$(\nabla_y u)_{i,j} = \begin{cases} u_{i,j+1} - u_{i,j} & \text{if } j < N \\ 0 & \text{if } j = N \end{cases} \quad (31)$$

for $i, j = 1, \dots, N$. Notice that the gradient is discretized using forward differences and $\nabla^{+,+} u$ could be a more explicit notation. For simplicity we have preferred to use ∇u . Other choices of the gradient are possible; this one will be convenient for the developments below.

The Euclidean scalar product in Y is defined in the standard way by

$$\langle \xi, \tilde{\xi} \rangle_Y = \sum_{1 \leq i,j \leq N} (\xi_{i,j}^1 \tilde{\xi}_{i,j}^1 + \xi_{i,j}^2 \tilde{\xi}_{i,j}^2)$$

for every $\xi = (\xi^1, \xi^2), \tilde{\xi} = (\tilde{\xi}^1, \tilde{\xi}^2) \in Y$. The norm of $\xi = (\xi^1, \xi^2) \in Y$ is, as usual, $\|\xi\|_Y = \langle \xi, \xi \rangle_Y^{1/2}$. We denote the Euclidean norm of a vector $v \in \mathbb{R}^2$ by $|v|$. Then the discrete total variation is

$$J_d(u) = \|\nabla u\|_Y = \sum_{1 \leq i,j \leq N} |(\nabla u)_{i,j}|. \quad (32)$$

We have

$$J_d(u) = \sup_{\xi \in Y, |\xi_{i,j}| \leq 1 \forall (i,j)} \langle \xi, \nabla u \rangle_Y. \quad (33)$$

By analogy with the continuous setting, we introduce a discrete divergence div as the dual operator of ∇ , i.e., for every $\xi \in Y$ and $u \in X$ we have

$$\langle -\operatorname{div} \xi, u \rangle_X = \langle \xi, \nabla u \rangle_Y.$$

One can easily check that div is given by

$$\begin{aligned} (\text{div } \xi)_{i,j} &= \begin{cases} \xi_{i,j}^1 - \xi_{i-1,j}^1 & \text{if } 1 < i < N \\ \xi_{i,j}^1 & \text{if } i = 1 \\ -\xi_{i-1,j}^1 & \text{if } i = N \end{cases} \\ &+ \begin{cases} \xi_{i,j}^2 - \xi_{i,j-1}^2 & \text{if } 1 < j < N \\ \xi_{i,j}^2 & \text{if } j = 1 \\ -\xi_{i,j-1}^2 & \text{if } j = N \end{cases} \end{aligned} \quad (34)$$

for every $\xi = (\xi^1, \xi^2) \in Y$.

We have

$$J_d(u) := \max_{\xi \in \mathcal{V}} \langle u, \text{div } \xi \rangle, \quad (35)$$

where

$$\mathcal{V} = \{\xi \in Y : |\xi_{i,j}|^2 - 1 \leq 0, \forall i, j \in \{1, \dots, N\}\}$$

Chambolle's Algorithm

Let us describe the dual formulation for solving the problem:

$$\min_{u \in X} J_d(u) + \frac{1}{2\lambda} \|u - f\|_X^2 \quad (36)$$

where $f \in X$. Using (35) we have

$$\begin{aligned} \min_{u \in X} J_d(u) + \frac{1}{2\lambda} \|u - f\|_X^2 &= \min_{u \in X} \max_{\xi \in \mathcal{V}} \langle u, \text{div } \xi \rangle + \frac{1}{2\lambda} \|u - f\|_X^2 \\ &= \max_{\xi \in \mathcal{V}} \min_{u \in X} \langle u, \text{div } \xi \rangle + \frac{1}{2\lambda} \|u - f\|_X^2. \end{aligned}$$

Solving explicitly the minimization in u , we have $u = f - \lambda \text{div } \xi$. Then

$$\begin{aligned} \max_{\xi \in \mathcal{V}} \min_{u \in X} \langle u, \text{div } \xi \rangle + \frac{1}{2\lambda} \|u - f\|_X^2 &= \max_{\xi \in \mathcal{V}} \langle f, \text{div } \xi \rangle - \frac{\lambda}{2} \|\text{div } \xi\|_X^2 \\ &= -\frac{\lambda}{2} \min_{\xi \in \mathcal{V}} \left(\left\| \text{div } \xi - \frac{f}{\lambda} \right\|_X^2 - \left\| \frac{f}{\lambda} \right\|_X^2 \right). \end{aligned}$$

Thus if ξ^* is the solution of

$$\min_{\xi \in \mathcal{V}} \left\| \operatorname{div} \xi - \frac{f}{\lambda} \right\|_X^2. \quad (37)$$

then $u = f - \lambda \operatorname{div} \xi^*$ is the solution of (36).

Notice that $\operatorname{div} \xi^*$ is the projection of $\frac{f}{\lambda}$ onto the convex set

$$K_d := \{\operatorname{div} \xi : |\xi_{i,j}| \leq 1, \forall i, j \in \{1, \dots, N\}\}.$$

As in [25], the Karush–Kuhn–Tucker Theorem yields the existence of Lagrange multipliers $\alpha_{i,j} \geq 0$ for the constraints $\xi \in \mathcal{V}$, such that we have for each $(i, j) \in \{1, \dots, N\}^2$

$$\nabla[\operatorname{div} \xi - \lambda^{-1} f]_{i,j} - \alpha_{i,j}^* \xi_{i,j} = 0, \quad (38)$$

with either $\alpha_{i,j}^* > 0$ and $|\xi_{i,j}| = 1$, or $\alpha_{i,j}^* = 0$ and $|\xi_{i,j}| \leq 1$. In the later case, we have $\nabla[\operatorname{div} \xi - \lambda^{-1} f]_{i,j} = 0$. In any case, we have

$$\alpha_{i,j}^* = |\nabla[\operatorname{div} \xi - \lambda^{-1} f]_{i,j}|. \quad (39)$$

Let $v > 0$, $\xi^0 = 0$, $p \geq 0$. We solve (38) using the following gradient descent (or fixed point) algorithm:

$$\xi_{i,j}^{p+1} = \xi_{i,j}^p + v \nabla[\operatorname{div} \xi^p - \lambda^{-1} f]_{i,j} - v |\nabla[\operatorname{div} \xi^p - \lambda^{-1} f]_{i,j}| \xi_{i,j}^{p+1}; \quad (40)$$

hence

$$\xi_{i,j}^{p+1} = \frac{\xi_{i,j}^p + v \nabla[\operatorname{div} \xi^p - \lambda^{-1} f]_{i,j}}{1 + v |\nabla[\operatorname{div} \xi^p - \lambda^{-1} f]_{i,j}|}. \quad (41)$$

Observe that $|\xi_{i,j}^p| \leq 1$ for all $i, j \in \{1, \dots, N\}$ and every $p \geq 0$.

Theorem 7. *In the discrete framework, assuming that $v < \frac{1}{8}$, then $\operatorname{div} \xi^p$ converges to the projection of $\frac{f}{\lambda}$ onto the convex set K_d . If $\operatorname{div} \xi^*$ is that projection, then $u = f - \lambda \operatorname{div} \xi^*$ is the solution of (36).*

In Fig. 2 we display some results obtained using Chambolle's algorithm with different set of parameters, namely, $\lambda = 5, 10$.

Today, the algorithms Nesterov [49], Beck and Teboulle [12], or the primal-dual approaches described in the next section provide more efficient ways to solve this dual problem.

Fig. 2 Denoising results obtained with Chambolle's algorithm. (a) *Top left*: the original image. (b) *Top right*: the image with a Gaussian noise of standard deviation $\sigma = 10$. (c) *Bottom left*: the result obtained with $\lambda = 5$. (d) *Bottom right*: the result obtained with $\lambda = 10$

Primal-Dual Approaches

The primal gradient descent formulation is based on the solution of (36). The dual gradient descent algorithm corresponds to (41). The primal-dual formulation is based on the formulation

$$\min_{u \in X} \max_{\xi \in \mathcal{V}} G(u, \xi) := \langle u, \operatorname{div} \xi \rangle + \frac{1}{2\lambda} \|u - f\|_X^2$$

and performs a gradient descent in u and gradient ascent in ξ .

Given the intermediate solution (u^k, ξ^k) at iteration step k we update the dual variable by solving

$$\max_{\xi \in \mathcal{V}} G(u^k, \xi). \quad (42)$$

Since the gradient ascent direction is $\nabla_\xi G(u^k, \xi) = -\nabla u^k$, we update ξ as

$$\xi^{k+1} = P_{\mathcal{V}} \left(\xi^k - \frac{\tau_k}{\lambda} \nabla u^k \right), \quad (43)$$

where τ_k denotes the dual stepsize and $P_{\mathcal{V}}$ denotes the projection onto the convex set \mathcal{V} . The projection $P_{\mathcal{V}}$ can be computed as in (41) or simply as

$$(P_{\mathcal{V}} \xi)_{i,j} = \frac{\xi_{i,j}}{\max(|\xi_{i,j}|, 1)}.$$

Now we update the primal variable u by a gradient descent step of

$$\min_{u \in X} G(u, \xi^{k+1}). \quad (44)$$

The gradient ascent direction is $\nabla_u G(u, \xi^{k+1})$ and the update is

$$u^{k+1} = u^k - \theta_k (\lambda \operatorname{div} \xi^{k+1} + u^k - f), \quad (45)$$

where θ_k denotes the primal stepsize.

The primal-dual scheme was introduced in [57]. The convergence is empirically observed for a variety of suitable stepsize pairs (τ, θ) and is given in terms of the product $\tau\theta$. For instance, convergence is reported for increasing values θ_k and $\tau_k \theta_k \leq 0.5$, see [57]. This has been theoretically explained for a variant of the scheme proposed in [29], while a general convergence proof has been given in [15].

The primal gradient descent and the dual projected gradient descent method are special cases of the above algorithm. Indeed if one solves the problem (42) exactly (taking $\tau_k = \infty$ in (43)) the resulting algorithm is

$$u^{k+1} = u^k - \theta_k \left(-\lambda \operatorname{div} \frac{\nabla u^k}{|\nabla u^k|} + u^k - f \right), \quad (46)$$

with the implicit convention that we may take any element in the unit ball of \mathbb{R}^2 when $\nabla u^k = 0$.

If we solve (44) exactly and still apply gradient ascent to (42), the resulting algorithm is

$$\xi^{k+1} = P_{\mathcal{V}} \left(\xi^k + \tau_k \nabla \left(\operatorname{div} \xi^k - \frac{f}{\lambda} \right) \right), \quad (47)$$

which essentially corresponds to (41).

The primal-dual approach can be extended to the total variation deblurring problem

$$\min_{u \in X} \quad J_d(u) + \frac{1}{2\lambda} \|Bu - f\|_X^2 \quad (48)$$

where $f \in X$ and B is a matrix representing the discretization of the blurring operator H .

The primal-dual scheme is based on the formulation

$$\min_{u \in X} \max_{\xi \in \mathcal{V}} \quad \langle u, \operatorname{div} \xi \rangle + \frac{1}{2\lambda} \|Bu - f\|_X^2, \quad (49)$$

and the numerical scheme can be written as

$$\begin{aligned} \xi^{k+1} &= P_{\mathcal{V}}(\xi^k - \tau_k \nabla u^k) \\ u^{k+1} &= u^k - \theta^k (-\operatorname{div} \xi^{k+1} + \lambda B^t(Bu^{k+1} - f)). \end{aligned} \quad (50)$$

Since B is the matrix of a convolution operator, the second equation can be solved explicitly using the FFT. Convergence is empirically observed for a variety of suitable stepsize pairs (τ, θ) and is given in terms of the product $\tau\theta$, see [57] and a proof in [15]. See also [29] for an explicit rule for acceleration, with proofs of convergence. For a detailed study of different primal-dual methods we refer to [37].

6 Numerical Algorithms: Maximum-Flow Methods

It has been noticed probably first in [51] that Maximal-flow/minimum-cut techniques could be used to solve discrete problems of the form (14), that is, to compute finite sets minimizing a discrete variant of the perimeter and an additional external field term. Combined with (a discrete equivalent of) Proposition 1, this leads to efficient techniques for solving (only) the denoising problem (8), including a method, due to D. Hochbaum, to compute an exact solution in polynomial time (up to machine precision). A slightly more general problem is considered in [27], where the authors describe in detail algorithms which solve the problem with an arbitrary precision.

Discrete Perimeters and Discrete Total Variation

We will call a discrete total variation any convex, nonnegative function $J : \mathbb{R}^M \rightarrow [0, +\infty]$ satisfying a discrete *co-area* formula:

$$J(u) = \int_{-\infty}^{+\infty} J(\chi^{\{u \geq s\}}) ds \quad (51)$$

where $\chi^{\{u \geq s\}} \in \{0, 1\}^M$ denotes the vector such that $\chi_i^{\{u \geq s\}} = 0$ if $u_i \leq s$ and $\chi_i^{\{u \geq s\}} = 1$ if $u_i \geq s$.

As an example we can consider the (anisotropic) discrete total variation

$$J(u) = \sum_{\substack{1 \leq i < N \\ 1 \leq j \leq N}} |u_{i+1,j} - u_{i,j}| + \sum_{\substack{1 \leq i \leq N \\ 1 \leq j < N}} |u_{i,j+1} - u_{i,j}| \quad (52)$$

In this case $u = (u_{i,j})_{i,j=1}^N$ can be written as a vector in \mathbb{R}^M with $M = N^2$. Then, (51) obviously holds since for any $a, b \in \mathbb{R}$, we have $|a - b| = \int_{-\infty}^{+\infty} |\chi_{\{a>s\}} - \chi_{\{b>s\}}| ds$.

Observe, on the other hand, that the discretization (36) does not enter this category (unfortunately). In fact, a discrete total variation will be always very anisotropic (or “crystalline”).

We assume that J is not identically $+\infty$. Then, we can derive from (51) the following properties [27]:

Proposition 3. *Let J be a discrete total variation. Then:*

1. *J is positively homogeneous: $J(\lambda u) = \lambda J(u)$ for any $u \in \mathbb{R}^M$ and $\lambda \geq 0$.*
2. *J is invariant by addition of a constant: $J(c\mathbf{1} + u) = J(u)$ for any $u \in \mathbb{R}^M$ and $c \in \mathbb{R}$, where $\mathbf{1} = (1, \dots, 1) \in \mathbb{R}^M$ is a constant vector. In particular, $J(\mathbf{1}) = 0$.*
3. *J is lower semicontinuous.*
4. *$p \in \partial J(u) \Leftrightarrow (\forall z \in \mathbb{R}, p \in \partial J(\chi^{\{u \geq z\}}))$.*
5. *J is submodular: for any $u, u' \in \{0, 1\}^M$,*

$$J(u \vee u') + J(u \wedge u') \leq J(u) + J(u'). \quad (53)$$

More generally, this will hold for any $u, u' \in \mathbb{R}^M$.

Conversely, if $J : \{0, 1\}^M \rightarrow [0, +\infty]$ is a submodular function with $J(0) = J(\mathbf{1}) = 0$, then the co-area formula (51) extends it to \mathbb{R}^M into a convex function, hence a discrete total variation.

If J is a discrete total variation, then the discrete counterpart of Proposition 1 holds:

Proposition 4. *Let J be a discrete total variation. Let $f \in \mathbb{R}^M$ and let $u \in \mathbb{R}^M$ be the (unique) solution of*

$$\min_{u \in \mathbb{R}^M} \lambda J(u) + \frac{1}{2} \|u - f\|^2 \quad (54)$$

Then, for all $s > 0$, the characteristic functions of the super-level sets $E_s = \{u \geq s\}$ and $E'_s = \{u > s\}$ (which are different only if $s \in \{u_i, i = 1, \dots, M\}\}$ are

respectively the largest and smallest minimizer of

$$\min_{\theta \in \{0,1\}^M} \lambda J(\theta) + \sum_{i=1}^M \theta_i(s - f_i). \quad (55)$$

The proof is quite clear, since the only properties which were used for showing Proposition 1 were (a) the co-area formula of Theorem 1 and (b) the submodularity of the perimeters (10).

As a consequence, Problem (54) can be solved by successive minimizations of (55), which in turn can be done by computing a maximal flow through a graph, as will be explained in the next section. It seems that efficiently solving the successive minimizations has been first proposed in the seminal work of Eisner and Severance [36] in the context of augmenting-path maximum-flow algorithms. It was then developed, analyzed, and improved by Gallo, Grigoriadis, and Tarjan [39] for preflow-based algorithms. Successive improvements were also proposed by Hochbaum [42], specifically for the minimization of (54). We also refer to [26, 33] for variants, and to [45] for detailed discussions about this approach.

Graph Representation of Energies for Binary MRF

It was first observed by Picard and Ratliff [51] that binary Ising-like energies, that is, of the form

$$\sum_{i,j} \alpha_{i,j} |\theta_i - \theta_j| - \sum_i \beta_i \theta_i, \quad (56)$$

$\alpha_{i,j} \geq 0$, $\beta_i \in \mathbb{R}$, $\theta_i \in \{0, 1\}$, could be represented on a graph and minimized by standard optimization techniques, and more precisely using maximum-flow algorithms. Kolmogorov and Zabih [44] showed that the submodularity of the energy is a necessary condition, while, up to sums of ternary submodular interactions, it is also a sufficient condition in order to be representable on a graph. (But other energies are representable, and it does not seem to be known whether any submodular J can be represented on a graph, see [27, Appendix B] and the references therein.)

In case $J(u)$ has only pairwise interactions, as in (52), then Problem (55) has exactly the form (56), with $\alpha_{i,j} = \lambda$ if nodes i and j correspond to neighboring pixels, 0 else, and β_i is $s - f_i$.

Let us build a graph as follows: we consider $\mathcal{V} = \{1, \dots, M\} \cup \{S\} \cup \{T\}$ where the two special nodes S and T are respectively called the “source” and the “sink.” We consider then oriented edges (S, i) and (i, T) , $i = 1, \dots, M$, and (i, j) , $1 \leq i, j \leq M$, and to each edge we associate a capacity defined as follows:

$$\begin{cases} c(S, i) = \beta_i^- & i = 1, \dots, M, \\ c(i, T) = \beta_i^+ & i = 1, \dots, M, \\ c(i, j) = \alpha_{i,j} & 1 \leq i, j \leq M. \end{cases} \quad (57)$$

Here $\beta_i^+ = \max\{0, \beta_i\}$ and $\beta_i^- = \max\{0, -\beta_i\}$, so that $\beta_i = \beta_i^+ - \beta_i^-$. By convention, we consider there is no edge between two nodes if the capacity is zero. Let us denote by \mathcal{E} the set of edges with nonzero capacity and by $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ the resulting oriented graph.

We then define a “cut” in the graph as a partition of \mathcal{E} into two sets \mathcal{S} and \mathcal{T} , with $S \in \mathcal{S}$ and $T \in \mathcal{T}$. The cost of a cut is then defined as the total sum of the capacities of the edges that start on the source side of the cut and land on the sink side:

$$C(\mathcal{S}, \mathcal{T}) = \sum_{\substack{(\mu, v) \in \mathcal{E} \\ \mu \in \mathcal{S}, v \in \mathcal{T}}} c(\mu, v).$$

Then, if we let $\theta \in \{0, 1\}^M$ be the characteristic function of $\mathcal{S} \cap \{1, \dots, M\}$, we have

$$\begin{aligned} C(\mathcal{S}, \mathcal{T}) &= \sum_{i=1}^M (1 - \theta_i) \beta_i^- + \theta_i \beta_i^+ + \sum_{i,j=1}^M \alpha_{i,j} (\theta_i - \theta_j)^+ \\ &= \sum_{i,j=1}^M \alpha_{i,j} (\theta_i - \theta_j)^+ + \sum_{i=1}^M \theta_i \beta_i + \sum_{i=1}^M \beta_i^- \end{aligned}$$

If $\alpha_{i,j} = \alpha_{j,i}$ (but other situations are also interesting), this is nothing else than energy (56), up to a constant.

Thus, the problem of finding a minimum of (56) [or (55)] can be reformulated as the problem of finding a minimal cut in the graph. Very efficient algorithms are available, based on a duality result of Ford and Fulkerson [1]. It states that the maximum flow on the graph constrained by the capacities of the edges is equal to the minimal cost of a cut. The problem reduces then to find the maximum flow in the graph. This is precisely defined as follows: starting from S , we “push” a quantity $(x_{\mu,v})$ along the oriented edges $(\mu, v) \in \mathcal{E}$ of the graph, with the constraint that along each edge,

$$0 \leq x_{\mu,v} \leq c(\mu, v)$$

and that each “interior” node i must satisfy the flow conservation constraint

$$\sum_{\mu} x_{\mu,i} = \sum_{\mu} x_{i,\mu}$$

(while the source S only sends flow to the network, and the sink T only receives).

It is clear that the total flow $f(x) = \sum_i x_{S,i} = \sum_i x_{i,T}$ which can be sent is bounded from above, and not hard to show that a bound is given by a minimal-cost cut $(\mathcal{S}, \mathcal{T})$. The duality theorem of Ford and Fulkerson expresses the fact that this bound is actually reached by the maximal flow $(x_{\mu,v})_{(\mu,v) \in \mathcal{E}}$ (which maximizes

$f(x)$), and the partition $(\mathcal{S}, \mathcal{T})$ is obtained by cutting along the saturated edges (μ, v) , where $x_{\mu,v} = c_{\mu,v}$ while $x_{v,\mu} = 0$.

We can find starting from S the first saturated edge along the graph, and cut there, or do the same starting from T and scanning the reverse graph: for $\beta_i = s - f_i$, this will usually give the same solution except for a finite number of levels s , which correspond exactly to the levels $\{u_i : i = 1, \dots, M\}$ of the solution of (54) and are called the “breakpoints.”

Several efficient algorithms are available to compute a maximum flow in polynomial time [1]. Although the time complexity of the algorithm in [16], of Boykov and Kolmogorov, is not polynomial, this algorithm seems to outperform others in terms in time computations, as it is particularly designed for the graphs with low connectivity which arise in image processing.

The idea of a “parametric maximum-flow algorithm” [39] is to reuse the same graph (and the “residual graph” which remains after a run of a max-flow algorithm) to solve problems (55) for increasing values $s \in \{s_0, s_1, \dots, s_n\}$. This is easily shown to solve (54) up to an arbitrary precision (and in polynomial time, see [39]). It seems this idea was already present in a paper of Eisner and Severance [36].

However, it was shown in [42] by D. Hochbaum that in fact the *exact* solution to (54) can be computed, also in polynomial time. Let us now explain the basic idea of this approach; for details we refer to [27, 42].

Let $u = (u_i)_{i=1}^M$ be the (unique) solution of (54). Proposition 4 tells us that as s varies, problem (55) has the same solution $\chi^{\{u \geq s\}}$ as long as s does not cross any of the values $\{u_i : i = 1, \dots, M\}$, which are precisely the breakpoints.

Assume we have found, for two levels $s_1 < s_2$, solutions $\theta^1 \geq \theta^2$ of (55) and assume also that these solutions differ. It means that there is a breakpoint u_{i_0} in between: there is at least one location i_0 (and possibly other) with $s_1 \leq u_{i_0} \leq s_2$.

Suppose for a while that the value u_{i_0} were the *only* breakpoint between s_1 and s_2 (that is, at no other location i_1 , we can have both $s_1 \leq u_{i_1} \leq s_2$ and $u_{i_0} \neq u_{i_1}$).

In this case, for $s \in [s_1, s_2]$, the optimal energy should be

$$\mathcal{F}(s) = \mathcal{F}_1(s) = \left(\lambda J(\theta^1) - \sum_{i=1}^M \theta_i^1 f_i \right) + s \sum_{i=1}^M \theta_i^1$$

if $s \leq u_{i_0}$, and

$$\mathcal{F}(s) = \mathcal{F}_2(s) = \left(\lambda J(\theta^2) - \sum_{i=1}^M \theta_i^2 f_i \right) + s \sum_{i=1}^M \theta_i^2$$

for $s \geq u_{i_0}$. And the value u_{i_0} is the necessary (only) solution of the equation $\mathcal{F}_1(u_{i_0}) = \mathcal{F}_2(u_{i_0})$.

Observe that in any case, as $\theta^1 \geq \theta^2$ and they are different, the slope of the affine function $\mathcal{F}_1(s)$ is strictly above the slope of the affine function $\mathcal{F}_2(s)$. Since also $\mathcal{F}_1(s_1) \leq \mathcal{F}_2(s_1)$ (as θ^1 is optimal for s_1) and $\mathcal{F}_2(s_2) \leq \mathcal{F}_1(s_2)$, there is always a (unique) value $s_3 \in [s_1, s_2]$ for which $\mathcal{F}_1(s_3) = \mathcal{F}_2(s_3)$.

The idea of the algorithm is now clear: we have to compute a new maximal flow (which, in fact, reuses the residual flows from the computations of θ^1 and θ^2) to solve (55) for the level $s = s_3$. We find a solution θ^3 , of energy

$$\mathcal{F}_3(s_3) = \left(\lambda J(\theta^3) - \sum_{i=1}^M \theta_i^3 f_i \right) + s_3 \sum_{i=1}^M \theta_i^3$$

Then, there are two cases:

- Either $\mathcal{F}_3(s_3) = \mathcal{F}_1(s_3) = \mathcal{F}_2(s_3)$: in this case we have found a breakpoint, and there is no other in the interval $[s_1, s_2]$. Hence, the level sets $\{u \geq s\}$ have been found for all values $s \in [s_1, s_2]$: $\chi^{\{u \geq s\}} = \theta^1$ for $s \in [s_1, s_3]$ and θ^2 for $s \in [s_3, s_2]$.
- Or $\mathcal{F}_3(s_3) < \mathcal{F}_1(s_3) = \mathcal{F}_2(s_3)$. Then, in particular, it must be that the solution θ^3 differs from both θ^1 and θ^2 (otherwise the energies would be the same). Hence we can start again to try solving the problem at the levels s_4 and s_5 which solve $\mathcal{F}_1(s_4) = \mathcal{F}_3(s_4)$ and $\mathcal{F}_3(s_5) = \mathcal{F}_2(s_5)$. Now, since there are only a finite number of possible sets θ solving (55) (bounded by M , as the solutions are nonincreasing with s), this situation can occur at most a finite number of times, bounded by M .

In practice, this can be done in a very efficient way, using “residual graphs” to start the new maximal-flow algorithms, and to compute efficiently the new levels where to cut (there is no need, in fact, to compute the values $\lambda J(\theta) + \sum_i \theta_i f_i$ and $\sum_i \theta_i$ for this). See [27, 42] for details.

For experimental results in the case of total variation denoising we refer to [26, 27, 33, 40].

7 Other Problems: Anisotropic Total Variation Models

Global Solutions of Geometric Problems

The theory of anisotropic perimeters developed in [7] permits to extend model (28) to general anisotropic perimeters, including as particular cases the geodesic active contour model with an inflating force [19, 43], and a model for edge linking [22]. This permits to find the global minima of geometric problems that appear in image processing [22, 24, 27, 32].

The Anisotropic Total Variation and Perimeter Let us define the general notion of total variation with respect to an anisotropy. Following [7] we say that a function $\phi : \Omega \times \mathbb{R}^N \rightarrow [0, \infty)$ is a *metric integrand* if ϕ is a Borel function satisfying the conditions:

$$\text{for a.e. } x \in \Omega, \text{ the map } \xi \in \mathbb{R}^N \rightarrow \phi(x, \xi) \text{ is convex,} \quad (58)$$

$$\phi(x, t\xi) = |t|\phi(x, \xi) \quad \forall x \in \Omega, \quad \forall \xi \in \mathbb{R}^N, \quad \forall t \in \mathbb{R}, \quad (59)$$

and there exists a constant $\Lambda > 0$ such that

$$0 \leq \phi(x, \xi) \leq \Lambda \|\xi\| \quad \forall x \in \Omega, \quad \forall \xi \in \mathbb{R}^N. \quad (60)$$

We could be more precise and use the term symmetric metric integrand, but for simplicity we use the term metric integrand. Recall that the polar function $\phi^0 : \Omega \times \mathbb{R}^N \rightarrow \mathbb{R} \cup \{+\infty\}$ of ϕ is defined by

$$\phi^0(x, \xi^*) = \sup\{\langle \xi^*, \xi \rangle : \xi \in \mathbb{R}^N, \phi(x, \xi) \leq 1\}. \quad (61)$$

The function $\phi^0(x, \cdot)$ is convex and lower semicontinuous.

Let

$$\mathcal{K}_\phi(\Omega) := \{\sigma \in X_\infty(\Omega) : \phi^0(x, \sigma(x)) \leq 1 \text{ for a.e. } x \in \Omega, [\sigma \cdot v^\Omega] = 0\}.$$

Definition 3. Let $u \in L^1(\Omega)$. We define the ϕ -total variation of u in Ω as

$$\int_{\Omega} |Du|_\phi := \sup \left\{ \int_{\Omega} u \operatorname{div} \sigma \, dx : \sigma \in \mathcal{K}_\phi^\infty(\Omega) \right\}, \quad (62)$$

We set $\operatorname{BV}_\phi(\Omega) := \{u \in L^1(\Omega) : \int_{\Omega} |Du|_\phi < \infty\}$ which is a Banach space when endowed with the norm $|u|_{\operatorname{BV}_\phi(\Omega)} := \int_{\Omega} |u| \, dx + \int_{\Omega} |Du|_\phi$.

We say that $E \subseteq \mathbb{R}^N$ has finite ϕ -perimeter in Ω if $\chi_E \in \operatorname{BV}_\phi(\Omega)$. We set

$$P_\phi(E, \Omega) := \int_{\Omega} |D\chi_E|_\phi.$$

If $\Omega = \mathbb{R}^N$, we denote $P_\phi(E) := P_\phi(E, \mathbb{R}^N)$. By assumption (60), if $E \subseteq \mathbb{R}^N$ has finite perimeter in Ω it has also finite ϕ -perimeter in Ω .

A Variational Problem and Its Connection with Geometric Problems Let $\phi : \Omega \times \mathbb{R}^N \rightarrow \mathbb{R}$ be a metric integrand in Ω and $h \in L^\infty(\Omega)$, $h(x) > 0$ a.e., with $\int_{\Omega} \frac{1}{h(x)} \, dx < \infty$. Let us consider the problem

$$\min_{u \in \operatorname{BV}_\phi(\Omega)} \int_{\Omega} |Du|_\phi + \int_{\partial\Omega} \phi(x, v^\Omega)|u| \, d\mathcal{H}^{N-1} + \frac{\lambda}{2} \int_{\Omega} h(u - f)^2 \, dx, \quad (63)$$

where v^Ω denotes the outer unit normal to $\partial\Omega$. To shorten the expressions inside the integrals we shall write h, u instead of $h(x), u(x)$, with the only exception of $\phi(x, v^\Omega)$. The following result was proved in [22].

Theorem 8. (i) Let $f \in L^2(\Omega, h dx)$, i.e., $\int_{\Omega} f(x)^2 h(x) dx < \infty$. Then there is a unique solution of the problem (63).

(ii) If $u \in \text{BV}_{\phi}(\Omega) \cap L^2(\Omega, h dx)$ be the solution of the variational problem (63) with $f = 1$. Then $0 \leq u \leq 1$ and the level sets $E_s := \{x \in \Omega : u(x) \geq s\}$, $s \in (0, 1]$, are solutions of

$$\min_{F \subseteq \Omega} P_{\phi}(F) - \mu |F|_h. \quad (64)$$

where $|F|_h = \int_F h(x) dx$. As in the Euclidian case, the solution of (64) is unique for any $s \in (0, 1]$ up to a countable exceptional set.

(iii) When λ is big enough, the level set associated with the maximum of u , $\{u = \|u\|_{\infty}\}$, is the maximal (ϕ, h) -Cheeger set of Ω , i.e., is a minimizer of the problem

$$\inf \left\{ \frac{P_{\phi}(F)}{|F|_h} : F \subseteq \overline{\Omega} \text{ of finite perimeter, } |F|_h > 0 \right\}. \quad (65)$$

The computation of the maximal (ϕ, h) -Cheeger set [together with the solution of the family of problems (64)] can be computed by adapting Chambolle's algorithm [25] described in section ‘‘Chambolle's Algorithm.’’

Example 1. We illustrate this formalism with two examples: (a) the geodesic active contour model and (b) a model for edge linking.

(a) *The geodesic active contour model.* Let $I : \Omega \rightarrow \mathbb{R}^+$ be a given image in $L^{\infty}(\Omega)$, G be a Gaussian function, and

$$g(x) = \frac{1}{\sqrt{1 + |\nabla(G * I)|^2}}, \quad (66)$$

(where in $G * I$ we have extended I to \mathbb{R}^N by taking the value 0 outside Ω). Observe that $g \in C(\overline{\Omega})$ and $\inf_{x \in \overline{\Omega}} g(x) > 0$. The geodesic active contour model [19, 43] with an inflating force corresponds to the case where $\phi(x, \xi) = g(x)|\xi|$ and $|Du|_{\phi} = g(x)|Du|$ and $h(x) = 1$, $x \in \Omega$. The purpose of this model is to locate the boundary of an object of the image at the points where the gradient is large. The presence of the inflating term helps to avoid minima collapsing into a point. The model was initially formulated [19, 43] in a level set framework In this case we may write $P_g(F)$ instead of $P_{\phi}(F)$, and we have $P_g(F) := \int_{\partial^* F} g d\mathcal{H}^{N-1}$, where $\partial^* F$ is the reduced boundary of F [9].

In this case the Cheeger sets are a particular instance of geodesic active contour with an inflating force whose constant is $\mu = C_{\Omega}^{g,1}$. An interesting feature of this formalism is that it permits to define local Cheeger sets as local (regional) maxima of the function u . They are Cheeger sets in a subdomain of Ω . They can be identified with boundaries of the image and the above formalism

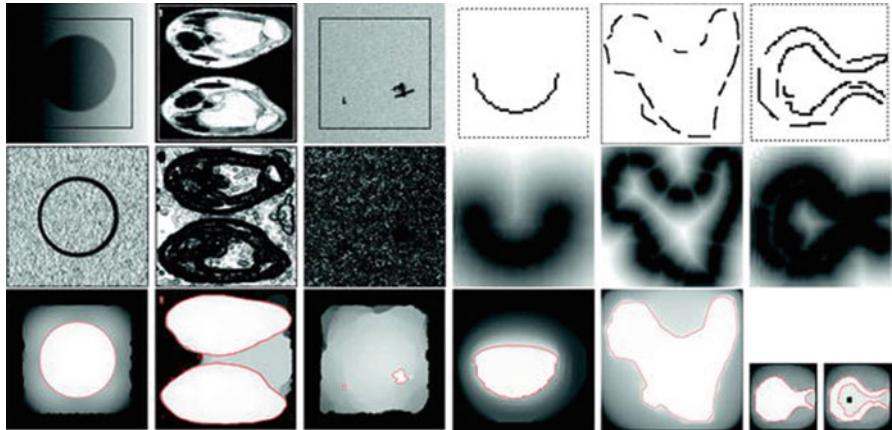

Fig. 3 Geodesic active contours and edge linking experiments. The *first row* shows the images I to be processed. The *first three columns* correspond to segmentation experiments, the *last three* are edge linking experiments. The *second row* shows the weights g used for each experiment (white is 1, black is 0), in the first two cases $g = (\sqrt{1 + |\nabla(G * I)|^2})^{-1}$, for the third $g = 0.37(\sqrt{0.1 + |\nabla(G * I)|^2})^{-1}$, and for the linking experiments $g = d_S$, the scaled distance function to the given edges. The *third row* shows the disjoint minimum g -Cheeger sets extracted from u (shown in the background); there are 1, 7, 2, 1, 1, and 1 sets, respectively. The last linking experiment illustrates the effect of introducing a barrier in the initial domain (black square)

permits to compute several active contours at the same time (the same holds true for the edge linking model).

- (b) *An edge linking model.* Another interesting application of the above formalism is to edge linking. Given a set $\Gamma \subseteq \Omega$ (which may be curves if $\Omega \subseteq \mathbb{R}^2$ or pieces of surface if $\Omega \subseteq \mathbb{R}^3$), we define $d_\Gamma(x) = \text{dist}(x, \Gamma)$ and the anisotropy $\phi(x, \xi) = d_\Gamma(x)|\xi|$. In that case, we experimentally see that the Cheeger set determined by this anisotropy links the set of curves (or surfaces) Γ . If Γ is a set of edges computed with an edge detector we obtain a set or curves ($N = 2$) or surfaces ($N = 3$) linking them.

Notice that, for a given choice of ϕ , we actually find many *local* ϕ -Cheeger sets, disjoint from the global minimum, that appear as local minima of the Cheeger ratio on the tree of connected components of upper level sets of u . The computation of those sets is partially justified by Proposition 6.11 in [22]. These are the sets which we show on the following experiments.

Let us mention the formulation of active contour models without edges proposed by Chan–Vese in [31] can also be related to the general formulation (64).

In Fig. 3, we display some local ϕ -Cheeger sets of 2D images for the choices of metric ϕ corresponding to geodesic active contour models with an inflating force (the first three columns) and to edge linking problems (the last three columns). The first row displays the original images, and the second row displays the metric

$g = (\sqrt{1 + |\nabla(G * I)|^2})^{-1}$ or $g = d_S$. The last row displays the resulting segmentation or set of linked edges, respectively. Let us remark here a limitation of this approach that can be observed in the last subfigure. Even if this linking is produced, the presence of a bottleneck (bottom right subfigure) makes the d_S -Cheeger set to be a set with large volume. This limitation can be circumvented by adding barriers in the domain Ω : we can enforce hard restrictions on the result by removing from the domain some points that we do not want to be enclosed by the output set of curves.

A Convex Formulation of Continuous Multilabel Problems

Let us consider the variational problem

$$\min_{u \in BV(\Omega), 0 \leq u \leq M} \int_{\Omega} |Du| + \int_{\Omega} W(x, u(x)) dx, \quad (67)$$

where $W : \Omega \times \mathbb{R} \rightarrow \mathbb{R}^+$ is a potential which is Borel measurable in x and continuous in u , but not necessarily convex. Thus the functional is nonlinear and non-convex. The functional can be relaxed to a convex one by considering the subgraph of u as an unknown.

Our purpose is to write the nonlinearities in (67) in a “convex way” by introducing a new auxiliary variable [52]. This will permit to use standard optimization algorithms. The treatment here will be heuristic.

Without loss of generality, let us assume that $M = 1$. Let $\phi(x, s) = H(u(x) - s)$, where $H = \chi_{[0, +\infty)}$ is the Heaviside function and $s \in \mathbb{R}$. Notice that the set of points where $u(x) > s$ (the subgraph of u) is identified as $\phi(x, s) = 1$. That is, $\phi(x, s)$ is an embedding function for the subgraphs of u . This permits to consider the problem as a binary set problem. The graphs of u is a “cut” in ϕ .

Let

$$\mathcal{A} := \{\phi \in BV(\Omega \times [0, 1]) : \phi(x, s) \in \{0, 1\}, \forall (x, s) \in \Omega \times [0, 1]\}.$$

Using the definition of anisotropic total variation [7] we may write the energy in (67) in terms of ϕ as

$$\begin{aligned} \min_{\phi \in \mathcal{A}} & \int_{\Omega} \int_0^1 (|D_x \phi| + W(x, s)|\partial_s \phi(x, s)|) dx dt + \\ & \int_{\Omega} (W(x, 0)|\phi(x, 0) - 1| + W(x, 1)|\phi(x, 1)|) dx, \end{aligned} \quad (68)$$

where the boundary conditions $\phi(x, 0) = 1, \phi(x, 1) = 0$ are taken in a variational sense.

Although the energy (68) is convex in ϕ the problem is non-convex since the minimization is carried on \mathcal{A} which is a non-convex set. The proposal in [52] is to relax the variational problem by allowing ϕ to take values in $[0, 1]$. This leads to the following class of admissible functionals:

$$\tilde{\mathcal{A}} := \{\phi \in \text{BV}(\Omega \times [0, 1]) : \phi(x, s) \in [0, 1], \forall (x, s) \in \Omega \times [0, 1], \phi_s \leq 0\}. \quad (69)$$

The associated variational problem is written as

$$\begin{aligned} \min_{\phi \in \tilde{\mathcal{A}}} & \int_{\Omega} \int_0^1 (|D_x \phi| + W(x, s)|\partial_s \phi(x, s)|) dx dt + \\ & \int_{\Omega} (W(x, 0)|\phi(x, 0) - 1| + W(x, 1)|\phi(x, 1)|) dx. \end{aligned} \quad (70)$$

This problem is now convex and can be solved using the dual or primal-dual numerical schemes explained in sections “Chambolle’s Algorithm” and “Primal-Dual Approaches.” Formally, the level sets of a solution of (70) give solutions of (67). This can be proved using the developments in [7, 22].

In [30] the authors address the problem of convex formulation of multilabel problems with finitely many values including (67) and the case of non-convex neighborhood potentials like the Potts model or the truncated total variation. The general framework permits to consider the relaxation in $\text{BV}(\Omega)$ of functionals of the form

$$F(u) := \int_{\Omega} f(x, u(x), \nabla u(x)) dx \quad (71)$$

where $u \in W^{1,1}(\Omega)$ and $f : \Omega \times \mathbb{R} \times \mathbb{R}^N \rightarrow [0, \infty[$ be a Borel function such that $f(x, z, \xi)$ is a convex function of ξ for any $(x, z) \in \Omega \times \mathbb{R}^N$ satisfying some coercivity assumption in ξ . Let f^* denote the Legendre–Fenchel conjugate of f with respect to ξ . If

$$\begin{aligned} K := \{\phi = (\phi^x, \phi^s) : \Omega \times \mathbb{R} \rightarrow \mathbb{R}^2 : \phi \text{ is smooth and} \\ f^*(x, s, \phi^x(x, s)) \leq \phi^s(x, s)\}. \end{aligned}$$

then the lower semicontinuous relaxation of F is

$$\mathcal{F}(u) = \sup_{\phi \in K} \int_{\Omega} \int_{\mathbb{R}} \phi \cdot D\chi_{\{(x,s):s < u(x)\}}.$$

Based on this formula one can use a dual or a primal-dual numerical scheme to minimize $\mathcal{F}(u)$ if one knows how to compute the projection onto the convex set K . We refer to [30, 52] for details.

8 Other Problems: Image Restoration

To approach the problem of image restoration from a numerical point of view we shall assume that the image formation model incorporates the sampling process in a regular grid

$$f_{i,j} = (h * u)_{i,j} + n_{i,j}, \quad (i, j) \in \{1, \dots, N\}^2, \quad (72)$$

where $u : \mathbb{R}^2 \rightarrow \mathbb{R}$ denotes the ideal undistorted image, $h : \mathbb{R}^2 \rightarrow \mathbb{R}$ is a blurring kernel, f is the observed sampled image which is represented as a function $f : \{1, \dots, N\}^2 \rightarrow \mathbb{R}$, and $n_{i,j}$ is, as usual, a white Gaussian noise with zero mean and standard deviation σ .

Let us denote by Ω_N the interval $[0, N]^2$. As we said in the introduction, in order to simplify this problem, we assume that h, u are functions defined in Ω_N and are periodic of period N in each direction. To fix ideas, we assume that $h, u \in L^2(\Omega_N)$, so that $h * u$ is a continuous function in Ω_N and the samples $(h * u)_{i,j}$, $(i, j) \in \{1, \dots, N\}^2$, have sense.

Let us define the discrete functional

$$J_d^\beta(u) = \sum_{1 \leq i, j \leq N} \sqrt{\beta^2 + |(\nabla u)_{i,j}|^2}, \quad \beta \geq 0.$$

For any function $w \in L^2(\Omega_N)$, its Fourier coefficients are

$$\hat{w}_{\frac{l}{N}, \frac{j}{N}} = \int_{\Omega_N} w(x, y) e^{-2\pi i \frac{(lx+jy)}{N}} \quad \text{for } (l, j) \in \mathbb{Z}^2.$$

Our plan is to compute a band limited approximation to the solution of the restoration problem for (72). For that we define

$$\mathcal{B} := \left\{ u \in L^2(\Omega_N) : \hat{u} \text{ is supported in } \left\{ -\frac{1}{2} + \frac{1}{N}, \dots, \frac{1}{2} \right\} \right\}.$$

We notice that \mathcal{B} is a finite-dimensional vector space of dimension N^2 which can be identified with X . Both $J(u) = \int_{\Omega_N} |Du|$ and $J_d^0(u)$ are norms on the quotient space \mathcal{B}/\mathbb{R} ; hence they are equivalent. With a slight abuse of notation we shall indistinctly write $u \in \mathcal{B}$ or $u \in X$.

We shall assume that the convolution kernel $h \in L^2(\Omega_N)$ is such that \hat{h} is supported in $\{-\frac{1}{2} + \frac{1}{N}, \dots, \frac{1}{2}\}$ and $\hat{h}(0, 0) = 1$.

In the discrete framework, the ROF model for restoration is

$$\text{Minimize}_{u \in X} J_d^\beta(u) \quad (73)$$

$$\text{subject to } \sum_{i,j=1}^N |(h * u)_{i,j} - f_{i,j}|^2 \leq \sigma^2 N^2. \quad (74)$$

Notice again that the image acquisition model (1) is only incorporated through a global constraint. In practice, the above problem is solved via the following unconstrained formulation:

$$\min_{u \in X} \max_{\alpha \geq 0} J_d^\beta(u) + \frac{\alpha}{2} \left[\frac{1}{N^2} \sum_{i,j=1}^N |(h * u)_{i,j} - f_{i,j}|^2 - \sigma^2 \right] \quad (75)$$

where $\alpha \geq 0$ is a Lagrange multiplier. The appropriate value of α can be computed using Uzawa's algorithm [3] so that the constraint (74) is satisfied. Recall that if we interpret α^{-1} as a penalization parameter which controls the importance of the regularization term, and we set this parameter to be small, then homogeneous zones are well denoised while highly textured regions will lose a great part of its structure. On the contrary, if α^{-1} is set to be small, texture will be kept but noise will remain in homogeneous regions. On the other hand, as the authors of [3] observed, if we use the constrained formulation (73)–(74) or, equivalently (75), then the Lagrange multiplier does not produce satisfactory results since we do not keep textures and denoise flat regions simultaneously, and they proposed to incorporate the image acquisition model as a set of local constraints.

Following [3], we propose to replace the constraint (74) by

$$G * (h * u - f)_{i,j} \leq \sigma^2, \quad \forall (i, j) \in \{1, \dots, N\}^2, \quad (76)$$

where G is a discrete convolution kernel such that $G_{i,j} > 0$ for all $(i, j) \in \{1, \dots, N\}^2$. The effective support of G must permit the statistical estimation of the variance of the noise with (76) [3]. Then we shall minimize the functional $J_d^\beta(u)$ on X submitted to the family of constraints (76) (plus eventually the constraint $\sum_{i,j=1}^N (h * u)_{i,j} = \sum_{i,j=1}^N f_{i,j}$). Thus, we propose to solve the optimization problem:

$$\begin{aligned} & \min_{u \in \mathcal{B}} J_d^\beta(u) \\ & \text{subject to } G * (h * u - f)_{i,j}^2 \leq \sigma^2 \quad \forall (i, j). \end{aligned} \quad (77)$$

This problem is well posed, i.e., there exists a solution and is unique if $\beta > 0$ and $\inf_{c \in \mathbb{R}} G * (f - c)^2 > \sigma^2$. In case that $\beta = 0$ and $\inf_{c \in \mathbb{R}} G * (f - c)^2 > \sigma^2$, then $h * u$ is unique. Moreover, it can be solved with a gradient descent approach and Uzawa's method [3].

To guarantee that the assumptions of Uzawa's method hold we shall use a gradient descent strategy. For that, let $v \in X$ and $\gamma > 0$. At each step we have

to solve a problem like

$$\begin{aligned} & \min_{u \in \mathcal{B}} \gamma |u - v|_X^2 + J_d^\beta(u) \\ & \text{subject to } G * (h * u - f)_{i,j}^2 \leq \sigma^2 \quad \forall(i, j). \end{aligned} \quad (78)$$

We solve (78) using the unconstrained formulation

$$\min_{u \in X} \max_{\alpha \geq 0} \mathcal{L}^\gamma(u, \{\alpha\}; v),$$

where $\alpha = (\alpha_{i,j})_{i,j=1}^N$ and

$$\mathcal{L}^\gamma(u, \{\alpha\}; v) = \gamma |u - v|_X^2 + J_d^\beta(u) + \sum_{i,j=1}^N \alpha_{i,j} (G * (h * u - f)_{i,j}^2 - \sigma^2).$$

Algorithm: TV-Based Restoration Algorithm with Local Constraints

1. Set $u_0 = 0$ or, better, $u_0 = f$. Set $n = 0$.
2. Use Uzawa's algorithm to solve the problem

$$\min_{u \in X} \max_{\alpha \geq 0} \mathcal{L}^\gamma(u, \{\alpha\}; u^n), \quad (79)$$

that is:

- (a) Choose any set of values $\alpha_{i,j}^0 \geq 0$, $(i, j) \in \{1, \dots, N\}^2$, and $u_0^n = u^n$. Iterate from $p = 0$ until convergence of α^p the following steps:
- (b) With the values of α^p solve $\text{DP}(\gamma, u^n)$:

$$\min_u \mathcal{L}^\gamma(u, \{\alpha^p\}; u^n)$$

starting with the initial condition u_p^n . Let u_{p+1}^n be the solution obtained.

- (c) Update α in the following way:

$$\alpha_{i,j}^{p+1} = \max(\alpha_{i,j}^p + \rho(G * (h * u_p^n - f)_{i,j}^2 - \sigma^2), 0) \quad \forall(i, j).$$

Let u^{n+1} be the solution of (79). Stop when convergence of u^n .

We notice that, since $\gamma > 0$, Uzawa's algorithm converges if $f \in h * \mathcal{B}$. Moreover, if u^0 satisfies the constraints, then u^n tends to a solution u of (77) as $n \rightarrow \infty$ [3].

Finally, to solve problem (79) in Step 2(b) of the Algorithm we use either the extension of Chambolle's algorithm [25] to the restoration case if we use $\beta = 0$, or the quasi-Newton method as in [38] adapted to solve (79) when $\beta > 0$. For more details, we refer to [3, 38] and references therein.

Some Restoration Experiments

To simulate our data we use the modulation transfer function corresponding to SPOT 5 HRG satellite with Hipermode sampling (see [53] for more details):

$$\hat{h}(\eta_1, \eta_2) = e^{-4\pi\beta_1|\eta_1|} e^{-4\pi\alpha\sqrt{\eta_1^2 + \eta_2^2}} \text{sinc}(2\eta_1)\text{sinc}(2\eta_2)\text{sinc}(\eta_1), \quad (80)$$

where $\eta_1, \eta_2 \in [-1/2, 1/2]$, $\text{sinc}(\eta_1) = \sin(\pi\eta_1)/(\pi\eta_1)$, $\alpha = 0.58$, and $\beta_1 = 0.14$. Then we filter the reference image given in Fig. 4a with the filter (80) and we add some Gaussian white noise of zero mean and standard deviation σ (in our case $\sigma = 1$, which is a realistic assumption for the case of satellite images [53]) to obtain the image displayed in Fig. 4b.

Figure 5a displays the restoration of the image in Fig. 4b obtained using the Algorithm of last section with $\beta = 0$. We have used a Gaussian function G of radius 6. The mean value of the constraint is $\text{mean}((G * (Ku - f))^2) = 1.0933$ and RMSE = 7.9862. Figure 5b displays the function $\alpha_{i,j}$ obtained.

Figure 6 displays some details of the results that are obtained using a single global constraint (74) and show its main drawbacks. Figure 6a corresponds to the result obtained with the Lagrange multiplier $\alpha = 10$ (thus, the constraint (74) is satisfied). The result is not satisfactory because it is difficult to denoise smooth regions and keep the textures at the same time. Figure 6b shows that most textures are lost when using a small value of α ($\alpha = 2$) and Fig. 6c shows that some noise is present if we use a larger value of α ($\alpha = 1,000$). This result is to be compared with the same detail of Fig. 5a which is displayed in Fig. 6d.

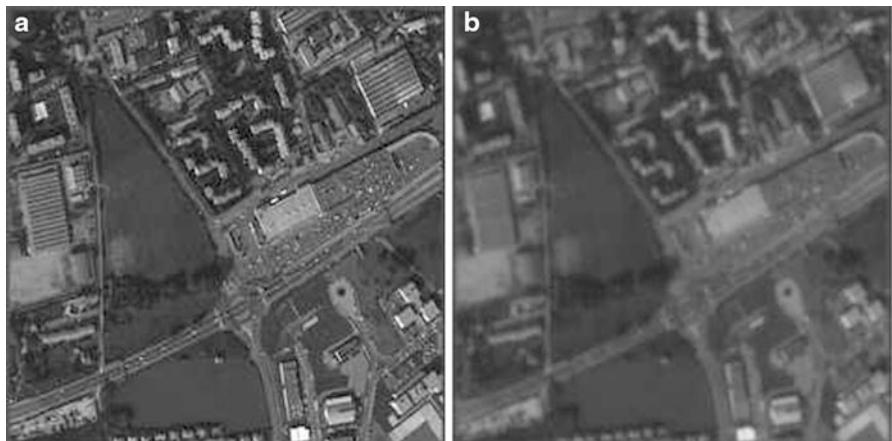

Fig. 4 Reference image and a filtered and noised image. (a) Left: reference image. (b) Right: the data. This image has been generated applying the MTF given in (80) to the top image and adding a Gaussian white noise of zero mean and standard deviation $\sigma = 1$

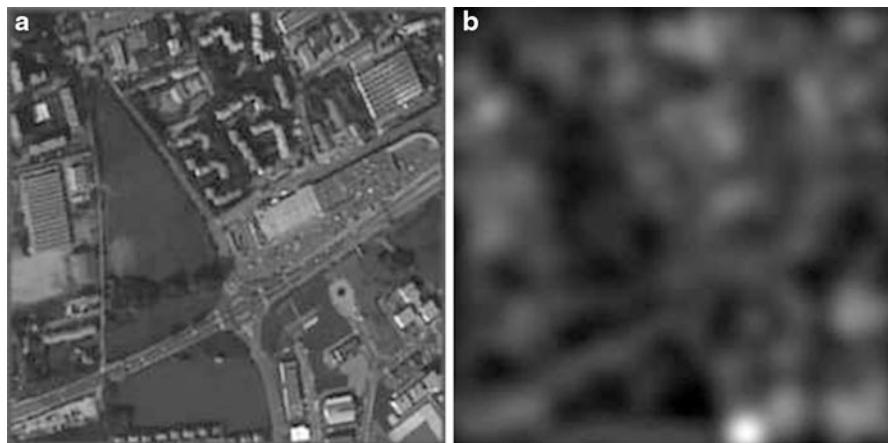

Fig. 5 Restored image with local Lagrange multipliers. (a) Left: the restored image corresponding to the data given in Fig. 4b. The restoration has been obtained using the Algorithm of last section with a Gaussian function G of radius 6. (b) Right: the function $\alpha_{i,j}$ obtained

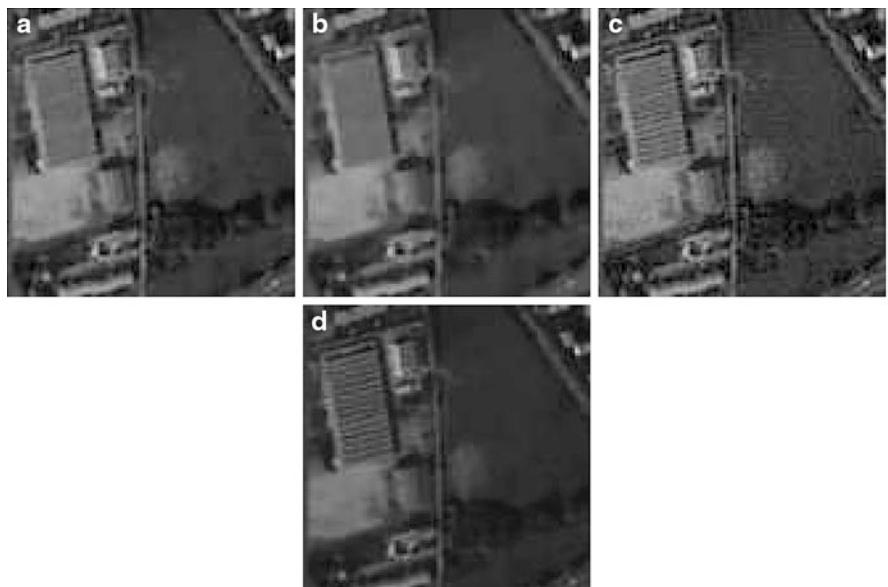

Fig. 6 A detail of the restored images with global and local constraints. Top: (a), (b), and (c) display a detail of the results that are obtained using a single global constraint (74) and show its main drawbacks. Figure (a) corresponds to the result obtained with the value of α such that the constraint (74) is satisfied, in our case $\alpha = 10$. Figure (b) shows that most textures are lost when using a small value of α ($\alpha = 2$) and Figure (c) shows that some noise is present if we use a larger value of α ($\alpha = 1,000$). Bottom: (d) displays the same detail of Fig. 5a which has been obtained using restoration with local constraints

The Image Model

For the purpose of image restoration the process of image formation can be modeled in a first approximation by the formula [53]

$$f = Q\{\Pi(h * u) + n\}, \quad (81)$$

where u represents the photonic flux, h is the point spread function of the optical-sensor joint apparatus, Π is a sampling operator, i.e., a Dirac comb supported by the centers of the matrix of digital sensors, n represents a random perturbation due to photonic or electronic noise, and Q is a uniform quantization operator mapping \mathbb{R} to a discrete interval of values, typically $[0, 255]$.

The Modulation Transfer Function for Satellite Images We describe here a simple model for the Modulation Transfer Function of a general satellite. More details can be found in [53] where specific examples of MTF for different acquisition systems are shown. The MTF used in our experiments (80) corresponds to a particular case of the general model described below [53].

Recall that the MTF, which we denote by \hat{h} , is the Fourier transform of the point spread function of the system. Let $(\eta_1, \eta_2) \in [-1/2, 1/2]^2$ denote the coordinates in the frequency domain. There are different parts in the acquisition system that contribute to the global transfer function: the optical system, the sensor, and the blur effects due to motion. Since each subsystem is considered as linear and translation invariant, it is modeled by a convolution operator. The kernel k of the joint system is thus the convolution of the point spread functions of the separated systems.

- **Sensors:** In CCD arrays every sensor has a sensitive region where all the photons that arrive are integrated. This region can be approximated by a unit square $[-c/2, c/2]^2$ where c is the distance between consecutive sensors. Its impulse response is then the convolution of two pulses, one in each spatial direction. The corresponding transfer function also includes the effect of the conductivity (diffusion of information) between neighboring sensors, which is modeled by an exponential decay factor; thus:

$$\hat{h}_S(\eta_1, \eta_2) = \text{sinc}(\eta_1 c) \text{sinc}(\eta_2 c) e^{-2\pi\beta_1 c |\eta_1|} e^{-2\pi\beta_2 c |\eta_2|},$$

where $\text{sinc}(\eta_1) = \sin(\pi\eta_1)/(\pi\eta_1)$ and $\beta_1, \beta_2 > 0$.

- **Optical system:** The optical system has essentially two effects on the image: it projects the objects from the object plane to the image plane and degrades it. The degradation of the image due to the optical system makes that a light point source loses definition and appears as a blurred (small) region. This effect can be explained by the wave nature of light and its diffraction theory. Discarding other degradation effects due to the imperfect optical systems like lens aberrations [11], the main source of degradation will be the diffraction of the light when passing through a finite aperture: those systems are called diffraction limited systems.

Assuming that the optical system is linear and translation invariant we know that it can be modeled by a convolution operator. Indeed, if the system is linear and translation invariant, it suffices to know the response of the system to a light point source located at the origin, which is modeled by a Dirac delta function δ , since any other light distribution could be approximated (in a weak topology) by superpositions of Dirac functions. The convolution kernel is, thus, the result of the system acting on δ .

If we measure the light intensity and we use a circular aperture the MTF is considered as an isotropic low-pass filter

$$\hat{h}_O(\eta_1, \eta_2) = e^{-2\pi\alpha c \sqrt{\eta_1^2 + \eta_2^2}}, \quad \alpha > 0.$$

- **Motion:** each sensor counts the number of photons that arrive to its sensitive region during a certain time of acquisition. During the sampling time the system moves a distance τ and so does the sensor; this produces a motion blur effect in the motion direction (d_1, d_2) :

$$\hat{h}_M(\eta_1, \eta_2) = \text{sinc}((\eta_1, \eta_2), (d_1, d_2)\tau).$$

Finally, the global MTF is the product of each of these intermediate transfer functions modeling the different aspects of the satellite:

$$\hat{h}(\eta_1, \eta_2) = \hat{h}_S \hat{h}_O \hat{h}_M.$$

Noise We shall describe the typical noise in case of a *CCD* array. Light is constituted by photons (quanta of light) and those photons are counted by the detector. Typically, the sensor registers light intensity by transforming the number of photons which arrive to it into an electric charge, counting the electrons which the photons take out of the atoms. This is a process of a quantum nature and therefore there are random fluctuations in the number of photons and photoelectrons on the photoactive surface of the detector. To this source of noise we have to add the thermal fluctuations of the circuits that acquire and process the signal from the detector's photoactive surface. This random thermal noise is usually described by a zero-mean white Gaussian process. The photoelectric fluctuations are more complex to describe: for low light levels, photoelectric emission is governed by Bose–Einstein statistics, which can be approximated by a Poisson distribution whose standard deviation is equal to the square root of the mean; for high light levels, the number of photoelectrons emitted (which follows a Poisson distribution) can be approximated by a Gaussian distribution which, being the limit of a Poisson process, inherits the relation between its standard deviation and its mean [11]. In a first approximation this noise is considered as spatially uncorrelated with a uniform power spectrum, thus a white noise. Finally, both sources of noise are assumed to be independent.

Taken together, both sources of noise are approximated by a Gaussian white noise, which is represented in the basic equation (81) by the noise term n . The average signal to noise ratio, called the *SNR*, can be estimated by the quotient between the signals average and the square root of the variance of the signal.

The detailed description of the noise requires knowledge of the precise system of image acquisition. More details in the case of satellite images can be found in [53] and references therein.

9 Final Remarks: A Different Total Variation-Based Approach to Denoising

Let us briefly comment on the interesting work [47] which interprets the total variation model for image denoising in a Bayesian way leading to a different algorithm based on stochastic optimization which produces better results.

We work again in the discrete setting and consider the image model

$$f_{i,j} = u_{i,j} + n_{i,j} \quad (i, j) \in \{1, \dots, N\}^2, \quad (82)$$

where $n_{i,j}$ is a white Gaussian noise with zero mean and standard deviation σ .

The solution of (36) can be viewed as a Maximum a Posteriori (MAP) estimate of the original image u . Let $\beta > 0$ and let p_β be the prior probability density function defined by

$$p_\beta(u) \propto e^{-\beta J_d(u)} \quad u \in X,$$

where we have omitted the normalization constant. The prior distribution models the gradient norms of each pixel as independent and identically distributed random variables following a Laplace distribution. Although the model does not exactly fit the reality since high gradient norms in real images are concentrated along curves and are not independent, it has been found to be convenient and efficient for many tasks in image processing and we follow it here.

Since the probability density of f given u is the density for $n = f - u$, then

$$p(f|u) \propto e^{-\frac{\|f-u\|_X^2}{2\sigma^2}}.$$

Using Bayes rule, the posterior density of u given f is

$$p_\beta(u|f) = \frac{1}{Z} p(f|u) p_\beta(u) = \frac{1}{Z} e^{-\left(\frac{\|f-u\|_X^2}{2\sigma^2} + \beta J_d(u)\right)}, \quad (83)$$

where $Z = \int_{\mathbb{R}^{N^2}} e^{-\left(\frac{\|f-u\|_X^2}{2\sigma^2} + \beta J_d(u)\right)} du$ is the normalization constant making the mass of $p_\beta(u|f)$ to be 1. Then the maximization of the a posteriori density (83) is equivalent to the minimization problem (36) provided that $\beta\sigma^2 = \lambda$.

Fig. 7 (a) Left: the result obtained by computing $E(u|f)$ and $\beta\sigma^2 = \lambda = 20$, $\sigma = 10$ (image courtesy of Cécile Louchet). (b) Right: the result obtained using Chambolle's algorithm with $\lambda = 20$

The estimation of u proposed in [47] consists in computing the expected value of u given f :

$$E(u|f) = \frac{1}{Z} \int_{\mathbb{R}^{N^2}} u p_\beta(u|f) du = \frac{1}{Z} \int_{\mathbb{R}^{N^2}} ue^{-\left(\frac{\|f-u\|_X^2}{2\sigma^2} + \beta J_d(u)\right)} du. \quad (84)$$

This estimate requires to compute an integral in a high dimensional space. In [47], the authors propose to approximate this integral with a Markov Chain Monte-Carlo algorithm (MCMC). In Fig. 7a we display the result of denoising the image in Fig. 2b which has a noise of standard deviation $\sigma = 10$ with the parameter $\beta = \frac{20}{\sigma^2}$. In Fig. 7b we display the denoising of the same image using Chambolle's algorithm with $\lambda = 20$. Notice that in both cases the parameter λ is the same.

10 Conclusion

We have given in this chapter an overview of recent developments on the total variation model in imaging. Its strong influence comes from its ability to recover the image discontinuities and is the basis of numerous applications to denoising, optical flow, stereo imaging and 3D surface reconstruction, segmentation, or interpolation to mention some of them. We have reported the recent theoretical progress on the understanding of its main qualitative features. We have also reviewed the main numerical approaches to solve different models where total variation appears. We have described both the main iterative schemes and the global optimization methods based on the use of max-flow algorithms. Then, we reviewed the use of anisotropic total variation models to solve different geometric problems and its recent use in

finding a convex formulation of some nonconvex total variation problems. We have also studied the total variation formulation of image restoration and displayed some results. We have also reviewed a very recent point of view which interprets the total variation model for image denoising in a Bayesian way, leading to a different algorithm based on stochastic optimization which produces better results.

Acknowledgments We would like to thank Cécile Louchet for providing us the experiments of Sect. 9 and Gabriele Facciolo and Enric Meinhardt for the experiments in section “Global Solutions of Geometric Problems”. V. Caselles acknowledges partial support by PNP-GC project, reference MTM2006-14836, and also by “ICREA Acadèmia” for excellence in research funded by the Generalitat de Catalunya.

the most popular and successful methodologies for image restoration. New developments continue to expand the capability of the basic method in various aspects. Many faster numerical algorithms and more sophisticated applications have been proposed. This chapter reviews some of these recent developments.

1 Introduction

Images acquired through an imaging system are inevitably degraded in various ways. The types of degradation include noise corruption, blurring, missing values in the pixel domain or transformed domains, intensity saturation, jittering, etc. Such degradations can have adverse effects on high-level image processing tasks such as object detection and recognition. Image restoration aims at recovering the original image from its degraded version(s) to facilitate subsequent processing tasks. Image data differ from many other kinds of data due to the presence of edges, which are important features in human perception. It is therefore essential to preserve and even reconstruct edges in the processing of images. Variational methods for image restoration have been extensively studied in the past couple of decades. A promise of these methods is that the geometric regularity of the resulting images is explicitly controlled by using well-established descriptors in geometry. For example, smoothness of object boundaries can be easily manipulated by controlling their length. There has also been much research in designing variational methods for preserving other important image features such as textures.

Among the various restoration problems, denoising is perhaps the most fundamental one. Indeed, all algorithms for solving ill-posed restoration problems have to have some denoising capabilities either explicitly or implicitly, for otherwise they cannot cope with any error (noise) introduced during image acquisition or numerical computations. Moreover, the noise removal problem boils down to the fundamental problem of modeling natural images which has great impacts on any image processing tasks. Therefore, research on image denoising has been very active.

2 Background

Total variation (TV)-based image restoration models are introduced by Rudin, Osher, and Fatemi (ROF) in their seminal work [51] on edge-preserving image denoising. It is one of the earliest and best-known examples of variational partial differential equation (PDE)-based edge-preserving denoising models. In this model, the geometric regularity of the resulting image is explicitly imposed by reducing the amount of oscillation while allowing for discontinuities (edges). The unconstrained version introduced in [1] reads:

$$\inf_{u \in L^2(\Omega)} \int_{\Omega} |\nabla u| + \mu \int_{\Omega} (u - f)^2 d\mathbf{x}.$$

Here, Ω is the image domain, $f : \Omega \rightarrow \mathcal{R}$ is the observed noisy image, $u : \Omega \rightarrow \mathcal{R}$ is the denoised image, and $\mu \geq 0$ is a parameter depending on the noise level. The first term is the *total variation* (TV) which is a measure of the amount of oscillation in the resulting image u . Its minimization would reduce the amount of oscillation which presumably reduces noise. The second term is the L^2 distance between u and f , which encourages the denoised image to inherit most features from the observed data. Thus, the model trades off the closeness to f by gaining the regularity of u . The noise is assumed to be additive and Gaussian with zero mean. If the noise variance level σ^2 is known, then the parameter μ can be treated as the Lagrange multiplier, restraining the resulting image to be consistent with the known noise level, i.e., $\int_{\Omega} (u - f)^2 d\mathbf{x} = |\Omega| \sigma^2$ [16].

The ROF model is simple and elegant for edge-preserving denoising. Since its introduction, this model has ignited a great deal of research in constructing more sophisticated variants which can give better reconstructed images, designing faster numerical algorithms for solving the optimization problem numerically, and finding new applications in various domains. In a previous book chapter [21] published in 2005, the authors surveyed some recent progresses in the research of total variation-based models. The present chapter aims at highlighting some exciting latest developments in numerical methods and applications of total variation-based methods since the last survey.

3 Mathematical Modeling and Analysis

In this section, the basic definition of total variation and some of its variants are presented. Then, some recent TV-based mathematical models in imaging are reviewed.

Variants of Total Variation

Basic Definition

The use of TV as a regularizer has been shown to be very effective for processing images because of its ability to preserve edges. Being introduced for different reasons, several variants of TV can be found in the literature. Some variants can handle more sophisticated data such as vector-valued imagery and matrix-valued tensors; some are designed to improve restoration quality, and some are modified versions for the ease of numerical implementation. It is worthwhile to review the basic definition and its variants.

In Rudin, Osher, and Fatemi's work [51], the TV of an image $f : \Omega \rightarrow \mathcal{R}$ is defined as

$$\int_{\Omega} |\nabla f| d\mathbf{x},$$

where $\Omega \subseteq \mathbb{R}^2$ is a bounded open set. Since the image f may contain discontinuities, the gradient ∇f must be interpreted in a generalized sense. It is well known that elements of the Sobolev space $W^{1,1}(\Omega)$ cannot have discontinuities [2]. Therefore, the TV cannot be defined through the completion of the space C^1 of continuously differentiable functions under the Sobolev norm. The ∇f is thus interpreted as a distributional derivative, and its integral is interpreted as a distributional integral [40]. Under this framework, the minimization of TV naturally leads to a PDE with a distribution as a solution.

Besides defining TV as a distributional integral, other perspectives can offer some unique advantages. A set theoretical way is to define TV as a Radon measure of the domain Ω [50]. This has an advantage of allowing Ω to be a more general set. But a more practical and simple alternative is the “dual formulation.” It uses the usual trick in defining weak derivatives – integration by parts – together with the Fenchel transform,

$$\int_{\Omega} |\nabla f| = \sup \left\{ \int_{\Omega} f \operatorname{div} \mathbf{g} d\mathbf{x} \mid \mathbf{g} \in C_c^1(\Omega, \mathbb{R}^2), |\mathbf{g}(\mathbf{x})| \leq 1 \forall \mathbf{x} \in \Omega \right\} \quad (1)$$

where $f \in L^1(\Omega)$ and div is the divergence operator. Using this definition, one can bypass the discussion of distributions. It also plays an important role in many recent works in dual and primal-dual methods for solving TV minimization problems. The space BV can now be defined as

$$BV(\Omega) := \left\{ f \in L^1(\Omega) \mid \int_{\Omega} |\nabla f| < \infty \right\}.$$

Equipped with the norm $\|f\|_{BV} = \|f\|_{L^1} + \int_{\Omega} |\nabla f|$, this space is complete and is a proper superset of $W^{1,1}(\Omega)$ [32].

Multichannel TV

Many practical images are acquired in a multichannel way, where each channel emphasizes a specific kind of signal. For example, color images are often acquired through the RGB color components, whereas microscopy images consist of measurements of different fluorescent labels. The signals in the different channels are often correlated (contain redundant information). Therefore, in many practical situations, regularization of multichannel images should not be done independently on each channel.

There are several existing ways to generalize TV to vectorial data. A review of some generalizations can be found in [20]. Many generalizations are very intuitive. But only some of them have a natural dual formulation. Sapiro and Ringach [52] proposed to define

$$\int_{\Omega} |\nabla f| := \int_{\Omega} \sqrt{\sum_{i=1}^M |\nabla f_i|^2} d\mathbf{x} = \int_{\Omega} |\nabla f|_F d\mathbf{x},$$

where $f = (f_1(\mathbf{x}), f_2(\mathbf{x}), \dots, f_M(\mathbf{x}))$ is the vectorial data with M channels. Thus, it is the integral of the Frobenius norm $|\cdot|_F$ of the Jacobian ∇f . The dual formulation given in [10] is

$$\sup \left\{ \int_{\Omega} \langle f, \operatorname{div} \mathbf{g} \rangle d\mathbf{x} \mid \mathbf{g} \in C_c^1(\Omega, \mathbb{R}^{2 \times M}), |\mathbf{g}(\mathbf{x})|_F \leq 1 \forall \mathbf{x} \in \Omega \right\},$$

where $\langle f, \operatorname{div} \mathbf{g} \rangle = \sum_{i=1}^M f_i \operatorname{div} \mathbf{g}_i$.

Matrix-Valued TV

In applications such as diffusion tensor imaging (DTI), the measurements at each spatial location are represented by a diffusion tensor, which is a 3×3 symmetric positive semi-definite matrix. Recent efforts have been devoted to generalize the TV to matrix-valued images. Some natural generalizations can be obtained by identifying an $M \times N$ matrix with an MN vector, so that a vector-valued total variation can be applied. This was done by Tschumperlé and Deriche [57], who generalized the vectorial TV of [7]. The main challenge is to preserve the positive definiteness of the denoised solution. This will be elaborated in section ‘‘Diffusion Tensors Images.’’

Another interesting approach proposed by Setzer et al. [54] is the so-called operator-based regularization. Given a matrix-valued function $f = (f_{ij}(\mathbf{x}))$, define a matrix function $A := (a_{ij})$ where $a_{ij} = |\nabla f_{ij}|^2$. Let $\Phi(A)$ be the matrix obtained by replacing each eigenvalue λ of A with $\sqrt{\lambda}$. Then the total variation is defined to be $\int_{\Omega} |\Phi(A)|_F d\mathbf{x}$, where $|\cdot|_F$ is the Frobenius norm. While this formulation seems complicated, its first variation turns out to have a nice simple formula. However, when combined with the ROF model, the preservation of positive definiteness is an issue.

Discrete TV

The ROF model is cast as an infinite-dimensional optimization problem over the BV space. To solve the problem numerically, one must discretize the problem at some stage. The approach proposed by Rudin et al. in [51] is to ‘‘optimize then discretize.’’ The gradient flow equation is discretized with a standard finite difference scheme. This method works very well in the sense that the numerical solution converges to a steady state which is qualitatively consistent with the expected result of the (continuous) ROF model. However, to the best of the authors’ knowledge, a theoretical proof of convergence of the numerical solution to the exact solution of the gradient flow equation as the grid size tends to zero is not yet available. A standard convergence result of finite difference schemes for nonlinear PDE is based on the compactness of TV-bounded sets in L^1 [46]. However, proving TV boundedness in two or more dimensions is often difficult.

An alternative approach is to ‘‘discretize then optimize.’’ In this case, only one has to solve a finite-dimensional optimization problem, whose numerical solution can in many cases be shown to converge. But the convergence of the exact solution

of the finite-dimensional problems to the exact solution of the original infinite-dimensional problem is often hard to obtain too. So, both approaches suffer from the theoretical convergence problem. But the latter method has a precise discrete objective to optimize.

To discretize the ROF objective, the fitting term is often straightforward. But the discretization of the TV term has a strong effect on the numerical schemes. The most commonly used versions of discrete TV are

$$\|f\|_{TV} = \sum_{i=1}^{m-1} \sum_{j=1}^{n-1} \sqrt{(f_{i+1,j} - f_{i,j})^2 + (f_{i,j+1} - f_{i,j})^2} \Delta x, \quad (2)$$

$$\|f\|_{TV} = \sum_{i=1}^{m-1} \sum_{j=1}^{n-1} (|f_{i+1,j} - f_{i,j}| + |f_{i,j+1} - f_{i,j}|) \Delta x, \quad (3)$$

where $f = (f_{i,j})$ is the discrete image and Δx is the grid size. They are sometimes referred as the *isotropic* and *anisotropic* versions, respectively, for they are a formal discretization of the isotropic TV $\int_{\Omega} \sqrt{f_x^2 + f_y^2} d\mathbf{x}$ and the anisotropic TV $\int_{\Omega} (|f_x| + |f_y|) d\mathbf{x}$, respectively. The anisotropic TV is not rotational invariant; an image and its rotation can have a different TV value. Therefore, the discrete TV (3) deviates from the original isotropic TV. But being a piecewise linear function, some numerical techniques for quadratic and linear problems can be applied. Indeed, by introducing some auxiliary variables, the corresponding discrete ROF objective can be converted into a canonical quadratic programming problem [30].

Besides using finite difference approximations, a recent popular way is to represent TV on graphs [27]. To make the problem fully discrete, the range of the image is quantized to a finite set of K integers only, usually 0–255. The image is “leveled,” so that $f_{i,j}^k = 1$ if the intensity of the (i, j) th pixel is at most k , and $f_{i,j}^k = 0$ otherwise. Then, the TV is given by

$$\|f\|_{TV} = \sum_{k=0}^{K-1} \sum_{i,j} \sum_{s,t} w_{i,j,s,t} |f_{i,j}^k - f_{s,t}^k|, \quad (4)$$

where $w_{i,j,s,t}$ is a nonnegative weight. A simple choice is the four-connectivity model, where $w_{i,j,s,t} = 1$ if $|i - s| + |j - t| \leq 1$ and $w_{i,j,s,t} = 0$ otherwise. In this case, it becomes the anisotropic TV (3). Different choices of the weights penalize edges in different orientations.

A related concept introduced by Shen and Kang is the *quantum total variation* [55]. They studied the ROF model when the range of an image is a finite discrete set (preassigned or determined on the fly), but the image domain is a continuous one. The model is suitable for problems such as bar code scanning, image quantization, and image segmentation. An elegant analysis of the model and some stochastic gradient descent algorithms were presented there.

Nonlocal TV

First proposed by Buades et al. [11], the nonlocal means algorithm renounces the use of local smoothness to denoise an image. Patches which are spatially far away but photometrically similar are also utilized in the estimation process – a paradigm which has been used in texture synthesis [28]. The denoising results are surprisingly good. Since then, the use of nonlocal information becomes increasingly popular. In particular, Bresson and Chan [10] and Gilboa and Osher [31] considered the nonlocal TV. The nonlocal gradient $\nabla_{NL} f$ for a pair of points $\mathbf{x} \in \Omega$ and $\mathbf{y} \in \Omega$ is defined by

$$\nabla_{NL} f(\mathbf{x}, \mathbf{y}) = \sqrt{w(\mathbf{x}, \mathbf{y})} (f(\mathbf{x}) - f(\mathbf{y})),$$

where $w(\mathbf{x}, \mathbf{y})$ is a nonnegative weight function which is presumably a similarity measure between a patch around \mathbf{x} and a patch around \mathbf{y} . As an illustration, a simple choice of the weight function is

$$w(\mathbf{x}, \mathbf{y}) = \alpha_1 e^{-|\mathbf{x}-\mathbf{y}|^2/\sigma_1^2} + \alpha_2 e^{-|F(\mathbf{x})-F(\mathbf{y})|^2/\sigma_2^2},$$

where α_i and σ_i are positive constants, and $F(\mathbf{x})$ is a feature vector derived from a patch around \mathbf{x} . The constants α_i may sometimes be defined to depend on \mathbf{x} , so that the total weight over all $\mathbf{y} \in \Omega$ is normalized to 1. In this case, the weight function is nonsymmetric with respect to its arguments. The first term in w is a measure of geometric similarity, so that nearby pixels have a higher weight. The second term is a measure of photometric similarity. The feature vector F can be the color histogram or any texture descriptor over a window around \mathbf{x} . The norm of the nonlocal gradient at \mathbf{x} is defined by

$$|\nabla_{NL} f(\mathbf{x})| = \sqrt{\int_{\Omega} [\nabla_{NL} f(\mathbf{x}, \mathbf{y})]^2 d\mathbf{y}},$$

which adds up all the squared intensity variation relative to $f(\mathbf{x})$, weighted by the similarity between the corresponding pair of patches. The nonlocal TV is then naturally defined by summing up all the norms of the nonlocal gradients over the image domain:

$$\int_{\Omega} |\nabla_{NL} f| d\mathbf{x}.$$

Therefore, the nonlocal TV is small if, for each pair of similar patches, the intensity difference between their centers is small. An advantage of using the nonlocal TV to regularize images is its tendency to preserve highly repetitive patterns better. In practice, the weight function is often truncated to reduce the computation costs spent in handling the many less similar patches.

Further Applications

Inpainting in Transformed Domains

After the release of the image compression standard JPEG2000, images can be formatted and stored in terms of wavelet coefficients. For instance, in Acrobat 6.0 or later, users can opt to use JPEG2000 to compress embedded images in a PDF file. During the process of storing or transmission, some wavelet coefficients may be lost or corrupted. This prompts the need of restoring missing information in wavelet domains. The setup of the problem is as follows. Denote the standard orthogonal wavelet expansion of the images f and u by

$$f(\alpha) = \sum_{j,k} \alpha_{j,k} \psi_{j,k}(x), \quad j \in \mathbb{Z}, k \in \mathbb{Z}^2,$$

and

$$u(\beta) = \sum_{j,k} \beta_{j,k} \psi_{j,k}(x), \quad j \in \mathbb{Z}, k \in \mathbb{Z}^2,$$

where $\{\Psi_{j,k}\}$ is the wavelet basis, and $\{\alpha_{j,k}\}$, $\{\beta_{j,k}\}$ are the wavelet coefficients of f and u given by

$$\alpha_{j,k} = \langle f, \psi_{j,k} \rangle \quad \text{and} \quad \beta_{j,k} = \langle u, \psi_{j,k} \rangle,$$

respectively, for $j \in \mathbb{Z}$, $k \in \mathbb{Z}^2$. For convenience, $u(\beta)$ is denoted by u when there is no ambiguity. Assume that the wavelet coefficients in the index set I are known, i.e., the available wavelet coefficients are given by

$$\xi_{j,k} = \begin{cases} \alpha_{j,k}, & (j,k) \in I, \\ 0, & (j,k) \in \Omega \setminus I. \end{cases}$$

The aim of wavelet domain inpainting is to reconstruct the wavelet coefficients of u from the given coefficients ξ . It is well known that the inpainting problem is ill posed, i.e., it admits more than one solution. There are many different ways to fill in the missing coefficients, and therefore many different reconstructions in the pixel domain are possible. Regularization methods can be used to incorporate prior information about the reconstruction. In [23], Chan, Shen, and Zhou used TV to solve the wavelet inpainting problem, so that the missing coefficients are filled while preserving sharp edges in the pixel domain faithfully. More precisely, they considered the minimization of the following objective

$$F(\beta) = \frac{1}{2} \sum_{j,k} \chi_{j,k} (\xi_{j,k} - \beta_{j,k})^2 + \lambda \|u\|_{TV}, \quad (5)$$

with $\chi_{j,k} = 1$ if $(j, k) \in I$ and $\chi_{j,k} = 0$ if $(j, k) \in \Omega \setminus I$, and λ is the regularization parameter. The first term in F is the data-fitting term, and the second is the TV regularization term. The method Chan, Shen, and Zhou used to optimize the objective is the standard gradient descent. The method is very robust, but it often slows down significantly before it converges.

In [18], Chan, Wen, and Yip proposed an efficient *optimization transfer algorithm* to minimize the objective (5). An auxiliary variable ζ is introduced to yield a new objective function:

$$G(\zeta, \beta) = \frac{1+\tau}{2\tau} \left(\|\chi(\zeta - \xi)\|_2^2 + \tau \|\zeta - \beta\|_2^2 \right) + \lambda \|u(\beta)\|_{TV},$$

where χ denotes a diagonal matrix with diagonal entries $\chi_{j,k}$, and τ is an arbitrary positive parameter. The function G is a quadratic majorizing function [43] of F . The method also has a flavor of the splitting methods introduced in section “Splitting Methods.” But a major difference is that the method here solves the original problem (5) without any alteration. It can be easily shown that

$$F(\beta) = \min_{\zeta} G(\zeta, \beta)$$

for any positive regularization parameter τ . Thus, the minimization of G w.r.t. (ζ, β) is equivalent to the minimization of F w.r.t. β for any $\tau > 0$. Unlike the gradient descent method of [23], the optimization transfer algorithm avoids the use of derivatives of the TV. It also does not require smoothing out the TV to make it differentiable. The experimental results in [18] showed that the algorithm is very efficient and outperforms the gradient descent method.

Superresolution

Image superresolution refers to the process of increasing spatial resolution by fusing information from a sequence of low-resolution images of the same scene. The images are assumed to contain subpixel information (due to subpixel displacements or blurring), so that the superresolution is possible.

In [24], Chan et al. proposed a unified TV model for superresolution imaging problems. They focused on the problem of reconstructing a high-resolution image from several decimated, blurred, and noisy low-resolution versions of the high-resolution image. They derived a low-resolution image formation model which allows multiple-shifted and blurred low-resolution image frames, so that it subsumes several well-known models. The model also allows an arbitrary pattern of missing pixels (in particular an arbitrary pattern of missing frames). The superresolution image reconstruction problem is formulated as an optimization problem which combines the image formation model and the TV inpainting model. In this method, TV minimization is used to suppress noise amplification, repair corrupted pixels in regions without missing pixels, and reconstruct intensity levels in regions with missing pixels.

Image Formation Model The observation model, Chan et al. considered, consists of various degradation processes. Assume that a number of $m \times n$ low-resolution frames are captured by an array of charge-coupled device (CCD) sensors. The goal is to reconstruct an $Lm \times Ln$ high-resolution image. Thus, the resolution is increased by a factor of L in each dimension. Let u be the ideal $Lm \times Ln$ high-resolution clean image.

1. *Formation of low-resolution frames.* A low-resolution frame is given by

$$D_{p,q}Cu,$$

where C is an averaging filter with window size L -by- L , and $D_{p,q}$ is the downsampling matrix which, starting at the (p, q) th pixel, samples every other L pixels in both dimensions to form an $m \times n$ image.

2. *Blurring of frames.* This is modeled by

$$H_{p,q}D_{p,q}Cu,$$

where $H_{p,q}$ is the blurring matrix for the (p, q) th frame.

3. *Concatenation of frames.* The full set of L^2 frames are interlaced to form an $mL \times nL$ image:

$$Au,$$

where

$$A = \sum_{p,q} D_{p,q}^T H_{p,q} D_{p,q} C.$$

4. *Additive Noise.*

$$Au + \eta,$$

where each pixel in η is a Gaussian white noise.

5. *Missing pixels and missing frames.*

$$f = \Lambda_{\mathcal{D}}(Au + \eta),$$

where \mathcal{D} denotes the set of missing pixels, and $\Lambda_{\mathcal{D}}$ is the downsampling matrix from the image domain to \mathcal{D} .

6. *Multiple observations.* Finally, multiple observations of the same scene, but with different noise and blurring, are allowed. This leads to the model

$$f_r = \Lambda_{\mathcal{D}_r}(A_r u + \eta_r) \quad r = 1, \dots, R, \tag{6}$$

where

$$A_r = \sum_{p,q} D_{p,q}^T H_{p,q,r} D_{p,q} C.$$

TV Superresolution Imaging Model To invert the degradation processes in (6), a Tikhonov-type regularization model has been used. It requires minimization of the following energy:

$$F(u) = \frac{1}{2} \sum_{r=1}^R \|\Lambda_{\mathcal{D}_r} A_r u - f_r\|^2 + \lambda \|u\|_{TV}.$$

This model simultaneously performs denoising, deblurring, inpainting, and super-resolution reconstruction. Experimental results show that reasonably good reconstruction can be obtained even if five-sixth of the pixels are missing and the frames are blurred.

Image Segmentation

TV minimization problems also arise from image segmentation. When one seeks for a partition of the image into homogeneous segments, it is often helpful to regularize the shape of the segments. This can increase the robustness of the algorithm against noise and avoid spurious segments. It may also allow the selection of features of different scales. In the classical Mumford-Shah model [47], the regularization is done by minimizing the total length of the boundary of the segments. In this case, if one represents a segment by its characteristic function, then the length of its boundary is exactly the TV of the characteristic function. Therefore, the minimization of length becomes the minimization of TV of characteristic functions.

Given an observed image f on an image domain Ω , the piecewise constant Mumford-Shah model seeks a set of curves C and a set of constant $\mathbf{c} = (c_1, c_2, \dots, c_L)$ which minimize the energy functional given by

$$F^{MS}(C, \mathbf{c}) = \sum_{l=1}^L \int_{\Omega_l} [f(\mathbf{x}) - c_l]^2 d\mathbf{x} + \beta \cdot \text{Length}(C).$$

The curves in C partition the image into L mutually exclusive segments Ω_l for $l = 1, 2, \dots, L$. The idea is to partition the image, so that the intensity of f in each segment Ω_l is well approximated by a constant c_l . The goodness of fit is measured by the L^2 difference between f and c_l . On the other hand, a minimum description length principle is employed which requires the curves C to be as short as possible. This increases the robustness to noise and avoids spurious segments. The parameter $\beta > 0$ controls the trade-off between the goodness of fit and the length of the curves C . The Mumford-Shah objective is nontrivial to optimize especially when the curves need to be split and merged. Chan and Vese [24] proposed a level set-based method which can handle topological changes effectively. In the two-phase

version of this method, the curves are represented by the zero level set of a Lipschitz level set function Φ defined on the image domain. The objective function then becomes

$$\begin{aligned} F^{\text{CV}}(\phi, c_1, c_2) = & \int_{\Omega} H(\phi(\mathbf{x})) [f(\mathbf{x}) - c_1]^2 d\mathbf{x} \\ & + \int_{\Omega} [1 - H(\phi(\mathbf{x}))] [f(\mathbf{x}) - c_2]^2 d\mathbf{x} + \beta \int_{\Omega} |\nabla H(\phi)|. \end{aligned}$$

The function H is the Heaviside function defined by $H(x) = 1$ if $x \geq 0$, $H(x) = 0$ otherwise. In practice, we replace H by a smooth approximation H_ε , e.g.,

$$H_\varepsilon(x) = \frac{1}{2} \left[1 + \frac{2}{\pi} \arctan\left(\frac{x}{\varepsilon}\right) \right].$$

Although this method makes splitting and merging of curves a simple matter, the energy functional is non-convex which possesses many local minima. These local minima may correspond to undesirable segmentations; see [45].

Interestingly, for fixed c_1 and c_2 , the above non-convex objective can be reformulated as a convex problem, so that a global minimum can be easily computed; see [22, 56]. The globalized objective is given by

$$F^{\text{CEN}}(u, c_1, c_2) = \int_{\Omega} \left\{ [f(\mathbf{x}) - c_1]^2 - [f(\mathbf{x}) - c_2]^2 \right\} u(\mathbf{x}) d\mathbf{x} + \beta \int_{\Omega} |\nabla u| \quad (7)$$

which is minimized over all u satisfying the bilaterally constraints $0 \leq u \leq 1$ and all scalars c_1 and c_2 . After a solution u is obtained, a global solution to the original two-phase Mumford-Shah objective can be obtained by thresholding u with μ for almost every $\mu \in [0, 1]$, see [22, 56]. Some other proposals for computing global solutions can be found in [45].

To optimize the globalized objective function (7), Chan et al. [22] proposed to use an exact penalty method to convert the bilaterally constrained problem to an unconstrained problem. Then the gradient descent method is applied. This method is very robust and easy to implement. Moreover, the exact penalty method treats the constraints gracefully, as if there is no constraint at all. But of course the gradient descent is not particular fast.

In [42], Krishnan et al. considered the following discrete two-phase Mumford-Shah model:

$$F^{\text{CEN}}(u, c_1, c_2) = \langle s, u \rangle + \beta \|u\|_{TV} + \frac{\alpha}{2} \left\| u - \frac{1}{2} \right\|^2,$$

where $\langle \cdot, \cdot \rangle$ is the l^2 inner product, $s = (s_{i,j})$, and

$$s_{i,j} = (f_{i,j} - c_1)^2 - (f_{i,j} - c_2)^2.$$

The variable u is bounded by the bilateral constraints $0 \leq u \leq 1$. When $\alpha = 0$, this problem is convex but not strictly convex. When $\alpha > 0$, this problem is strictly convex. The additive constant $\frac{1}{2}$ is introduced in the third term so that the minimizer does not bias toward $u = 0$ or $u = 1$. This problem is exactly a TV denoising problem with bound constraints. Krishnan et al. proposed to use the primal-dual active-set method to solve the problem. Superlinear convergence has been established.

Diffusion Tensors Images

Recently, diffusion tensor imaging (DTI), a kind of magnetic resonance (MR) modality, becomes increasingly popular. It enables the study of anatomical structures such as nerve fibers in human brains noninvasively. Moreover, the use of direction-sensitive acquisitions results in its lower signal-to-noise ratio compared to convectional MR. At each voxel in the imaging domain, the anisotropy of diffusion water molecules is interested. Such an anisotropy can be described by a diffusion tensor D , which is a 3×3 positive semi-definite matrix. By standard spectral theory results, D can be factorized into

$$D = V\Lambda V^T,$$

where V is an orthogonal matrix whose columns are the eigenvectors of D , and Λ is a diagonal matrix whose diagonal entries are the corresponding eigenvalues. These eigenvalues provide the diffusion rate along the three orthogonal directions defined by the eigenvectors. The goal is to estimate the matrix D (one at each voxel) from the data. Under the Stejskal-Tanner model, the measurement S_k from the imaging device and the diffusion tensor are related by

$$S_k = S_0 e^{-bg_k^T D g_k}, \quad (8)$$

where S_0 is the baseline measurement, g_k is the prescribed direction in which the measurement is done, and $b > 0$ is a scalar depending the strength of the magnetic field applied and the acquisition time. Since D has six degrees of freedom, six measurements at different orientations are needed to reconstruct D . In practice, the measurements are very noisy. Thus, matrix D obtained by directly solving (8) for $k = 1, 2, \dots, 6$ may not be positive semi-definite and is error-prone. It is thus often helpful to take more than six measurements and to use some least squares methods or regularization to obtain a robust estimate while preserving the positive semi-definiteness for physical correctness.

In [60] Wang et al. and in [25] Christiansen et al. proposed an extension of the ROF to denoise tensor-valued data. Two major differences between the two works are that the former regularizes the Cholesky factor of D and uses a channel-by-channel TV regularization, whereas the latter regularizes the tensor D directly and uses a multichannel TV.

The method in [25] is two staged. The first stage is to estimate the diffusion tensors from the raw data based on the Stejskal-Tanner model (8). The obtained

tensors are often noisy and may not be positive semi-definite. The next stage is to use the ROF model to denoise the tensor while restricting the results to be positive semi-definite. The trick they used to ensure positive semi-definiteness is very simple and practical. They observed that a symmetric matrix is positive semi-definite if and only if it has a Cholesky factorization of the form

$$D = LL^T,$$

where L is a lower triangular matrix

$$L = \begin{bmatrix} l_{11} & 0 & 0 \\ l_{21} & l_{22} & 0 \\ l_{31} & l_{32} & l_{33} \end{bmatrix}.$$

Then one can easily express D in terms of l_{ij} for $1 \leq j \leq i \leq 3$:

$$D = D(L) = \begin{bmatrix} l_{11}^2 & l_{11}l_{21} & l_{11}l_{31} \\ l_{11}l_{21} & l_{21}^2 + l_{22}^2 & l_{21}l_{31} + l_{22}l_{32} \\ l_{11}l_{31} & l_{21}l_{31} + l_{22}l_{32} & l_{31}^2 + l_{32}^2 + l_{33}^2 \end{bmatrix}.$$

The ROF problem, written in a continuous domain, is then formulated as

$$\min_L \left\{ \frac{1}{2} \sum_{ij} \int_{\Omega} [d_{ij}(L) - \hat{d}_{ij}]^2 d\mathbf{x} + \lambda \sqrt{\sum_{ij} \left[\int_{\Omega} |\nabla d_{ij}(L)| \right]^2} \right\},$$

where $\hat{D} = (\hat{d}_{ij})$ is the observed noisy tensor field, and L is the unknown lower triangular matrix-valued function from Ω to $\mathcal{R}^{3 \times 3}$. Here, the matrix-valued version of TV is used. The objective is then differentiated w.r.t. the lower triangular part of L to obtain a system of six first-order optimality conditions. Once the optimal L is obtained, the tensor D can be formed by taking $D = LL^T$ which is a positive semi-definite.

The original ROF problem is strictly convex so that one can obtain the globally optimal solution. However, in this problem, due to the nonlinear change of variables from D to L , the problem becomes non-convex. But the authors of [25] reported that in their experiments, different initial data often resulted in the same solution, so that the non-convexity does not pose any significant difficulty to the optimization of the objective.

4 Numerical Methods and Case Examples

Fast numerical methods for TV minimization continue to be an active research area. Researchers from different fields have been bringing many fresh ideas to the

problem and led to many exciting results. Some categories of particular mention are dual/primal-dual methods, Bregman iterative methods, and graph cut methods. Many of these methods have a long history with a great deal of general theories developed. But when it comes to their application to the ROF model, many further properties and specialized refinements can be exploited to obtain even faster methods. Having said so, different algorithms may adopt different versions of TV. They have different properties and thus may be used for different purposes. Thus, some caution needs to be taken when one attempts to draw conclusions such as method A is faster than method B. Moreover, different methods have different degree of generality. Some methods can be extended directly to deblurring, while some can only be applied to denoising. (Of course, one can use an outer iteration to solve a deblurring problem by a sequence of denoising problems, so that any denoising algorithm can be used. But the convergence of the outer iteration has little, if not none, to do with the inner denoising algorithm.) This section surveys some recent methods for TV denoising and/or deblurring. The model considered here is a generalized ROF model which simultaneously performs denoising and deblurring. The objective function reads

$$F(u) = \frac{1}{2} \int_{\Omega} (Ku - f)^2 d\mathbf{x} + \lambda \int_{\Omega} |\nabla u|, \quad (9)$$

where K is a blurring operator and $\lambda > 0$ is the regularization parameter. For simplicity, we assume that K is invertible. When K is the identity operator, (9) is the ROF denoising model.

Dual and Primal-Dual Methods

The ROF objective is non-differentiable in flat regions where $|\nabla u| = 0$. This leads to much difficulty in the optimization process since gradient information (hence, Taylor's expansion) becomes unreliable in predicting the function value even locally. Indeed, the staircase effects of TV minimization can introduce some flat regions which make the problem worse. Even if the standard procedure of replacing the TV with a reasonably smoothed version is used so that the objective becomes differentiable, the Euler-Lagrange equation for (9) is still very stiff to solve. Higher-order methods such as Newton's methods often fail to work because higher-order derivatives are even less reliable.

Due to the difficulty in optimizing the ROF objective directly, much recent research has been directed toward solving some reformulated versions. In particular, methods based on dual and primal-dual formulations have been shown to be very fast in practice. Actually, the dual problem (see (12) below) also has its own numerical difficulties to face, e.g., the objective is rank deficient and some extra work is needed to deal with the constraints. But the dual formulation brings many well-developed ideas and techniques from numerical optimization to bear on this problem. Primal-dual methods have also been studied to combine information from

the primal and dual solutions. Several successful dual and primal-dual methods are reviewed.

Chan-Golub-Mulet's Primal-Dual Method

Some early work in dual and primal-dual methods for the ROF model can be found in [13, 20]. In particular, Chan, Golub, and Mulet (CGM) [20] introduced a primal-dual system involving a primal variable u and a Fenchel dual variable \mathbf{p} . It remains one of the most efficient methods today and is perhaps the most intuitive one. It is worthwhile to review it and see how it relates to the more recent methods. Their idea is to start with the Euler-Lagrange equation of (9):

$$K^T K u - K^T f - \lambda \operatorname{div} \left(\frac{\nabla u}{\sqrt{|\nabla u|^2 + \varepsilon}} \right) = 0. \quad (10)$$

Owing to the singularity of the third term, they introduced an auxiliary variable

$$\mathbf{p} = \frac{\nabla u}{\sqrt{|\nabla u|^2 + \varepsilon}}$$

to form the system

$$\begin{aligned} \mathbf{p} \sqrt{|\nabla u|^2 + \varepsilon} &= \nabla u \\ K^T K u - K^T f - \lambda \operatorname{div} \mathbf{p} &= 0. \end{aligned}$$

Thus, the blowup singularity is canceled. They proposed to solve this system by Newton's method which is well known to converge quadratically locally if the Jacobian of the system is Lipschitz. Global convergence is observed when coupled with a simple Armijo line search [8]. The variable \mathbf{p} is indeed the same as the Fenchel dual variable \mathbf{g} in (1) when $\nabla u \neq 0$ and $\varepsilon = 0$. Thus, \mathbf{p} is a smoothed version of the dual variable \mathbf{g} . Without the introduction of the dual variable, a direct application of the Newton's method to the Euler-Lagrange equation (10) often fails to converge because of the small domain of convergence.

Chambolle's Dual Method

A pure dual method is proposed by Chambolle in [14], where the ROF objective is written solely in terms of the dual variable. By the definition of TV in (1), it can be deduced using duality theory that

$$\begin{aligned} \inf_u \left\{ \frac{1}{2} \int_{\Omega} (Ku - f)^2 d\mathbf{x} + \lambda \int_{\Omega} |\nabla u| \right\} \\ \iff \inf_u \sup_{\|\mathbf{p}\| \leq 1} \left\{ \frac{1}{2} \int_{\Omega} (Ku - f)^2 d\mathbf{x} + \lambda \int_{\Omega} u \operatorname{div} \mathbf{p} d\mathbf{x} \right\} \end{aligned} \quad (11)$$

$$\begin{aligned} &\iff \sup_{|\mathbf{p}| \leq 1} \inf_u \left\{ \frac{1}{2} \int_{\Omega} (Ku - f)^2 d\mathbf{x} + \lambda \int_{\Omega} u \operatorname{div} \mathbf{p} d\mathbf{x} \right\} \\ &\iff \sup_{|\mathbf{p}| \leq 1} \left\{ -\frac{\lambda^2}{2} \int_{\Omega} \left| K^{-T} \operatorname{div} \mathbf{p} - \frac{f}{\lambda} \right|^2 d\mathbf{x} \right\}. \end{aligned} \quad (12)$$

The resulting problem has a quadratic objective with quadratic constraints. In contrast, the primal objective is only piecewise smooth which is badly behaved when $\nabla u = 0$. Thus the dual objective function is very simple, but additional efforts are needed to handle the constraints. One can write down the Karush-Kuhn-Tucker (KKT) optimality system [8] of the discretized objective, which amounts to solving a nonlinear system of equations involving complementarity conditions and inequality constraints on the Lagrange multipliers. Interestingly, the Lagrange multipliers have a closed-form solution which greatly simplifies the problem. More precisely, the KKT system consists of the equations

$$\mu p = H(\mathbf{p}) \quad (13)$$

$$\mu (|\mathbf{p}|^2 - 1) = 0 \quad (14)$$

$$\mu \geq 0 \quad (15)$$

$$|\mathbf{p}|^2 \leq 1, \quad (16)$$

where μ is the nonnegative Lagrange multiplier and

$$H(\mathbf{p}) := \nabla \left[(K^T K)^{-1} \operatorname{div} \mathbf{p} - \frac{1}{\lambda} K^{-1} f \right].$$

Since

$$\mu |\mathbf{p}| = |H(\mathbf{p})|,$$

if $|\mathbf{p}| = 1$, then $\mu = |H(\mathbf{p})|$; if $|\mathbf{p}| < 1$, then the complementarity (14) implies $\mu = 0$ and by (13) $H(\mathbf{p}) = 0$, so that μ is also equal to $|H(\mathbf{p})|$. This simplifies the KKT system into a nonlinear system of \mathbf{p} only

$$|H(\mathbf{p})| \mathbf{p} = H(\mathbf{p}).$$

Chambolle proposes a simple semi-implicit scheme to solve the system:

$$\mathbf{p}^{n+1} = \frac{\mathbf{p}^n + \tau H(\mathbf{p}^n)}{\mathbf{p}^n + \tau |H(\mathbf{p}^n)|}.$$

Here, τ is a positive parameter controlling the stepsize. The method is proven to be convergent for any

$$\tau \leq \frac{1}{8} \left\| (K^T K)^{-1} \right\|, \quad (17)$$

where $\|\cdot\|$ is the spectral norm. This method is also faithful to the original ROF problem; it does not require approximating the TV by smoothing.

The convergence rate of this method is at most linear, but for denoising problems, it usually converges fast (measured by the relative residual norm of the optimality condition) in the beginning but stagnates after some iterations (at a level several orders of magnitude higher than the machine epsilon). This is very typical for simple relaxation methods. Fortunately, visually good results (measured by the number of pixels having a gray level different from the optimal one after they are quantized to their 8-bit representation) are often achieved before the method stagnates [64]. However, when applied to deblurring, K is usually ill conditioned, so that the stepsize restriction (17) is too stringent. In this case, another outer iteration is often used in conjunction with the method; see the splitting methods in section ‘‘Splitting Methods.’’

Chambolle’s method has been successfully adapted to solve a variety of related image processing problems, e.g., the ROF with nonlocal TV [9], multichannel TV [10], and segmentation problems [4]. We remark that many other approaches for solving (12) have been proposed. A discussion of some first-order methods including projected gradient methods and Nesterov methods can be found in [3, 26, 61].

Primal-Dual Hybrid Gradient Method

As mentioned in the beginning of Sect. 4, the primal and dual problems have their own advantages and numerical difficulties to face. It is therefore tempting to combine the best of both. In [64], Zhu and Chan proposed the *primal-dual hybrid gradient* (PDHG) algorithm which alternates between primal and dual formulations.

The method is based on the primal-dual formulation

$$G(u, \mathbf{p}) := \frac{1}{2} \int_{\Omega} (Ku - f)^2 d\mathbf{x} + \lambda \int_{\Omega} u \operatorname{div} \mathbf{p} d\mathbf{x} \rightarrow \inf_u \sup_{|\mathbf{p}| \leq 1};$$

cf. formulation (11). By fixing its two variables one at a time, this saddle point formulation has two subproblems:

$$\sup_{|\mathbf{p}| \leq 1} G(u, \mathbf{p}) \quad \text{and} \quad \inf_u G(u, \mathbf{p}).$$

While one may obtain an optimal solution by solving the two subproblems to a high accuracy alternatively, the PDHG method applies only one step of gradient descent/ascent to each of the two subproblems alternatively. The rationale is that when neither of the two variables are optimal, there is little to gain by iterating each subproblem until convergence. Starting with an initial guess u^0 , the following two steps are repeated:

$$\begin{aligned} \mathbf{p}^{k+1} &= P_{|\mathbf{p}| \leq 1}(\mathbf{p}^k - \tau_k \nabla u^k) \\ u^{k+1} &= u^k - \theta_k (K^T(Ku^k - f) + \lambda \operatorname{div} \mathbf{p}^{k+1}) \end{aligned}$$

Here, $P_{|\mathbf{p}| \leq 1}$ is the projector onto the feasible set $\{\mathbf{p} : |\mathbf{p}| \leq 1\}$. The stepsizes τ_k and θ_k can be chosen to optimize the performance. Some stepping strategies were presented in [64]. In [65], Zhu, Wright, and Chan studied a variety of stepping strategies for a related dual method.

Numerical results in [64] show that this simple algorithm is faster than the split Bregman iteration (see section “Split Bregman Iteration”), which is faster than Chambolle’s semi-implicit dual method (see section “Chambolle’s Dual Method”). Some interesting connections between the PDHG algorithm and other algorithms such as *proximal forward-backward splitting*, *alternating minimization*, *alternating direction method of multipliers*, *Douglas-Rachford splitting*, *split inexact Uzawa*, and *averaged gradient* methods applied to different formulations of the ROF model are studied by Esser et al. in [29]. Such connections reveal some convergence theory of the PDHG algorithm in several important cases (special choices of the stepsizes) in a more general setting.

Semi-smooth Newton’s Method

Given the dual problem, it is natural to consider other methods to solve its optimality conditions (13)–(16). A standard technique in optimization to handle complementarity and Lagrange multipliers is to combine them into a single equality constraint. Observe that the constraints $a \geq 0$, $b \geq 0$ and $ab = 0$ can be consolidated into the equality constraint

$$\phi(a, b) := \sqrt{a^2 + b^2} - a - b = 0, \quad (18)$$

where ϕ is known as the Fischer-Burmeister function. Therefore, the KKT system (13)–(16) can be written as

$$\begin{aligned} \mu \mathbf{p} &= H(\mathbf{p}) \\ \phi\left(\mu, 1 - |\mathbf{p}|^2\right) &= 0. \end{aligned}$$

Ng et al. [48] observed that this system is semi-smooth and therefore proposed solving this system using a *semi-smooth Newton’s method*. In this method, if the Jacobian of the system is not defined in the classical sense due to the system’s lack of enough smoothness, then the Jacobian is replaced by a generalized Jacobian evaluated at a nearby point. It is proven that this method converges superlinearly if the system to solve is at least semi-smooth and if the generalized Jacobians at convergence satisfy some invertibility conditions. For the dual problem (12), the Newton’s equation may be singular. This problem is fixed by regularizing the Jacobian.

Primal-Dual Active-Set Method

Hintermüller and Kunisch [37] considered the Fenchel dual approach to formulate a constrained quadratic dual problem and derived a very effective active-set method to handle the constraints. The method separates the variables into active and inactive

sets, so that they can be treated differently accordingly to their characteristics. They considered the case of anisotropic discrete TV norm (3), so that the dual variable is bilaterally constrained, i.e., $-1 \leq \mathbf{p} \leq 1$, whereas the constraints in (12) are quadratic. In this setting, superlinear convergence can be established.

To deal with the bilateral constraints on \mathbf{p} , they proposed to use the *primal-dual active-set* (PDAS) algorithm. Consider the general quadratic problem,

$$\min_{y, v \leq \psi} \frac{1}{2} \langle y, Ay \rangle - \langle f, y \rangle,$$

where ψ is a given vector in \mathcal{R}^n . This problem includes (12) as a special instance. The KKT conditions are given by

$$\begin{aligned} Ay + v &= f, \\ v \odot (\psi - y) &= 0, \\ v &\geq 0, \\ \psi - y &\geq 0, \end{aligned}$$

where v is a vector of Lagrange multipliers and \odot denotes the entrywise product. The idea of the PDAS algorithm is to predict the active variables \mathcal{A} and inactive variables \mathcal{I} to speed up the determination of the final active and inactive variables. The prediction is done by comparing the closeness of v and $\psi - y$ to zero. If $\psi - y$ is c times closer to zero than v does, then the variable is predicted as active. The PDAS algorithm is given by

1. Initialize y^0, v^0 . Set $k = 0$.
2. Set $\mathcal{I}^k = \{i : v_i^k - c(\psi - y^k)_i \leq 0\}$ and $\mathcal{A}^k = \{i : v_i^k - c(\psi - y^k)_i > 0\}$.
3. Solve

$$\begin{aligned} Ay^{k+1} + v^{k+1} &= f, \\ y^{k+1} &= \psi \quad \text{on } \mathcal{A}^k, \\ v^{k+1} &= 0 \quad \text{on } \mathcal{I}^k. \end{aligned}$$

4. Stop or set $k = k + 1$ and return to Step 2.

Notice that the constraints $a \geq 0$, $b \geq 0$, and $ab = 0$ can be combined as a single equality constraint:

$$\min(a, cb) = 0$$

for any positive constant c . Thus, the KKT system can be written as

$$\begin{aligned} Ay + v &= f, \\ C(y, v) &= 0, \end{aligned}$$

where $C(y, v) = \min(v, c(\psi - y))$ for an arbitrary positive constant c . The function C is piecewise linear, whereas the Fisher-Burmeister formulation (18)

is nonlinear. More importantly, applying Newton's method (using a generalized derivative) to such a KKT system yields exactly the PDAS algorithm. This allows Hintermüller et al. to explain the local superlinear convergence of the PDAS algorithm for a class of optimization problems that include the dual of the anisotropic TV deblurring problem [36]. In [37], some conditional global convergence results based on the properties of the blurring matrix K have also been derived. Their formulation is based on the anisotropic TV norm, and the dual problem requires an extra l^2 regularization term when a deblurring problem is solved.

The dual problem (12) is rank deficient and does not have a unique solution in general. In [37], Hintermüller and Kunisch proposed to add a regularization term, so that the solution is unique. The regularized objective function is

$$\int_{\Omega} |K^{-1} \operatorname{div} \mathbf{p} - \lambda^{-1} f|^2 d\mathbf{x} + \gamma \int_{\Omega} |P\mathbf{p}|^2 d\mathbf{x},$$

where P is the orthogonal projector onto the null space of the divergence operator div . Later in [38], Hintermüller and Stadler showed that adding such a regularization term to the dual objective is equivalent to smoothing out the singularity of the TV in the primal objective. More precisely, the smoothed TV is given by $\int_{\Omega} \Phi(|\nabla f|) d\mathbf{x}$, where

$$\Phi(s) = \begin{cases} s & \text{if } |s| \geq \gamma, \\ \frac{\gamma}{2} + \frac{1}{2\gamma}s^2 & \text{if } |s| < \gamma. \end{cases}$$

An advantage of using this smoothed TV is that the staircase artifacts are reduced.

In [41, 42], Krishnan et al. considered the TV deblurring problem with bound constraints on the image u . An algorithm, called *nonnegatively constrained CGM*, combining the CGM and the PDAS algorithms has been proposed. The image u and its dual \mathbf{p} are treated as in the CGM method, whereas the bound constraints on u are treated as in the PDAS method. The resulting optimality conditions are shown to be semi-smooth. The scheme can also be interpreted as a *semi-smooth quasi-Newton's method* and is proven to converge superlinearly. The method is formulated for isotropic TV, but it can also be applied to anisotropic TV after minor changes.

However, Hintermüller and Kunisch's PDAS method [37] can only be applied to anisotropic TV because they used PDAS that can only handle linear constraints to treat the constraints on \mathbf{p} .

Bregman Iteration

Original Bregman Iteration

The *Bregman iteration* is proposed by Osher et al. in [49] for TV denoising. It has also been generalized to solving many convex inverse problems, e.g., [12]. In each

step, the signal removed in the previous step is added back. This is shown to alleviate the loss of contrast problem presented in the ROF model. Starting with the noisy image $f_0 = f$, the following steps are repeated for $j = 0, 1, 2, \dots$:

1. Set

$$u_{j+1} = \arg \min_u \left\{ \frac{1}{2} \int_{\Omega} (u - f_j)^2 d\mathbf{x} + \lambda \int_{\Omega} |\nabla u| \right\}.$$

2. Set $f_{j+1} = f_j + (f - u_{j+1})$.

In the particular case when f consists of a disk over a constant background, it can be proved that the loss of contrast can be totally recovered. Some theoretical analysis of the method can be found in [49].

For a general regularization functional $J(u)$, the Bregman distance is defined as

$$D_J^p(u, v) = J(u) - J(v) - \langle p, u - v \rangle,$$

where p is an element of the subgradient of J . In case of TV denoising, $J(u) = \lambda \int_{\Omega} |\nabla u|$. Then, starting with $f_0 = f$, the Bregman iteration is given by

1. Set

$$u_{j+1} = \arg \min_u \left\{ \frac{1}{2} \int_{\Omega} (u - f)^2 d\mathbf{x} + D_J^{p_j}(u, u_j) \right\}.$$

2. Set $f_{j+1} = f_j + (f - u_{j+1})$.

3. Set $p_{j+1} = f_{j+1} - f$.

In fact, steps 2 and 3 can be combined to $p_{j+1} = p_j + f - u_{j+1}$ without the need of keeping track of f_j . The above expression is for illustrating how the residual is added back to f_j . In this iteration, it has been shown that the Bregman distance between u_j and the *clean image* is monotonically decreasing as long as the L_2 -distance is larger than the magnitude of the noise component. But if one iterates until convergence, then $u_j \rightarrow f$, i.e., one just gets the noisy image back. This counterintuitive feature is indeed essential to solving other TV minimization problems, e.g., the basis pursuit problem presented next.

The Basis Pursuit Problem

An interesting feature of the Bregman iteration is that, in the discrete setting, if one replaces the term $\|u - f\|^2$ in the objective by $\|Au - f\|^2$, where $Au = f$ is underdetermined, then upon convergence of the Bregman iterations, one obtains the solution of the following *basis pursuit problem* [63]:

$$\min_u \{J(u) | Au = f\}.$$

When $\|Au - f\|^2$ is used in the objective instead of $\|u - f\|^2$, the Bregman iteration is given by:

1. Set

$$u_{j+1} = \arg \min_u \left\{ \frac{1}{2} \int_{\Omega} (Au - f)^2 d\mathbf{x} + D_J^{p_j}(u, u_j) \right\}.$$

2. Set $f_{j+1} = f_j + (f - Au_{j+1})$.

3. Set $p_{j+1} = A^T(f_{j+1} - f)$.

Split Bregman Iteration

Recently, Goldstein and Osher [35] proposed the *split Bregman iteration* which can be applied to solve the ROF problem efficiently. The main idea is to introduce a new variable so that the TV minimization becomes an L^1 minimization problem which can be solved efficiently by the Bregman iteration. This departs from the original Bregman iteration which solves a sequence of ROF problems to improve the quality of the restored image by bringing back the loss signal. The original Bregman iteration is not iterated until convergence. Moreover, it assumes the availability of a basic ROF solver. The split Bregman method, on the other hand, is an iterative method whose iterates converge to the solution of the ROF problem. In this method, a new variable $\mathbf{q} = \nabla u$ is introduced into the objective function:

$$\min_{u, \mathbf{q}} \left\{ \frac{1}{2} \int_{\Omega} (u - f)^2 d\mathbf{x} + \lambda \int_{\Omega} |\mathbf{q}| d\mathbf{x} \right\}. \quad (19)$$

This problem is solved using a penalty method to enforce the constraint $\mathbf{q} = \nabla u$. The objective with an added penalty is given by

$$G(u, \mathbf{q}) = \frac{\alpha}{2} \int_{\Omega} |\mathbf{q} - \nabla u|^2 d\mathbf{x} + \frac{1}{2} \int_{\Omega} (u - f)^2 d\mathbf{x} + \lambda \int_{\Omega} |\mathbf{q}| d\mathbf{x}. \quad (20)$$

Notice that if the variables (u, \mathbf{q}) are denoted by \mathbf{y} , then the above objective can be identified as

$$\min_{\mathbf{y}} \left\{ \frac{\alpha}{2} \int_{\Omega} |A\mathbf{y}|^2 d\mathbf{x} + J(\mathbf{y}) \right\},$$

where

$$\begin{aligned} A\mathbf{y} &= \mathbf{q} - \nabla u, \\ J(\mathbf{y}) &= \frac{1}{2} \int_{\Omega} (u - f)^2 d\mathbf{x} + \lambda \int_{\Omega} |\mathbf{q}| d\mathbf{x}. \end{aligned}$$

This is exactly the basis pursuit problem when $\alpha \rightarrow \infty$. Actually, even with a fixed finite α , as mentioned in section “The Basis Pursuit Problem,” when the Bregman

iteration is used, it converges to the solution of the problem

$$\min_{\mathbf{y}} \{J(\mathbf{y}) \mid A\mathbf{y} = 0\},$$

so that the constraint $\mathbf{q} = \nabla u$ is satisfied at convergence.

It is interesting to note that the split Bregman iteration can be viewed as a forward-backward splitting method [53]. Yet another point of view is provided next.

Augmented Lagrangian Method

In [62, 63], it is recognized that the split Bregman iteration is an *augmented Lagrangian method* [33]. This explains some good convergence behaviour of the split Bregman iteration. To motivate the augmented Lagrangian method, consider a general objective function $J(u)$ with equality constraint $H(u) = 0$. The idea of penalty methods is to solve a sequence of unconstrained problems

$$\min_u \left\{ J(u) + \frac{1}{\beta} \|H(u)\|^2 \right\}$$

with $\beta \rightarrow 0^+$, so that the constraint $H(u) = 0$ is enforced asymptotically. However, one may run into the embarrassing situation where both $H(u(\beta))$ (where $u(\beta)$ is the optimal u for a given β) and β converge to zero in the limit. This could mean that the objective function is stiff when β is very small. The idea of augmented Lagrangian methods is to use a *fixed* parameter. But the penalty term is added to the Lagrangian function, so that the resulting problem is equivalent to the original problem even without letting $\beta \rightarrow 0^+$. The augmented Lagrangian function is

$$L(u, v) = J(u) + v \cdot H(u) + \frac{1}{\beta} \|H(u)\|^2,$$

where v is a vector of Lagrange multipliers. Solving $\frac{\partial L}{\partial u} = \frac{\partial L}{\partial v} = 0$ for a saddle point yields exactly $H(u) = 0$ for any $\beta > 0$. The Bregman iteration applied to the penalized objective (20) is indeed computing a saddle point of the augmented Lagrangian function of (19) rather than optimizing (20) itself. Therefore, the constraint $\nabla u = \mathbf{q}$ accompanied with (19) is exact even with a fixed α .

Graph Cut Methods

Recently, there is a burst of interest in graph cut methods for solving various variational problems. The promises of these methods are that they are fast for many practical problems and they can provide globally optimal solution even for “non-convex problems.” The discussion below is extracted from [15, 27]. Readers are referred to [15, 27] and the references therein for a more thorough discussion of the subject. Since graph cut problems are combinatoric, the objective has to be cast in

a fully discrete way. That is, not only the image domain has to be discretized to a finite set but also the range of the intensity values. Therefore, in this framework, the given m -by- n image f is a function from $\mathbb{Z}_m \times \mathbb{Z}_n$ to \mathbb{Z}_K . The ROF problem thus becomes

$$F(u) = \frac{1}{2} \sum_{i=1}^m \sum_{j=1}^n (u_{i,j} - f_{i,j})^2 + \lambda \|u\|_{TV} \rightarrow \min_{u: \mathbb{Z}_m \times \mathbb{Z}_n \rightarrow \mathbb{Z}_K},$$

where $\|u\|_{TV}$ is a discrete TV (4). The next question is how to transform this problem to a graph cut problem in such a way that it can be solved efficiently. It turns out that the (fully discretized) ROF problem can be converted to a finite sequence of graph cut problems. This is due to the co-area formula which is unique to TV. Details are described next.

Leveling the Objective

Some notations and basic concepts are in place. For simplicity, the following discrete TV is adopted:

$$\|u\|_{TV} = \sum_{i=1}^{m-1} \sum_{j=1}^{n-1} |u_{i+1,j} - u_{i,j}| + |u_{i,j+1} - u_{i,j}|,$$

which is the anisotropic TV in (3), but with the range of u restricted to \mathbb{Z}_K . Recall that the binary image u^k is defined such that each $u_{i,j}^k$ equals 1 if $u_{i,j} \leq k$ and equals 0 otherwise. Thus, it is the k th lower level set of u . Then the co-area formula states that the discrete TV can be written as

$$\|u\|_{TV} = \sum_{k=0}^{K-2} \|u^k\|_{TV}.$$

Thus, it reduces to the TV of each “layer”. Note that the TV of the $(K-1)$ st level set must be zero, and therefore the above sum is only up to $K-2$.

The fitting term in the objective can also be treated similarly as follows. Notice that for any function $g_{i,j}(s)$, it holds that

$$\begin{aligned} g_{i,j}(s) &= \sum_{k=0}^{s-1} [g_{i,j}(k+1) - g_{i,j}(k)] + g_{i,j}(0) \\ &= \sum_{k=0}^{K-2} [g_{i,j}(k+1) - g_{i,j}(k)] \chi_{k < s} + g_{i,j}(0), \end{aligned}$$

where $\chi_{k < s} = 1$ if $k < s$ and 0 otherwise. Define $g_{i,j}(k) = \frac{1}{2}(s - f_{i,j})^2$. Then,

$$\begin{aligned}\frac{1}{2}(u_{i,j} - f_{i,j})^2 &= g_{i,j}(u_{i,j}) \\ &= \sum_{k=0}^{K-2} [g_{i,j}(k+1) - g_{i,j}(k)] \chi_{k < u_{i,j}} + g_{i,j}(0) \\ &= \sum_{k=0}^{K-2} [g_{i,j}(k+1) - g_{i,j}(k)] (1 - u_{i,j}^k) + g_{i,j}(0).\end{aligned}$$

As a result, the ROF objective can be expressed as

$$\sum_{k=0}^{K-2} \left\{ \sum_{i,j} [g_{i,j}(k+1) - g_{i,j}(k)] (1 - u_{i,j}^k) + \lambda \|u^k\|_{TV} \right\} + C,$$

where $C = \sum_{i,j} g_{i,j}(0)$.

By defining the objective function

$$F^k(v^k) = \sum_{i,j} [g_{i,j}(k+1) - g_{i,j}(k)] (1 - v_{i,j}^k) + \lambda \|v^k\|_{TV},$$

where v^k is a binary function, the ROF problem is seen to be equivalent to

$$\min_{v^1, v^2, \dots, v^{K-2}} \sum_{k=0}^{K-2} F^k(v^k)$$

subject to the inclusion constraints $v_{i,j}^k \leq v_{i,j}^{k+1}$ for all i, j, k . The constraints make sure the binary functions $\{v^k\}_k$ define the lower level sets of some function v . A very important result is that the minimization can be done independently for each v^k ; amazingly, the solutions $\{v^k\}$ satisfy the inclusion property automatically! See [27] for further details.

Defining a Graph

To minimize each F^k w.r.t. a binary function v^k , a graph cut method is used. First observe that since $g_{i,j}(k) = \frac{1}{2}(k - f_{i,j})^2$, F^k can be simplified to

$$F^k(v^k) = \sum_{i,j} \left[\frac{1}{2} + (k - f_{i,j}) \right] (1 - v_{i,j}^k) + \lambda \|v^k\|_{TV}.$$

By absorbing some constants and dropping the superscript on v^k , the objective takes the following form:

$$F^k(v) = \sum_{i,j} \left(f_{i,j} - k - \frac{1}{2} \right) v_{i,j} + \lambda \|v\|_{TV}. \quad (21)$$

Then, a graph with $mn + 2$ nodes is constructed in the following way:

1. Each of the mn pixels is a node, labeled by (i, j) for $i = 1, 2, \dots, m$ and $j = 1, 2, \dots, n$.
2. Add two additional nodes, called the source S and the sink T .
3. For each (i, j) , connect it to $(i \pm 1, j)$ and $(i, j \pm 1)$ with capacity λ .
4. For each (i, j) , connect S to it with capacity $\frac{1}{2} + k - f_{i,j}$ if $\frac{1}{2} + k - f_{i,j} > 0$ and connect it to T with capacity $f_{i,j} - k - \frac{1}{2}$ if $f_{i,j} - k - \frac{1}{2} > 0$.

A cut (a.k.a. an *st*-cut) in the graph is a partition $(\mathcal{S}, \mathcal{T})$ such that $\mathcal{S} \in \mathcal{S}$ and $\mathcal{T} \in \mathcal{T}$. The cost of the cut $\mathcal{C}(\mathcal{S}, \mathcal{T})$ is defined as the sum of the capacities of all edges from \mathcal{S} to \mathcal{T} . For a given cut, let $v_{i,j}$ equals 1 if $(i, j) \in \mathcal{S}$ and equals 0 if $(i, j) \in \mathcal{T}$. Then it can be verified that

$$\begin{aligned} C(\mathcal{S}, \mathcal{T}) = \sum_{i,j} \max \left\{ \frac{1}{2} + k - f_{i,j}, 0 \right\} v_{i,j} + \max \left\{ f_{i,j} - k - \frac{1}{2}, 0 \right\} \\ (1 - v_{i,j}) + \lambda \|v^k\|_{TV} \end{aligned}$$

which is the same as F^k in (21), up to the constant $\sum_{i,j} \max \{f_{i,j} - k, 0\}$. Therefore, computing the minimum cut is equivalent to minimizing (21). It is also well known that the minimum cut problem is equivalent to the maximum flow problem.

Recall that there are $K - 1$ graphs to cut. A simple way is to do them one by one using any classical maximum flow algorithm. But one can exploit the inclusion property to reduce the work; for instance, see the divide-and-conquer algorithm proposed in [27].

In graph cut methods, a fundamental question is what kind of optimization problems can be transformed to a graph cut problem. A particularly relevant question is whether a function is levelable, i.e., its minimization can be done by first solving the simpler problem on each of its level set, followed by assembling the resulting level sets. Interestingly, the only levelable convex regularization function (satisfying some very natural and mild conditions) is TV [27]. This indicates that TV is much more than just an ordinary semi-norm.

Quadratic Programming

The discrete anisotropic TV is a piecewise linear function. Fu et al. [30] showed that by introducing some auxiliary variables, one can transform the TV to a linear function but with some additional linear constraints. Together with the fitting term, the problem to solve has a quadratic objective function with linear constraints.

The objective function considered is by Fu et al.

$$F(u) = \frac{1}{2} \|Ku - f\|^2 + \lambda \sum_{i,j} |u_{i+1,j} - u_{i,j}| + |u_{i,j+1} - u_{i,j}|,$$

which can also be written as

$$F(u) = \frac{1}{2} \|Ku - f\|^2 + \lambda \|Ru\|_1$$

where R is a $2mn$ -by- mn matrix. If the original isotropic TV is used, then it cannot be written in this form.

The trick they used is to let $v = Ru$ and then split it into positive and negative parts: $v^+ = \max(v, 0)$ and $v^- = \max(-v, 0)$. Then, the objective can be written as

$$G(u, v^+, v^-) = \frac{1}{2} \|Ku - f\|^2 + \lambda (1^T v^+ + 1^T v^-),$$

which is a quadratic function. But some linear constraints are added:

$$\begin{aligned} Ru &= v^+ - v^-, \\ v^+, v^- &\geq 0. \end{aligned}$$

Now, this problem can be solved by standard primal-dual interior-point methods. Here, “dual” refers to the Lagrange multipliers for the linear constraints. The major steps can be summarized as follows:

1. Write down the KKT system of optimality conditions, which has a form of $f(x, \mu, s) = 0$, where $x \geq 0$ is the variable of the original problem ($x = (u, v^+, v^-)$ in the present case); μ is the Lagrange multipliers for the equality constraints; and $s \geq 0$ is the Lagrange multipliers for the inequality constraints.
2. Relax the complementarity $xs = 0$ (part of $f(x, \mu, s) = 0$) to $xs = v$, where $v > 0$.
3. Solve the relaxed problem $f_v(x, \mu, s) = 0$ by Newton’s method.
4. After each Newton’s iteration, reduce the value of v so that the solution of $f(x, \mu, s) = 0$ is obtained at convergence.

In this method, the relaxed complementarity $xs = v$ forces the variables x, s to lie in the interior of the feasible region. Once the variables are away from the boundary, the problem becomes a nice unconstrained quadratic problem locally. The main challenge here is that the linear system to solve in each Newton’s iteration becomes increasingly ill conditioned. Under this framework, bound constraints such as $u_{\min} \leq u \leq u_{\max}$ or any linear equality constraints can be easily added.

Second-Order Cone Programming

The trick to “linearize” the TV presented in the last section does not work for isotropic TV. Goldfarb and Yin [34] proposed a *second-order cone programming*

(SOCP) formulation which works for the isotropic version (2). Moreover, its connection to SOCP allows the use of available SOCP solvers to obtain the solutions. The problem they considered is the constrained ROF problem:

$$\min_u \|u\|_{TV}$$

subject to

$$\|u - f\| \leq \sigma,$$

where σ is the standard deviation of the noise which is assumed to be known.

Let $w_{i,j}^x = u_{i+1,j} - u_{i,j}$ and $w_{i,j}^y = u_{i,j+1} - u_{i,j}$. The TV becomes

$$\sum_{i,j} \sqrt{\left(w_{i,j}^x\right)^2 + \left(w_{i,j}^y\right)^2}.$$

By introducing the variables $v = f - u$ and t and the constraint

$$\left(w_{i,j}^x\right)^2 + \left(w_{i,j}^y\right)^2 \leq t_{i,j}^2,$$

the TV minimization problem becomes

$$\begin{aligned} & \min \sum_{i,j} t_{i,j} \\ \text{s.t. } & u + v = f \\ & w_{i,j}^x = u_{i+1,j} - u_{i,j} \\ & w_{i,j}^y = u_{i,j+1} - u_{i,j} \\ & (\sigma, v) \in \text{cone}^{mn+1} \\ & (t_{i,j}, w_{i,j}^x, w_{i,j}^y) \in \text{cone}^3. \end{aligned}$$

Here, cone^n is the second-order cone in \mathcal{R}^n :

$$\{x \in \mathbb{R}^n : \|(x_2, x_3, \dots, x_n)\| \leq x_1\}.$$

The optimal solution satisfies

$$t_{i,j}^2 = \left(w_{i,j}^x\right)^2 + \left(w_{i,j}^y\right)^2,$$

so that

$$\sum_{i,j} t_{i,j} = \sum_{i,j} \sqrt{\left(w_{i,j}^x\right)^2 + \left(w_{i,j}^y\right)^2} = \|u\|_{TV}.$$

A SOCP formulation of the dual ROF problem is also given in [34].

The SOCP can be solved by interior-point methods. The above formulation can be slightly simplified by eliminating u . But the number of variables (hence, the size of the Newton's equation) is still several times larger than the original problem. Goldfarb and Yin proposed a domain decomposition method to split the large programming problem into smaller ones, so that each subproblem can be solved efficiently. Of course, the convergence rate of the method deteriorates as the domain is further split.

Majorization-Minimization

Majorization-minimization(MM) (or *minorization-maximization*) [43] is a well-studied technique in optimization. The main idea is that at each step of the method, the objective function is replaced by a simple one, called the *surrogate function*, such that its minimization is easy to carry out and the result gives a smaller objective value of the original problem. For a given objective, usually many surrogate functions are possible. In many cases, one can even reduce multidimensional problems into a set of one-dimensional problems. Methods of this class have been heavily used in statistics communities. Indeed expectation-maximization (EM) algorithms are special cases of MM.

The use of MM to solving discrete TV problems can be traced back to the study of emission and transmission tomography reconstruction problems by Lange and Carson in [44]. Recently, some authors have applied the method to solving TV deblurring problems [6]. However, the method is actually the same as the classical lagged diffusivity fixed point iteration proposed by [58] for the particular surrogate function used in [6]. Nevertheless, it is still worthy to present the framework here because other surrogate functions can lead to different schemes.

Denote by u^k the k th iterate. In this method, the surrogate function (majorizer) $Q(u|u^k)$ is defined such that

$$\begin{aligned} F(u^k) &= Q(u^k|u^k) \\ F(u) &\leq Q(u|u^k), \text{ for all } u \end{aligned}$$

Then, the next iterate is defined to be the minimizer of the surrogate function

$$u^{k+1} := \arg \min_u Q(u|u^k).$$

In this way, the following monotonic decreasing property holds

$$F(u^{k+1}) \leq Q(u^{k+1}|u^k) \leq Q(u^k|u^k) = F(u^k).$$

Presumably, the function Q should be chosen so that its minimum is easy to compute. In many applications, it may even be chosen to have a separable form

$$Q(u|u^k) = Q_1(u_1|u^k) + Q_2(u_2|u^k) + \cdots + Q_n(u_n|u^k),$$

so that its minimization reduces to n 's one-dimensional (1D) problems. A promise of this method is that each iteration is very easy to carry out, which compensates its linear-only convergence. To construct a surrogate Q_{TV} for TV, first note that

$$\sqrt{a} = \left(\sqrt[4]{b} \right) \left(\frac{\sqrt{a}}{\sqrt[4]{b}} \right) \leq \frac{\sqrt{b}}{2} + \frac{a}{2\sqrt{b}}$$

for all $a, b \geq 0$. Let D_x and D_y be the forward difference operator in x and in y directions, respectively. Then,

$$\begin{aligned} \|u\|_{TV} &= \sum_{i,j} \sqrt{(D_x u_{i,j})^2 + (D_y u_{i,j})^2} \\ &\leq \frac{1}{2} \sum_{i,j} \sqrt{(D_x u_{i,j}^k)^2 + (D_y u_{i,j}^k)^2} + \frac{1}{2} \sum_{i,j} \frac{(D_x u_{i,j})^2 + (D_y u_{i,j})^2}{\sqrt{(D_x u_{i,j}^k)^2 + (D_y u_{i,j}^k)^2}} \end{aligned}$$

The surrogate is thus defined as

$$Q_{TV}(u|u^k) = \frac{1}{2} \|u^k\|_{TV} + \frac{1}{2} \sum_{i,j} \frac{(D_x u_{i,j})^2 + (D_y u_{i,j})^2}{\sqrt{(D_x u_{i,j}^k)^2 + (D_y u_{i,j}^k)^2}}$$

which is quadratic in u . Notice that the 2D discrete gradient matrix is given by

$$\nabla = \begin{bmatrix} \nabla_n \otimes I_m \\ I_n \otimes \nabla_m \end{bmatrix},$$

where ∇_m is the m -by- m 1D forward difference matrix (under Neumann boundary conditions)

$$\nabla_m = \begin{bmatrix} -1 & 1 & & & \\ & -1 & 1 & & \\ & & \ddots & \ddots & \\ & & & -1 & 1 \\ & & & & 0 \end{bmatrix}$$

Let $\lambda_{i,j}^k = 1/\sqrt{(D_x u_{i,j}^k)^2 + (D_y u_{i,j}^k)^2}$ and let

$$\Lambda^k = \text{diag}(\lambda_{1,1}^k, \dots, \lambda_{m,n}^k, \lambda_{1,1}^k, \dots, \lambda_{m,n}^k).$$

The surrogate becomes

$$Q_{TV}(u|u^k) = \frac{1}{2} \|u^k\|_{TV} + \frac{1}{2} u^T \nabla^T \Lambda^k \nabla u.$$

In this case, the minimization of Q_{TV} cannot be reduced to a set of 1D problems. But it does become quadratic.

Finally, the majorizer for the ROF model is

$$Q(u|u^k) = \frac{1}{2} \|Ku - f\|^2 + \lambda Q_{TV}(u|u^k).$$

While this method completely bypasses the need to optimize the TV term directly, each iteration requires solving the linear system

$$(K^T K + \lambda \nabla^T \Lambda^k \nabla) u^{k+1} = K^T f.$$

This scheme is exactly the lagged diffusivity fixed point iteration. Assume that K is full rank, then the linear system is positive definite. A standard way is to use preconditioned conjugate gradient to solve. Many preconditioners have been proposed for this problem in the 1990s, e.g., cosine transform and multigrid and multiplicative operator splitting; see [17] and the references therein. However, due to the highly varying coefficients in Λ^k , it can be nontrivial to solve efficiently.

Splitting Methods

Recently, there have been several proposals for solving TV deblurring problems based on the idea of separating the deblurring process and the TV regularization process. Many of them are based on the idea that the minimization of an objective of the form

$$F(u) = J_1(u) + J_2(Au),$$

with A a linear operator, can be approximated by the minimization of either of the following two objectives:

$$\begin{aligned} G(u, v) &= J_1(u) + \frac{\alpha}{2} \|u - v\|^2 + J_2(Av), \\ G(u, v) &= J_1(u) + \frac{\alpha}{2} \|Au - v\|^2 + J_2(v), \end{aligned}$$

where α is a large scalar. Then G is minimized w.r.t. u and v alternatively. In this way, at each iteration, the minimization of J_1 and J_2 is done separately. The same idea can be generalized to split an objective with n terms to an objective with n variables.

Consider the discrete ROF model:

$$F(u) = \frac{1}{2} \|Ku - f\|^2 + \lambda \|\nabla u\|_1.$$

Huang et al. [39] and Bresson and Chan [10] considered the splitting

$$G(u, v) = \frac{1}{2} \|Ku - f\|^2 + \frac{\alpha}{2} \|u - v\|^2 + \lambda \|\nabla v\|_1.$$

In this case, the minimization w.r.t. u becomes

$$(K^T K + \alpha I) u = K^T f + \alpha v,$$

which can be solved with the fast Fourier transform (FFT) in $O(N \log N)$ operations when the blurring matrix K can be diagonalized by a fast transform matrix. The minimization w.r.t. v is the ROF denoising problem which can be solved using any of the aforementioned denoising method. Both [39] and [10] employed Chambolle's dual algorithm. The point is that solving TV denoising is much easier than solving TV deblurring (directly). Moreover, some algorithms such as those based on graph cut cannot be applied to deblurring directly. The reason is that the pixel values in the fitting are no longer separable, which in turn makes the fitting term not "levelable." However, using the splitting technique, one can now apply graph cut methods to solve each denoising problem.

This method is generally very fast. Moreover, it often works for a large range of α . But when α is too large, the Chambolle's iteration may slow down. This splitting method has also been applied to other image processing problems such as segmentation [10].

An alternative splitting is proposed by Wang et al. [59]. The bivariate function they used is given by

$$G(u, v) = \frac{1}{2} \|Ku - f\|^2 + \frac{\alpha}{2} \|\nabla u - v\|^2 + \lambda \|v\|_1.$$

The minimization w.r.t. u requires solving

$$(K^T K - \alpha \Delta) u = K^T f + \alpha v,$$

where Δ is the 2D Laplacian. This equation can again be solved with FFT in $O(N \log N)$ operations. The minimization w.r.t. v s decoupled into N minimization problems (one for each pixel) of two variables. A simple closed-form solution for the 2D minimization problems is available. Therefore, the computation cost per iteration is even less than the approach taken in [39] and [10]. Remark that this objective is indeed the same as the split Bregman method (20). A difference is that when the split Bregman iteration converges, it holds exactly that $\nabla u = v$. But the simple alternating minimization used in most splitting methods does not guarantee $\nabla u = v$ at convergence.

An alternative splitting is introduced by Bect et al. in [5]. It is based on the observation that, for any symmetric positive definite matrix B with $\|B\| < 1$, it holds that

$$\langle Bv, v \rangle = \min_{u \in \mathbb{R}^N} \left\{ \|u - v\|^2 + \langle Cu, u \rangle \right\}$$

for all $v \in \mathcal{R}^N$, where $C = B(I - B)^{-1}$. Then, the ROF model can be formulated as the minimization of the following bivariate function:

$$G(u, v) = \frac{1}{2\mu} \left(\|u - v\|^2 + \langle Cu, u \rangle \right) + \frac{1}{2} \left(\|f\|^2 - 2 \langle Kv, f \rangle \right) + \lambda \|\nabla v\|_1,$$

where $\mu > 0$ such that $\mu \|K^T K\| < 1$ and $B = \mu K^T K$. The minimization of G w.r.t. u has a closed-form solution $u = (I - B)v = (I - \mu K^T K)v$. The minimization of G w.r.t. v is a TV denoising problem. At convergence, the minimizer of F is exactly recovered. An interesting property of this splitting is that it does not involve any matrix inversion in the alternating minimization of G .

5 Conclusion

In this chapter, some recent developments of numerical methods for TV minimization and their applications are reviewed. The chosen topics only reflect the interest of the authors and are by no means comprehensive. It is also hoped that this chapter can serve as a guide to recent literature on some of these recent developments.

Abstract

This chapter presents an overview of the Mumford and Shah model for image segmentation. It discusses its various formulations, some of its properties, the mathematical framework, and several approximations. It also presents numerical algorithms and segmentation results using the Ambrosio-Tortorelli phase-field approximations on one hand and level set formulations on the other hand. Several applications of the Mumford-Shah problem to image restoration are also presented.

1 Introduction

An important problem in image analysis and computer vision is the segmentation one, aiming to partition a given image into its constituent objects, or to find boundaries of such objects. This chapter is devoted to the description, analysis, approximations, and applications of the classical Mumford and Shah functional proposed for image segmentation. In [61–63], David Mumford and Jayant Shah have formulated an energy minimization problem that allows to compute optimal piecewise-smooth or piecewise-constant approximations u of a given initial image g . Since then, their model has been analyzed and considered in depth by many authors by studying properties of minimizers, approximations, and applications to image segmentation, image partition, image restoration, and more generally image analysis and computer vision.

Let $\Omega \subset \mathbb{R}^d$ be the image domain (an interval if $d = 1$; a rectangle in the plane if $d = 2$; or a rectangular parallelepiped if $d = 3$). More generally, it is assumed that Ω is open, bounded, and connected. Let $g: \Omega \rightarrow \mathbb{R}$ be a given grayscale image (a signal in one dimension, a planar image in two dimensions, or a volumetric image in three dimensions). It is natural and without losing any generality to assume that g is a bounded function in Ω , thus $g \in L^\infty(\Omega)$.

As formulated by Mumford and Shah [63], the *segmentation problem* in image analysis and computer vision consists in computing a decomposition

$$\Omega = \Omega_1 \cup \Omega_2 \cup \dots \cup \Omega_n \cup K$$

of the domain of the image g such that

1. The image g varies smoothly and/or slowly *within* each Ω_i .
2. The image g varies discontinuously and/or rapidly across most of the boundary K between different Ω_i .

From the point of view of approximation theory, the segmentation problem may be restated as seeking ways to define and compute *optimal approximations* of a general function $g(x)$ by piecewise-smooth functions $u(x)$, i.e., functions u whose restrictions u_i to the pieces Ω_i of a decomposition of the domain Ω are continuous or differentiable.

In what follows, Ω_i will be disjoint connected open subsets of a domain Ω , each one with a piecewise-smooth boundary, and K will be a closed set, as the union of boundaries of Ω_i inside Ω , thus

$$\Omega = \Omega_1 \cup \Omega_2 \cup \dots \cup \Omega_n \cup K, \quad K = \Omega \cap (\partial\Omega_1 \cup \dots \cup \partial\Omega_n).$$

The functional E to be minimized for image segmentation is defined by [61–63],

$$E(u, K) = \mu^2 \int_{\Omega} (u - g)^2 dx + \int_{\Omega/K} |\nabla u|^2 dx + v |K|, \quad (1)$$

where $u : \Omega \rightarrow \mathbb{R}$ is continuous or even differentiable inside each Ω_i (or $u \in H^1(\Omega_i)$) and may be discontinuous across K . Here, $|K|$ stands for the total surface measure of the hypersurface K (the counting measure if $d = 1$, the length measure if $d = 2$, the area measure if $d = 3$). Later, $|K|$ will be defined by $\mathcal{H}^{d-1}(K)$, the $d - 1$ dimensional Hausdorff measure in \mathbb{R}^d .

As explained by Mumford and Shah, dropping any of these three terms in (1), $\inf E = 0$: without the first, take $u = 0$, $K = 0$; without the second, take $u = g$, $K = 0$; without the third, take, for example, in the discrete case K to be the boundary of all pixels of the image g , each Ω_i be a pixel and u to be the average (value) of g over each pixel. The presence of all three terms leads to nontrivial solutions u , and an optimal pair (u, K) can be seen as a cartoon of the actual image g , providing a simplification of g .

An important particular case is obtained when E is restricted to piecewise-constant functions u , i.e., $u = \text{constant } c_i$ on each open set Ω_i . Multiplying E by μ^{-2} gives

$$\mu^{-2} E(u, K) = \sum_i \int_{\Omega_i} (g - c_i)^2 dx + v_0 |K|,$$

where $v_0 = v/\mu^2$. It is easy to verify that this is minimized in the variables c_i by setting

$$c_i = \text{mean}_{\Omega_i}(g) = \frac{\int_{\Omega_i} g(x) dx}{|\Omega_i|},$$

where $|\Omega_i|$ denotes here the Lebesgue measure of Ω_i (e.g., area if $d = 2$, volume if $d = 3$), so it is sufficient to minimize

$$E_0(K) = \sum_i \int_{\Omega_i} (g - \text{mean}_{\Omega_i} g)^2 dx + v_0 |K|.$$

It is possible to interpret E_0 as the limit functional of E as $\mu \rightarrow 0$ [63].

Finally, the Mumford and Shah model can also be seen as a deterministic refinement of Geman and Geman's image restoration model [41].

2 Background: The First Variation

In order to better understand, analyze, and use the minimization problem (1), it is useful to compute its first variation with respect to each of the unknowns.

The definition of Sobolev functions $u \in W^{1,2}(U)$ [1] is now recalled, necessary to properly define a minimizer u when K is fixed.

Definition 1. Let $U \subset \mathbb{R}^d$ be an open set. Let $W^{1,2}(U)$ (or $H^1(U)$) denote the set of functions $u \in L^2(\Omega)$, whose first-order distributional partial derivatives belong to $L^2(U)$. This means that there are functions $u_1, \dots, u_d \in L^2(U)$ such that

$$\int_U u(x) \frac{\partial \phi}{\partial x_i}(x) dx = - \int_U u_i(x) \phi(x) dx$$

for $1 \leq i \leq d$ and for all functions $\phi \in C_c^\infty(U)$.

Let $\frac{\partial u}{\partial x_i}$ denote the distributional derivative u_i of u and $\nabla u = \left(\frac{\partial u}{\partial x_1}, \dots, \frac{\partial u}{\partial x_d} \right)$ its distributional gradient. In what follows, $|\nabla u|(x)$ denotes the Euclidean norm of the gradient vector at x . $H^1(U) = W^{1,2}(U)$ becomes a Banach space endowed with the norm

$$\|u\|_{W^{1,2}(U)} = \left[\int_U u^2 dx + \sum_{i=1}^d \int_U \left(\frac{\partial u}{\partial x_i} \right)^2 dx \right]^{1/2}.$$

Minimizing in u with K Fixed

K is assumed to be fixed, as a closed subset of the open and bounded set $\Omega \subset \mathbb{R}^d$, and denote by

$$E(u) = \mu^2 \int_{\Omega/K} (u - g)^2 dx + \int_{\Omega/K} |\nabla u|^2 dx,$$

for $u \in W^{1,2}(\Omega \setminus K)$, where $\Omega \setminus K$ is open and bounded, and $g \in L^2(\Omega \setminus K)$. The following classical results are obtained as consequences of the standard method of calculus of variations.

Proposition 1. *There is a unique minimizer of the problem*

$$\inf_{u \in W^{1,2}(\Omega \setminus K)} E(u). \quad (2)$$

Proof ([38]). First, note that $0 \leq \inf E < +\infty$, since choosing $u_0 \equiv 0$, then $E(u_0) = \mu^2 \int_{\Omega \setminus K} g^2(x) dx < +\infty$. Thus, let $m = \inf_u E(u)$ and $\{u_j\}_{j \geq 1} \in W^{1,2}(\Omega \setminus K)$ be a minimizing sequence such that $\lim_{j \rightarrow \infty} E(u_j) = m$.

Recall that for $u, v \in L^2$,

$$\left\| \frac{u+v}{2} \right\|_2^2 + \left\| \frac{u-v}{2} \right\|_2^2 = \frac{1}{2} \|u\|_2^2 + \frac{1}{2} \|v\|_2^2,$$

and so

$$\left\| \frac{u+v}{2} \right\|_2^2 = \frac{1}{2} \|u\|_2^2 + \frac{1}{2} \|v\|_2^2 - \left\| \frac{u-v}{2} \right\|_2^2. \quad (3)$$

Let $u, v \in W^{1,2}(\Omega \setminus K)$, thus $E(u), E(v) < \infty$, and apply (3) to $u - g$ and $v - g$, and then to ∇u and ∇v ; then

$$\begin{aligned} E\left(\frac{u+v}{2}\right) &= \frac{1}{2}E(u) + \frac{1}{2}E(v) - \frac{\mu^2}{4} \int_{\Omega \setminus K} |u-v|^2 dx - \frac{1}{4} \int_{\Omega \setminus K} |\nabla(u-v)|^2 dx \\ &= \frac{1}{2}E(u) + \frac{1}{2}E(v) - \begin{cases} \frac{\mu^2}{4} \|u-v\|_{W^{1,2}(\Omega \setminus K)}^2 + \left(1 - \frac{\mu^2}{4}\right) \|\nabla(u-v)\|_2^2 & \text{if } \frac{1}{4} \geq \frac{\mu^2}{4} \\ \frac{1}{4} \|u-v\|_{W^{1,2}(\Omega \setminus K)}^2 + \left(\frac{\mu^2}{4} - 1\right) \|\nabla(u-v)\|_2^2 & \text{if } \frac{1}{4} \leq \frac{\mu^2}{4} \end{cases}. \end{aligned} \quad (4)$$

Choosing $u, v \in W^{1,2}(\Omega \setminus K)$, such that $E(u), E(v) \leq m + \varepsilon$, then

$$\begin{aligned} m &\leq E\left(\frac{u+v}{2}\right) \leq m + \varepsilon - \\ &\begin{cases} \frac{\mu^2}{4} \|u-v\|_{W^{1,2}(\Omega \setminus K)}^2 + \left(1 - \frac{\mu^2}{4}\right) \|\nabla(u-v)\|_2^2 & \text{if } \frac{1}{4} \geq \frac{\mu^2}{4} \\ \frac{1}{4} \|u-v\|_{W^{1,2}(\Omega \setminus K)}^2 + \left(\frac{\mu^2}{4} - 1\right) \|\nabla(u-v)\|_2^2 & \text{if } \frac{1}{4} \leq \frac{\mu^2}{4} \end{cases} \end{aligned}$$

thus,

$$\|u-v\|_{W^{1,2}(\Omega \setminus K)}^2 \leq \begin{cases} \frac{4\varepsilon}{\mu^2} & \text{if } \frac{1}{4} \geq \frac{\mu^2}{4} \\ 4\varepsilon & \text{if } \frac{1}{4} \leq \frac{\mu^2}{4} \end{cases}. \quad (5)$$

Let $w_j = u_j - u_1$. From (5), $\{w_j\}$ is a Cauchy sequence in $W^{1,2}(\Omega \setminus K)$; let w denote its limit and set $u_0 = u_1 + w$. Then,

$$\begin{aligned} E(u_0) &= \mu^2 \|u_0 - g\|_2^2 + \|\nabla u_0\|_2^2 = \mu^2 \|(u_1 - g) + w\|_2^2 + \|\nabla u_1 + \nabla w\|_2^2 \\ &= \lim_{j \rightarrow +\infty} \left[\mu^2 \|(u_1 - g) + w_j\|_2^2 + \|\nabla u_1 + \nabla w_j\|_2^2 \right] \\ &= \lim_{j \rightarrow +\infty} E(u_j) = m, \end{aligned}$$

by the continuity of L^2 norms. This shows the existence of minimizers. The uniqueness follows from (5) by taking $\varepsilon = 0$.

Proposition 2. *The unique solution u of (2) is solution of the elliptic problem*

$$\int_{\Omega/K} \nabla u(x) \cdot \nabla v(x) dx = -\mu^2 \int_{\Omega/K} [u(x) - g(x)] v(x) dx, \quad \forall v \in W^{1,2}(\Omega/K), \quad (6)$$

or of

$$\Delta u = \mu^2(u - g)$$

in the sense of distributions in $\Omega \setminus K$, with associated boundary condition $\frac{\partial u}{\partial \vec{N}} = 0$ on $\partial(\Omega \setminus K)$, where \vec{N} is the exterior unit normal to the boundary.

Proof. Indeed, let $\varepsilon \mapsto A(\varepsilon) = E(u + \varepsilon v)$ for $\varepsilon \in \mathbb{R}$ and arbitrary $v \in W^{1,2}(\Omega \setminus K)$. Then, A is a quadratic function of ε , given by

$$\begin{aligned} A(\varepsilon) &= \mu^2 \int_{\Omega/K} (u - g)^2 dx + \varepsilon^2 \mu^2 \int_{\Omega/K} v^2 dx + 2\varepsilon \mu^2 \int_{\Omega/K} (u - g)v dx \\ &\quad + \int_{\Omega/K} |\nabla u|^2 dx + \varepsilon^2 \int_{\Omega/K} |\nabla v|^2 dx + 2\varepsilon \int_{\Omega/K} \nabla u \cdot \nabla v dx, \end{aligned}$$

with

$$\begin{aligned} A'(\varepsilon) &= 2\varepsilon \mu^2 \int_{\Omega/K} v^2 dx + 2\mu^2 \int_{\Omega/K} (u - g)v dx + 2\varepsilon \int_{\Omega/K} |\nabla v|^2 dx \\ &\quad + 2 \int_{\Omega/K} \nabla u \cdot \nabla v dx, \end{aligned}$$

and

$$A'(0) = 2\mu^2 \int_{\Omega/K} (u - g)v dx + 2 \int_{\Omega/K} \nabla u \cdot \nabla v dx,$$

Since $E(u) = A(0) \leq A(\varepsilon) = E(u + \varepsilon v)$ for all $\varepsilon \in \mathbb{R}$ and all $v \in W^{1,2}(\Omega \setminus K)$, it implies that $A'(0) = 0$ for all such v , which yields the weak formulation (6).

If in addition u would be a strong classical solution of the problem, or if it would belong to $W^{2,2}(\Omega \setminus K)$, then integrating by parts in the last relation gives

$$A'(0) = 2\mu^2 \int_{\Omega \setminus K} (u - g)v dx + 2 \int_{\Omega \setminus K} (\nabla u)v dx + 2 \int_{\partial(\Omega \setminus K)} \nabla u \cdot \vec{N} v dx = 0$$

Taking now $v \in C_0^1(\Omega \setminus K) \subset W^{1,2}(\Omega \setminus K)$ gives

$$\Delta u = \mu^2(u - g) \text{ in } \Omega \setminus K.$$

Using this and taking now $v \in C^1(\Omega \setminus K)$, the associated implicit boundary condition $\nabla u \cdot \vec{N} = \frac{\partial u}{\partial \vec{N}} = 0$ on the boundary of $\Omega \setminus K$ (in other words, on the boundary of Ω and of each Ω_i) is obtained.

Assume now that $g \in L^\infty(\Omega \setminus K)$, which is not a restrictive assumption when g represents an image. It can be shown that the unique minimizer u of (2) satisfies $\|u\|_\infty \leq \|g\|_\infty$ (as expected, due to the smoothing properties of the energy). To prove this, first the following classical lemma is stated (see, e.g., Ref. [38], Chapter A3).

Lemma 1. *If $\Omega \setminus K$ is open, and if $u \in W^{1,2}(\Omega \setminus K)$, then $u^+ = \max(u, 0)$ also lies in $W^{1,2}(\Omega \setminus K)$ and $|\nabla u^+(x)| \leq |\nabla u(x)|$ almost everywhere.*

Now let $u^*(x) = \max\{-\|g\|_\infty, \min(\|g\|_\infty, u(x))\}$ be the obvious truncation of u . Lemma 1 implies that $u^* \in W^{1,2}(\Omega \setminus K)$ and that $\int_{\Omega \setminus K} |\nabla u^*(x)|^2 dx \leq \int_{\Omega \setminus K} |\nabla u(x)|^2 dx$. Obviously, also $\int_{\Omega \setminus K} (u^* - g)^2 dx \leq \int_{\Omega \setminus K} (u - g)^2 dx$, thus $E(u^*) \leq E(u)$. But u is the unique minimizer of E ; therefore, $u(x) = u^*(x)$ almost everywhere and $\|u\|_\infty \leq \|g\|_\infty$.

Remark 1. Several classical regularity results for a weak solution u of (2) can be stated:

- If $g \in L^\infty(\Omega \setminus K)$, then $u \in C_{loc}^1(\Omega \setminus K)$ (see e.g., Ref. [38], Chapter A3).
- If $g \in L^2(\Omega \setminus K)$, then $u \in W_{loc}^{2,2}(\Omega \setminus K) = H_{loc}^2(\Omega \setminus K)$, which implies that u solves the PDE (see, e.g., Ref. [39], Chapter 6.3).

$$\Delta u = \mu^2(u - g) \text{ a.e. in } \Omega \setminus K.$$

3 Minimizing in K

Here we formally compute the first variation of $E(u, K)$ with respect to K . Let us assume that (u, K) is a minimizer of E from (1), and we vary K . Let us assume that locally, $K \cap U$ is the graph of a regular function ϕ , where U is a small neighborhood near a regular, simple point P of K .

Without loss of generality, it can be assumed that $U = D \times I$ where I is an interval in \mathbb{R} and $K \cap U = \{(x_1, x_2, \dots, x_d) \in U = D \times I : x_d = \phi(x_1, \dots, x_{d-1})\}$. Let u^+ denote the restriction of u to

$$U^+ = \{(x_1, x_2, \dots, x_d) : x_d > \phi(x_1, \dots, x_{d-1})\} \cap U,$$

and u^- the restriction of u to

$$U^- = \{(x_1, x_2, \dots, x_d) : x_d < \phi(x_1, \dots, x_{d-1})\} \cap U,$$

and choose H^1 extensions of u^+ from U^+ to U , and of u^- from U^- to U . For small ε , define a deformation K_ε of K inside U as the graph of

$$x_d = \phi(x_1, \dots, x_{d-1}) + \varepsilon \psi(x_1, \dots, x_{d-1}),$$

such that ψ is regular and zero outside D , and $K_\varepsilon = K$ outside U . Define

$$u_\varepsilon(x) = \begin{cases} u(x) & \text{if } x \notin U, \\ (\text{extension of } u^+)(x) & \text{if } x \in U, x \text{ above } K_\varepsilon \cap U \\ (\text{extension of } u^-)(x) & \text{if } x \in U, x \text{ above } K_\varepsilon \cap U. \end{cases}$$

Now, using $z = (x_1, \dots, x_{d-1})$,

$$\begin{aligned} E(u_\varepsilon, K_\varepsilon) - E(u, K) &= \mu^2 \int_U [(u_\varepsilon - g)^2 dx - (u - g)^2] dx \\ &\quad + \int_{U/K_\varepsilon} |\nabla u_\varepsilon|^2 dx - \int_{U/K} |\nabla u|^2 dx + v [|K_\varepsilon \cap U| - |K \cap U|] \\ &= \mu^2 \int_D \left(\int_{\phi(z)}^{\phi(z)+\varepsilon\psi(z)} [(u^- - g)^2 - (u^+ - g)^2] dx_d \right) dz \\ &\quad + \int_D \left(\int_{\phi(z)}^{\phi(z)+\varepsilon\psi(z)} [|\nabla u^-|^2 - |\nabla u^+|^2] dx_d \right) dz \\ &\quad + v \int_D \left[\sqrt{1 + |\nabla(\phi + \varepsilon\psi)|^2} - \sqrt{1 + |\nabla\phi|^2} \right] dz \end{aligned}$$

Thus,

$$\begin{aligned} \lim_{\varepsilon \rightarrow 0} \frac{E(u_\varepsilon, K_\varepsilon) - E(u, K)}{\varepsilon} &= \mu^2 \int_D [(u^- - g)^2 - (u^+ - g)^2] \Big|_{x_d=\phi(z)} \psi(z) dz \\ &\quad + \int_D \left[|\nabla u^-|^2 - |\nabla u^+|^2 \right] \Big|_{x_d=\phi(z)} \psi(z) dz + v \int_D \frac{\nabla\phi \cdot \nabla\psi}{\sqrt{1 + |\nabla\phi|^2}} dz = \end{aligned}$$

for all such ψ , since (u, K) is a minimizer. Integrating by parts, we formally obtain for all ψ :

$$\begin{aligned} \int_D \left\{ \left[(\mu^2(u^- - g)^2 + |\nabla u^-|^2) - (\mu^2(u^+ - g)^2 + |\nabla u^+|^2) \right] \Big|_{x_d=\phi(z)} \right. \\ \left. - v \operatorname{div} \left(\frac{\nabla\phi}{\sqrt{1 + |\nabla\phi|^2}} \right) \right\} \psi(z) dz = 0, \end{aligned}$$

and obtain the first variation with respect to K ,

$$\left[\mu^2(u^- - g)^2 + |\nabla u^-|^2 \right] - \left[\mu^2(u^+ - g)^2 + |\nabla u^+|^2 \right] - v \operatorname{div} \left(\frac{\nabla \phi}{\sqrt{1 + |\nabla \phi|^2}} \right) = 0 \quad (7)$$

on $K \cap U$. Noticing that the last term represents the curvature of $K \cap U$, and if we write the energy density as

$$e(u; x) = \mu^2(u(x) - g(x))^2 + |\nabla u(x)|^2,$$

we finally obtain

$$e(u^+) - e(u^-) + v \operatorname{curv}(K) = 0 \text{ on } K$$

(at regular points of K , provided that the traces of u and of $|\nabla u|$ on each side of K are taken in the sense of Sobolev traces).

This section is concluded by stating another important result from [63] regarding the type of singular points of K , when (u, K) is a minimizer of E from (1), in two dimensions, $d = 2$. For the rather technical proof of this result, the reader is referred to the instructive and inspiring constructions from [63].

Theorem 1. *Let $d = 2$. If (u, K) is a minimizer of $E(u, K)$ such that K is a union of simple $C^{1,1}$ -curves K_i meeting $\partial\Omega$ and meeting each other only at their endpoints, then the only vertices of K are:*

1. Points P on the boundary $\partial\Omega$ where one K_i meets $\partial\Omega$ perpendicularly
2. Triple points P where three K_i meet with angles $2\pi/3$
3. Crack tips where a K_i ends and meets nothing.

The later sections will discuss cases when the minimizer u is restricted to a specific class of piecewise-constant or piecewise-smooth functions.

4 Mathematical Modeling and Analysis: The Weak Formulation of the Mumford and Shah Functional

To better study the mathematical properties of the Mumford and Shah functional (1), it is necessary to define the measure of K as its $d - 1$ -dimensional Hausdorff measure $\mathcal{H}^{d-1}(K)$, which is the most natural way to extend the notion of length to nonsmooth sets. Recall the definition of the Hausdorff measure [4, 38, 40].

Definition 2. For $K \subset \mathbb{R}^d$ and $n > 0$, set

$$\mathcal{H}^n(K) = \sup_{\varepsilon > 0} \mathcal{H}_\varepsilon^n(K),$$

called the n -dimensional Hausdorff measure of the set K , where

$$\mathcal{H}_\varepsilon^n(K) = c_n \inf \left\{ \sum_{i=1}^{\infty} (\text{diam } A_i)^n \right\},$$

where the infimum is taken over all countable families $\{A_i\}_{i=1}^{\infty}$ of open sets A_i such that

$$K \subset \cup_{i=1}^{\infty} A_i \text{ and } \text{diam } A_i \leq \varepsilon \text{ for all } i.$$

Here, the constant c_n is chosen so that \mathcal{H}^n coincides with the Lebesgue measure on n planes.

Remark 2. When n is an integer and K is contained in a C^1 -surface of dimension n , $\mathcal{H}^n(K)$ coincides with its n -dimensional surface measure.

Consider a first variant of the functional,

$$E(u, K) = \mu^2 \int_{\Omega/K} (u - g)^2 dx + \int_{\Omega/K} |\nabla u|^2 dx + v\mathcal{H}^{d-1}(K). \quad (8)$$

In order to apply the direct method of calculus of variations for proving existence of minimizers, it is necessary to find a topology for which the functional is lower semicontinuous, while ensuring compactness of minimizing sequences. Unfortunately, the last functional $K \mapsto \mathcal{H}^{d-1}(K)$ is not lower semicontinuous with respect to any compact topology [4, 8, 38]. To overcome this difficulty, the set K is substituted by the jump set S_u of u , thus K is eliminated, and the problem, called the weak formulation, becomes, in its second variant,

$$\inf_u \left\{ F(u) = \mu^2 \int_{\Omega/S_u} (u - g)^2 dx + \int_{\Omega/S_u} |\nabla u|^2 dx + v\mathcal{H}^{d-1}(S_u) \right\}. \quad (9)$$

For illustration, also given is the weak formulation in one dimension, for signals. The problem of reconstructing and segmenting a signal u from a degraded input g deriving from a distorted transmission can be modeled as finding the minimum

$$\inf_u \left\{ \mu^2 \int_a^b (u - g)^2 dt + \int_{(a,b)/S_u} |u'|^2 dt + v\#(S_u) \right\}.$$

where $\Omega = (a, b)$, S_u denotes the set of discontinuity points of u in the interval (a, b) , and $\#(S_u) = \mathcal{H}^0(S_u)$ denotes the counting measure of S_u or its cardinal.

In order to show that (9) has a solution, the following notion of special functions of bounded variation and the following important lemma due to Ambrosio [3, 4] are necessary.

Definition 3. A function $u \in L^1(\Omega)$ is a special function of bounded variation on Ω if its distributional derivative can be written as

$$Du = \nabla u dx + (u^+ - u^-) \vec{N}_u \mathcal{H}^{d-1}|_{S_u}$$

such that $\nabla u \in L^1(\Omega)$, S_u is of finite Hausdorff measure, $(u^+ - u^-) \vec{N}_{u \chi S_u} \in L^1(\Omega, \mathcal{H}^{d-1}|_{S_u}, \mathbb{R}^d)$, where u^+ and u^- are the traces of u on each side of the jump part S_u , and \vec{N}_u is the unit normal to S_u . The space of special functions of bounded variation is denoted by $\text{SBV}(\Omega)$.

Lemma 2. Let $u_n \in \text{SBV}(\Omega)$ be a sequence of functions such that there exists a constant $C > 0$ with $|u_n(x)| \leq C < \infty$ a.e. $x \in \Omega$ and $\int_{\Omega} |\nabla u_n|^2 dx + \mathcal{H}^{d-1}(S_{u_n}) \leq C$. Then, there exists a subsequence u_{n_k} converging a.e. to a function $u \in \text{SBV}(\Omega)$. Moreover, ∇u_{n_k} converges weakly in $L^2(\Omega)^d$ to ∇u , and

$$\mathcal{H}^{d-1}(S_u) \leq \liminf_{n_k \rightarrow \infty} \mathcal{H}^{d-1}(S_{u_{n_k}}).$$

Theorem 2. Let $g \in L^\infty(\Omega)$, with $\Omega \subset \mathbb{R}^d$ open, bounded, and connected. There is a minimizer $u \in \text{SBV}(\Omega) \cap L^\infty(\Omega)$ of

$$F(u) = \mu^2 \int_{\Omega/S_u} (u - g)^2 dx + \int_{\Omega/S_u} |\nabla u|^2 dx + v \mathcal{H}^{d-1}(S_u).$$

Proof. Notice that $0 \leq \inf_{\text{SBV}(\Omega) \cap L^\infty(\Omega)} F < \infty$, because we can take $u_0 = 0 \in \text{SBV}(\Omega) \cap L^\infty(\Omega)$ and using the fact that $g \in L^\infty(\Omega) \subset L^2(\Omega)$, $F(u_0) < \infty$. Thus, there is a minimizing sequence $u_n \in \text{SBV}(\Omega) \cap L^\infty(\Omega)$ satisfying $\lim_{n \rightarrow \infty} F(u_n) = \inf F$. Also notice that, by the truncation argument from before, it can be assumed that $\|u_n\|_\infty \leq \|g\|_\infty < \infty$. Since $F(u_n) \leq C < \infty$ for all $n \geq 0$, and using $g \in L^\infty(\Omega) \subset L^2(\Omega)$, we deduce that $\|u_n\|_2 \leq C$ and $\int_{\Omega/S_{u_n}} |\nabla u_n|^2 dx + \mathcal{H}^{d-1}(S_{u_n}) < C$ for some positive real constant C . Using these and Ambrosio's compactness result, it can be deduced that there is a subsequence u_{n_k} of u_n , and $u \in \text{SBV}(\Omega)$, such that $u_{n_k} \rightharpoonup u$ in $L^2(\Omega)$, $\nabla u_{n_k} \rightharpoonup \nabla u$ in $L^2(\Omega)^d$. Therefore, $F(u) \leq \liminf_{n_k \rightarrow \infty} F(u_{n_k}) = \inf F$, and it can also be deduced that $\|u\|_\infty \leq \|g\|_\infty$.

For additional existence, regularity results and fine properties of minimizers, and for the connections between problems (8) and (9), the reader is referred to Dal Maso et al. [55, 56], the important monographs by Morel and Solimini [60], by Chambolle [26], by Ambrosio et al. [4], by David [38], and by Braides [19]. Existence and regularity of minimizers for the piecewise-constant case can be found in [63], Congedo and Tamanini [52, 57, 75, 76], and Larsen [51], among other works.

5 Numerical Methods: Approximations to the Mumford and Shah Functional

Since the original Mumford and Shah functional (1) (or its weak formulation (9)) is nonconvex, it has an unknown set K of lower dimension and is not the lower-semicontinuous envelope of a more amenable functional, and it is difficult to find smooth approximations and to solve the minimization in practice. Several approximations have been proposed, including the weak membrane model and the graduate non-convexity of Blake and Zisserman [16] (which can be seen as a discrete version of the Mumford and Shah segmentation problem); discrete finite differences approximations starting with the work of Chambolle [23–25] (also proving the Γ -convergence of Blake-Zisserman approximations to the weak Mumford-Shah functional in one dimension); finite element approximations by Chambolle and Dal Maso [27] and by Chambolle and Bourdin [17, 18]; phase-field elliptic approximations due to Ambrosio and Tortorelli [5, 6] (with generalizations presented by [19] and extensions by Shah [74], and Alicandro et al. [2]); region growing and merging methods proposed by Koepfler et al. [48], by Morel and Solimini [60], and by Dal Maso et al. [55, 56] and level set approximations proposed by Chan and Vese [29–32, 79], by Samson et al. [71], and by Tsai et al. [78]; and approximations by nonlocal functionals by Braides and Dal Maso [20], among other approximations. Presented in this section in much more detail are the phase-field elliptic approximations and the level set approximations together with their applications.

For proving the convergence of some of these approximations to the Mumford and Shah functional, the notion of Γ -convergence is used, which is briefly recalled below. The interested reader is referred to Dal Maso [54] for a comprehensive introduction to Γ -convergence.

The reader is referred to the monographs and textbooks by Braides [19], by Morel and Solimini [60], and by Ambrosio et al. [4] on detailed presentations of approximations to the Mumford and Shah functional.

Definition 4. Let $X = (X, D)$ be a metric space. We say that a sequence $F_j: X \rightarrow [-\infty, +\infty]$ Γ -converges to $F: X \rightarrow [-\infty, +\infty]$ (as $j \rightarrow \infty$) if for all $u \in X$ we have

1. (\liminf inequality) for every sequence $(u_j) \subset X$ converging to u ,

$$F(u) \leq \liminf_j F_j(u_j) \tag{10}$$

2. (existence of a recovery sequence) there exists a sequence $(u_j) \subset X$ converging to u such that

$$F(u) \geq \limsup_j F_j(u_j),$$

or, equivalently by (10),

$$F(u) = \lim_j F_j(u_j).$$

The function F is called the Γ -limit of (F_j) (with respect to D), and we write $F = \Gamma\text{-}\lim_j F_j$.

The following fundamental theorem is essential in the convergence of some of the approximations.

Theorem 3 (Fundamental Theorem of Γ -convergence). *Let us suppose that $F = \Gamma\text{-}\lim_j F_j$, and let a compact set $C \subset X$ exist such that $\inf_X F_j = \inf_C F_j$ for all j . Then, there is minimum of F over X such that*

$$\min_X F = \liminf_j \inf_X F_j,$$

and if $(u_j) \subset X$ is a converging sequence such that $\lim_j F_j(u_j) = \lim_j \inf_X F_j$, then its limit is a minimum point of F .

6 Ambrosio and Tortorelli Phase-Field Elliptic Approximations

A specific strategy, closer to the initial formulation of the Mumford-Shah problem in terms of pairs $(u, K = S_u)$, is based on the approximation by functionals depending on two variables (u, v) , the second one related to the set $K = S_u$.

7 Approximations of the Perimeter by Elliptic Functionals

The Modica-Mortola theorem [58, 59] enables the variational approximation of the perimeter functional $E \mapsto P(E, \Omega) = \int_{\Omega} |D\chi_E| < \infty$ of an open subset E of Ω by the quadratic, elliptic functionals

$$MM_{\varepsilon}(v) = \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{W(v)}{\varepsilon} \right) dx, \quad v \in W^{1,2}(\Omega),$$

where $W(t)$ is a “double-well” potential. For instance, choosing $W(t) = t^2(1-t)^2$, assuming that Ω is bounded with Lipschitz boundary and setting $MM_{\varepsilon}(v) = \infty$ if $v \in L^2(\Omega) \setminus W^{1,2}(\Omega)$, the functionals $MM_{\varepsilon}(v)$ Γ -converge in $L^2(\Omega)$ to

$$F(v) = \begin{cases} \frac{1}{3}P(E, \Omega) & \text{if } v = \chi_E \text{ for some } E \in \mathcal{B}(\Omega), \\ \infty & \text{otherwise,} \end{cases}$$

where $\mathcal{B}(\Omega)$ denotes the σ -algebra of Borel subsets of Ω .

Minimizing the functional $MM_\varepsilon(v)$ with respect to v yields the associated Euler-Lagrange equation and boundary condition,

$$W'(v) = 2\varepsilon^2 \Delta v \text{ in } \Omega, \quad \frac{\partial v}{\partial \vec{N}} = 0 \text{ on } \partial\Omega,$$

which can be easily solved in practice by finite differences.

8 Ambrosio-Tortorelli Approximations

In the Mumford and Shah functional, the set $K = S_u$ is not necessarily the boundary of an open and bounded domain, but a construction similar to $MM_\varepsilon(v)$ can still be used, with the potential $W(t) = \frac{1}{4}(1-t)^2$ instead. Ambrosio and Tortorelli proposed two elliptic approximations [5, 6] to the weak formulation of the Mumford and Shah problem. Presented is the second one [6], being simpler than the first one [5], and commonly used in practice.

Let $X = L^2(\Omega)^2$ and let us define

$$AT_\varepsilon(u, v) = \int_{\Omega} (u - g)^2 dx + \beta \int_{\Omega} v^2 |\nabla u|^2 dx + \alpha \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{(v-1)}{4\varepsilon} \right) dx \quad (11)$$

if $(u, v) \in W^{1,2}(\Omega)^2$, $0 \leq v \leq 1$, and $AT_\varepsilon(u, v) = +\infty$ otherwise.

Also defined is the limiting Mumford-Shah functional,

$$F(u, v) = \begin{cases} \int_{\Omega} (u - g)^2 dx + \beta \int_{\Omega} |\nabla u|^2 + \alpha \mathcal{H}^{d-1}(S_u) & \text{if } u \in SBV(\Omega), \ v \equiv 1, \\ +\infty & \text{otherwise.} \end{cases}$$

Theorem 4. AT_ε Γ -converges to F as $\varepsilon \downarrow 0$ in $L^2(\Omega)$. Moreover, AT_ε admits a minimizer $(u_\varepsilon, v_\varepsilon)$ such that up to subsequences, u_ε converges to some $u \in SBV(\Omega)$ a minimizer of $F(u, 1)$ and $\inf AT_\varepsilon(u_\varepsilon, v_\varepsilon) \rightarrow F(u, 1)$.

Interesting generalizations of this result are given and proved by Braides in [19].

In practice, the Euler-Lagrange equations associated with the alternating minimization of AT_ε with respect to $u = u_\varepsilon$ and $v = v_\varepsilon$ are used and discretized by finite differences. These are

$$\frac{\partial AT_\varepsilon(u,v)}{\partial u} = 2(u - g) - 2\beta \operatorname{div}(v^2 \nabla u) = 0$$

$$\frac{\partial AT_\varepsilon(u,v)}{\partial v} = 2\beta v |\nabla u|^2 - 2\alpha \varepsilon \Delta v + \frac{\alpha}{2\varepsilon} (v-1).$$

One of the finite difference approximations to compute u and v in two dimensions $x = (x_1, x_2)$ is as follows. A time-dependent scheme is used in $u = u(x_1, x_2, t)$ and

a stationary semi-implicit fixed-point scheme in $v = v(x_1, x_2)$. Let $\Delta x_1 = \Delta x_2 = h$ be the step space, Δt be the time step, and $g_{i,j}, u_{i,j}^n, v_{i,j}^n$ be the discrete versions of g , and of u and v at iteration $n \geq 0$, for $1 \leq i \leq M$, $1 \leq j \leq N$. Initialize $u^0 = g$ and $v^0 = 0$.

For $n \geq 1$, compute and repeat to steady state, for $i = 2, \dots, M - 1$ and $j = 2, \dots, N - 1$ (combined with Neumann boundary conditions on $\partial\Omega$):

$$\begin{aligned} |\nabla u^n|_{i,j}^2 &= \left(\frac{u_{i+1,j}^n - u_{i,j}^n}{h} \right)^2 + \left(\frac{u_{i,j+1}^n - u_{i,j}^n}{h} \right)^2, \\ 0 &= 2\beta v_{i,j}^{n+1} |\nabla u^n|_{i,j}^2 - 2\frac{\alpha\varepsilon}{h^2} \left(v_{i+1,j}^n + v_{i-1,j}^n + v_{i,j+1}^n + v_{i,j-1}^n \right. \\ &\quad \left. - 4v_{i,j}^{n+1} \right) + \frac{\alpha}{2\varepsilon} \left(v_{i,j}^{n+1} - 1 \right), \\ \frac{u_{i,j}^{n+1} - u_{i,j}^n}{\Delta t} &= - \left(u_{i,j}^n - g_{i,j} \right) + \frac{\beta}{h^2} \left[\left(v_{i,j}^{n+1} \right)^2 \left(u_{i+1,j}^n - u_{i,j}^n \right) + \left(v_{i,j}^{n+1} \right)^2 \right. \\ &\quad \left. \left(u_{i,j+1}^n - u_{i,j}^n \right) - \left(v_{i-1,j}^{n+1} \right)^2 \left(u_{i,j}^n - u_{i-1,j}^n \right) - \left(v_{i,j-1}^{n+1} \right)^2 \left(u_{i,j}^n - u_{i,j-1}^n \right) \right] \end{aligned}$$

which is equivalent with

$$\begin{aligned} |\nabla u^n|_{i,j}^2 &= \left(\frac{u_{i+1,j}^n - u_{i,j}^n}{h} \right)^2 + \left(\frac{u_{i,j+1}^n - u_{i,j}^n}{h} \right)^2, \\ v_{i,j}^{n+1} &= \frac{\frac{\alpha}{2\varepsilon} + \frac{2\alpha\varepsilon}{h^2} \left(v_{i+1,j}^n + v_{i-1,j}^n + v_{i,j+1}^n + v_{i,j-1}^n \right)}{\frac{\alpha}{2\varepsilon} + 2\beta |\nabla u^n|_{i,j}^2 + \frac{8\alpha\varepsilon}{h^2}}, \\ u_{i,j}^{n+1} &= u_{i,j}^n + \Delta t \left\{ - \left(u_{i,j}^n - g_{i,j} \right) + \frac{\beta}{h^2} \left[\left(v_{i,j}^{n+1} \right)^2 \left(u_{i+1,j}^n - u_{i,j}^n \right) \right. \right. \\ &\quad + \left(v_{i,j}^{n+1} \right)^2 \left(u_{i,j+1}^n - u_{i,j}^n \right) - \left(v_{i-1,j}^{n+1} \right)^2 \left(u_{i,j}^n - u_{i-1,j}^n \right) \\ &\quad \left. \left. - \left(v_{i,j-1}^{n+1} \right)^2 \left(u_{i,j}^n - u_{i,j-1}^n \right) \right] \right\} \end{aligned}$$

Presented are experimental results obtained using the above Ambrosio-Tortorelli approximations applied to the well-known Barbara image shown in Fig. 1 left. Segmented images u are shown in Fig. 2, and the corresponding edge sets v are shown in Fig. 3 for varying coefficients $\alpha, \beta \in \{1, 5, 10\}$. We notice that less regularization (decreasing both α and β) gives more edges in v , as expected; thus, u is closer to g . Fixed α and increasing β give smoother image u and fewer edges in v . Keeping fixed β but varying α does not produce much variation in the results. Also shown in Fig. 1 right is the numerical energy versus iterations for the case $\alpha = \beta = 10, \varepsilon = 0.0001$.

Applications of the Ambrosio-Tortorelli approximations to image restoration will be presented in details in Sect. 5.

9 Level Set Formulations of the Mumford and Shah Functional

In this section are reviewed the level set formulations for minimizing the Mumford and Shah functional, as proposed initially by Chan and Vese [29–32, 79], and by Tsai et al. [78] (see also the related work by Samson et al. [71] and Cohen et al. [36, 37]). These make the link between curve evolution, active contours, and Mumford-Shah segmentation. These models have been proposed by restricting the set of minimizers u to specific classes of functions: piecewise constant, piecewise smooth, and with the edge set K represented by a union of curves or surfaces that are boundaries of open subsets of Ω . For example, if K is the boundary of an open-bounded subset of Ω , then it can be represented implicitly, as the zero-level line of a Lipschitz-continuous level set function. Thus, the set K as an unknown is substituted by an unknown function that defines it implicitly, and the Euler-Lagrange equations with respect to the unknowns can be easily computed and discretized.

Following the level set approach [67, 68, 72, 73], let $\phi: \Omega \rightarrow \mathbb{R}$ be a Lipschitz-continuous function. Recalled is the variational level set terminology that will be useful to rewrite the Mumford and Shah functional in terms of (u, ϕ) , instead of (u, K) . This is inspired by the work of Zhao et al. [83] on a variational level set approach for the motion of triple junctions in the plane.

Used here is the one-dimensional (1D) Heaviside function H , defined by

$$H(z) = \begin{cases} 1 & \text{if } z \geq 0 \\ 0 & \text{if } z < 0 \end{cases},$$

and its distributional derivative $\delta = H'$ (in the weak sense). In practice, it may be necessary to work with smooth approximations of the Heaviside and δ functions.

Fig. 2 Piecewise-smooth images u as minimizers of the Ambrosio-Tortorelli approximations for $\varepsilon = 0.0001$ and various values of (α, β)

Used here are the following C^∞ approximations as $\varepsilon \rightarrow 0$ given by [29, 31],

$$H_\varepsilon(z) = \frac{1}{2} \left[1 + \frac{2}{\pi} \arctan \left(\frac{z}{\varepsilon} \right) \right], \quad \delta_\varepsilon = H'_\varepsilon.$$

The area (or the volume) of the region $\{x \in \Omega : \phi(x) > 0\}$ is

$$A\{x \in \Omega : \phi(x) > 0\} = \int_{\Omega} H(\phi(x)) dx,$$

Fig. 3 Corresponding edge sets v as minimizers of the Ambrosio-Tortorelli approximations for $\varepsilon = 0.0001$ and various values of (α, β)

and for a level parameter $l \in \mathbb{R}$, the area (or volume) of the region $\{x \in \Omega : \phi(x) > l\}$ is

$$A\{x \in \Omega : \phi(x) > l\} = \int_{\Omega} H(\phi(x) - l) dx.$$

The perimeter (or more generally the surface area) of the region $\{x \in \Omega : \phi(x) > 0\}$ is given by

$$L\{x \in \Omega : \phi(x) > 0\} = \int_{\Omega} |DH(\phi)|,$$

which is the total variation of $H(\phi)$ in Ω , and the perimeter (or surface area) of $\{x \in \Omega : \phi(x) > l\}$ is

$$L\{x \in \Omega : \phi(x) > l\} = \int_{\Omega} |DH(\phi - l)|.$$

Given the image data $g \in L^{\infty}(\Omega) \subset L^2(\Omega)$ to be segmented, the averages of g over the (nonempty) regions $\{x \in \Omega : \phi(x) > 0\}$ and $\{x \in \Omega : \phi(x) < 0\}$, respectively, are

$$\frac{\int_{\Omega} g(x)H(\phi(x))dx}{\int_{\Omega} H(\phi(x))dx} \text{ and } \frac{\int_{\Omega} g(x)(1 - H(\phi(x)))dx}{\int_{\Omega} (1 - H(\phi(x)))dx} = \frac{\int_{\Omega} g(x)H(-\phi(x))dx}{\int_{\Omega} H(-\phi(x))dx}.$$

More generally, for a given level parameter $l \in \mathbb{R}$, the averages of g over the corresponding (nonempty) regions $\{x \in \Omega : \phi(x) > l\}$ and $\{x \in \Omega : \phi(x) < l\}$, respectively, are

$$\frac{\int_{\Omega} g(x)H(\phi(x) - l)dx}{\int_{\Omega} H(\phi(x) - l)dx} \text{ and } \frac{\int_{\Omega} g(x)H(l - \phi(x))dx}{\int_{\Omega} H(l - \phi(x))dx}.$$

Proved next is that if H and δ are substituted by the above C^{∞} approximations H_{ε} , δ_{ε} as $\varepsilon \rightarrow 0$, approximations of the area and length (perimeter) measures are obtained. It is obviously found that $H_{\varepsilon}(z) \rightarrow H(z)$ for all $z \in \mathbb{R}$, as $\varepsilon \rightarrow 0$, and that the approximating area term $A_{\varepsilon}(\phi) = \int_{\Omega} H_{\varepsilon}(\phi(x))dx$ converges to $A(\phi) = \int_{\Omega} H(\phi(x))dx$.

Generalizing a result of Samson et al. [71], it can be shown [35] that our approximating functional $L_{\varepsilon}(\phi) = \int_{\Omega} |DH_{\varepsilon}(\phi)|dx = \int_{\Omega} \delta_{\varepsilon}(\phi) |\nabla \phi| dx$ converges to the length $|K|$ of the zero-level line $K = \{x \in \Omega : \phi(x) = 0\}$, under the assumption that $\phi : \Omega \rightarrow \mathbb{R}$ is Lipschitz. The same result holds for the case of any l -level curve of ϕ and not only for the 0-level curve.

Theorem 5. *Let us define*

$$L_{\varepsilon}(\phi) = \int_{\Omega} |\nabla H_{\varepsilon}(\phi)| dx = \int_{\Omega} \delta_{\varepsilon}(\phi) |\nabla \phi| dx.$$

Then, we have

$$\lim_{\varepsilon \rightarrow 0} L_{\varepsilon}(\phi) = \int_{\{\phi=0\}} ds = |K|,$$

where $K = \{x \in \Omega : \phi(x) = 0\}$.

Proof. Using co-area formula [40], the following is found:

$$L_\varepsilon(\phi) = \int_{\mathbb{R}} \left[\int_{\phi=\rho} \delta_\varepsilon(\phi(x)) ds \right] d\rho = \int_{\mathbb{R}} \left[\delta_\varepsilon(\rho) \int_{\phi=\rho} ds \right] d\rho.$$

By setting $h(\rho) = \int_{\phi=\rho} ds$, the following is obtained

$$L_\varepsilon(\phi) = \int_{\mathbb{R}} \delta_\varepsilon(\rho) h(\rho) d\rho = \int_{\mathbb{R}} \frac{1}{\pi} \frac{\varepsilon}{\varepsilon^2 + \rho^2} h(\rho) d\rho.$$

By the change of variable $\theta = \frac{\rho}{\varepsilon}$, the following is obtained

$$\begin{aligned} \lim_{\varepsilon \rightarrow 0} L_\varepsilon(\phi) &= \lim_{\varepsilon \rightarrow 0} \int_{\mathbb{R}} \frac{1}{\pi} \frac{\varepsilon}{\varepsilon^2 + \varepsilon^2 \theta^2} h(\theta \varepsilon) d\theta = \lim_{\varepsilon \rightarrow 0} \int_{\mathbb{R}} \frac{1}{\pi} \frac{1}{1+\theta^2} h(\theta \varepsilon) d\theta \\ &= h(0) \int_{\mathbb{R}} \frac{1}{\pi} \frac{1}{1+\theta^2} d\theta = h(0) \frac{1}{\pi} \arctan \theta \Big|_{-\infty}^{+\infty} = h(0) = \int_{\phi=0} ds = |K|, \end{aligned}$$

which concludes the proof.

In general, this convergence result is valid for any approximations H_ε , δ_ε , under the assumptions

$$\lim_{\varepsilon \rightarrow 0} H_\varepsilon(z) = H(z) \text{ in } \mathbb{R}/\{0\},$$

$$\delta_\varepsilon = H_\varepsilon' \text{, } H_f \in C^1(\mathbb{R}), \int_{-\infty}^{+\infty} \delta_1(x) dx = 1.$$

10 Piecewise-Constant Mumford and Shah Segmentation Using Level Sets

Our first formulation is for the case when the unknown set of edges K can be represented by $K = \{x \in \Omega : \phi(x) = 0\}$ for some (unknown) Lipschitz function $\phi: \Omega \rightarrow \mathbb{R}$. In this case, the unknown minimizers u to functions are restricted taking two unknown values c_1 , c_2 , and the corresponding Mumford-Shah minimization problem can be expressed as [29, 31]

$$\begin{aligned} \inf_{c_1, c_2, \phi} E(c_1, c_2, \phi) &= \int_{\Omega} (g(x) - c_1)^2 H(\phi) dx + \int_{\Omega} (g(x) - c_2)^2 H(-\phi) dx \\ &\quad + v_0 \int_{\Omega} |DH(\phi)|. \end{aligned} \tag{12}$$

The unknown minimizer u is expressed as

$$u(x) = c_1 H(\phi(x)) + c_2 (1 - H(\phi(x))) = c_1 H(\phi(x)) + c_2 H(-\phi(x)).$$

H is substituted by its C^∞ approximation H_ε and instead

$$\begin{aligned} E_\varepsilon(c_1, c_2, \phi) &= \int_{\Omega} (g(x) - c_1)^2 H_\varepsilon(\phi) dx + \int_{\Omega} (g(x) - c_2)^2 H_\varepsilon(-\phi) dx \\ &\quad + v_0 \int_{\Omega} |\nabla H_\varepsilon(\phi)| dx. \end{aligned} \quad (13)$$

is minimized.

The associated Euler-Lagrange equations with respect to c_1 , c_2 , and ϕ are

$$c_1(\phi) = \frac{\int_{\Omega} g(x) H_\varepsilon(\phi(x)) dx}{\int_{\Omega} H_\varepsilon(\phi(x)) dx}, \quad c_2(\phi) = \frac{\int_{\Omega} g(x) H_\varepsilon(-\phi(x)) dx}{\int_{\Omega} H_\varepsilon(-\phi(x)) dx},$$

and, after simplifications,

$$\delta_\varepsilon(\phi) \left[(g(x) - c_1)^2 - (g(x) - c_2)^2 - \operatorname{div} \left(\frac{\nabla \phi}{|\nabla \phi|} \right) \right] = 0 \text{ in } \Omega, \quad (14)$$

with boundary conditions $\nabla \phi \cdot \vec{N} = 0$ on $\partial \Omega$. Since $\delta_\varepsilon > 0$ as defined, the factor $\delta_\varepsilon(\phi)$ can be removed from (14) or substituted by $|\nabla \phi|$ to obtain a more geometric motion extended to all level lines of ϕ , as in the standard level set approach.

This approach has been generalized by Chung and Vese in [34, 35], where more than one-level line of the same level set function ϕ can be used to represent the edge set K . Using m distinct real levels $\{l_1 < l_2 < \dots < l_m\}$, the function ϕ partitions the domain Ω into the following $m+1$ disjoint open regions, making up Ω , together with their boundaries:

$$\begin{aligned} \Omega_0 &= \{x \in \Omega : -\infty < \phi(x) < l_1\}, \\ \Omega_j &= \{x \in \Omega : l_j < \phi(x) < l_{j+1}\}, \quad 1 \leq j \leq m-1 \\ \Omega_m &= \{x \in \Omega : l_m < \phi(x) < +\infty\} \end{aligned}$$

The energy to minimize in this case, depending on $c_0, c_1, \dots, c_m, \phi$, will be

$$\begin{aligned} E(c_0, c_1, \dots, c_m, \phi) &= \int_{\Omega} |g(x) - c_0|^2 H(l_1 - \phi(x)) dx + \sum_{j=1}^{m-1} \int_{\Omega} |g(x) \\ &\quad - c_j|^2 H(\phi(x) - l_j) H(l_{j+1} - \phi(x)) dx + \int_{\Omega} |g(x) \\ &\quad - c_m|^2 H(\phi(x) - l_m) dx + v_0 \sum_{j=1}^m \int_{\Omega} |D H(\phi - l_j)|. \end{aligned} \quad (15)$$

The segmented image will be given by

$$\begin{aligned} u(x) &= c_0 H(l_1 - \phi(x)) + \sum_{j=1}^{m-1} c_j H(\phi(x) - l_j) H(l_{j+1} - \phi(x)) \\ &\quad + c_m H(\phi(x) - l_m). \end{aligned}$$

As before, to minimize the above energy, the Heaviside function H by H_ε , as $\varepsilon \rightarrow 0$, is approximated and substituted. The Euler-Lagrange equations associated with the corresponding minimization

$$\inf_{c_0, c_1, \dots, c_m, \phi} E_\varepsilon(c_0, c_1, \dots, c_m, \phi), \quad (16)$$

can be expressed as

$$\begin{cases} c_0(\phi) = \frac{\int_{\Omega} g(x) H_\varepsilon(l_1 - \phi(t, x)) dx}{\int_{\Omega} H_\varepsilon(l_1 - \phi(t, x)) dx}, \\ c_j(\phi) = \frac{\int_{\Omega} g(x) H_\varepsilon(\phi(t, x) - l_j) H_\varepsilon(l_{j+1} - \phi(t, x)) dx}{\int_{\Omega} H_\varepsilon(\phi(t, x) - l_j) H_\varepsilon(l_{j+1} - \phi(t, x)) dx}, \\ c_m(\phi) = \frac{\int_{\Omega} g(x) H_\varepsilon(\phi(t, x) - l_m) dx}{\int_{\Omega} H_\varepsilon(\phi(t, x) - l_m) dx}, \end{cases}$$

and

$$0 = |g - c_0|^2 \delta_\varepsilon(l_1 - \phi) + \sum_{j=1}^{m-1} |g - c_j|^2 [\delta_\varepsilon(l_{j+1} - \phi) H_\varepsilon(\phi - l_j) -] \delta_\varepsilon(\phi - l_j) H_\varepsilon(l_{j+1} - \phi) - |g - c_m|^2 \delta_\varepsilon(\phi - l_m) + v_0 \sum_{j=1}^m \left[\delta_\varepsilon(\phi - l_j) \operatorname{div} \left(\frac{\nabla \phi}{|\nabla \phi|} \right) \right], \frac{\partial \phi}{\partial \vec{N}} \Big|_{\partial \Omega} = 0,$$

where \vec{N} is the exterior unit normal to the boundary $\partial \Omega$.

Given here are the details of the numerical algorithm for solving (17) in two dimensions (x, y) , using gradient descent, in the case of one function ϕ with two levels $l_1 = 0, l_2 = l > 0$. Let $h = \Delta x = \Delta y$ be the space steps, Δt be the time step, and $\varepsilon = h$. Let (x_i, y_j) be the discrete points, for $1 \leq i, j \leq M$, and $g_{i,j} \approx g(x_i, y_j)$, $\phi_{i,j}^n \approx \phi(n \Delta t, x_i, y_j)$, with $n \geq 0$. Recall the usual finite differences formulas

$$\begin{aligned} \Delta_+^x \phi_{i,j} &= \phi_{i+1,j} - \phi_{i,j}, & \Delta_-^x \phi_{i,j} &= \phi_{i,j} - \phi_{i-1,j}, \\ \Delta_+^y \phi_{i,j} &= \phi_{i,j+1} - \phi_{i,j}, & \Delta_-^y \phi_{i,j} &= \phi_{i,j} - \phi_{i,j-1} \end{aligned}$$

Set $n = 0$, and start with $\phi_{i,j}^0$ given (defining the initial set of curves). Then, for each $n > 0$ until steady state:

1. Compute averages $c_0(\phi^n)$, $c_1(\phi^n)$, and $c_2(\phi^n)$.
2. Compute $\phi_{i,j}^{n+1}$, derived from the finite differences scheme:

$$\begin{aligned} \frac{\phi_{i,j}^{n+1} - \phi_{i,j}^n}{\Delta t} &= \delta_\varepsilon \left(\phi_{i,j}^n \right) \left[\frac{v_0}{h^2} \left(\Delta_-^x \left(\frac{\phi_{i+1,j}^n - \phi_{i,j}^{n+1}}{|\nabla \phi_{i,j}^n|} \right) + \Delta_-^y \left(\frac{\phi_{i,j+1}^n - \phi_{i,j}^{n+1}}{|\nabla \phi_{i,j}^n|} \right) \right) \right. \\ &\quad \left. + |g_{i,j} - c_0|^2 - |g_{i,j} - c_1|^2 H_\varepsilon(l - \phi_{i,j}^n) \right] + \delta_\varepsilon \left(\phi_{i,j}^n - l \right) \\ &\quad \left[\frac{v_0}{h^2} \left(\Delta_-^x \left(\frac{\phi_{i+1,j}^n - \phi_{i,j}^{n+1}}{|\nabla \phi_{i,j}^n|} \right) + \Delta_-^y \left(\frac{\phi_{i,j+1}^n - \phi_{i,j}^{n+1}}{|\nabla \phi_{i,j}^n|} \right) \right) \right. \\ &\quad \left. - |g_{i,j} - c_2|^2 + |g_{i,j} - c_1|^2 H_\varepsilon(\phi_{i,j}^n) \right], \end{aligned}$$

3. Where $|\nabla \phi_{i,j}^n| = \sqrt{\left(\frac{\phi_{i+1,j}^n - \phi_{i,j}^n}{h}\right)^2 + \left(\frac{\phi_{i,j+1}^n - \phi_{i,j}^n}{h}\right)^2}$. Let

$$\begin{aligned} C_1 &= \frac{1}{\sqrt{\left(\frac{\phi_{i+1,j}^n - \phi_{i,j}^n}{h}\right)^2 + \left(\frac{\phi_{i,j+1}^n - \phi_{i,j}^n}{h}\right)^2}}, \\ C_2 &= \frac{1}{\sqrt{\left(\frac{\phi_{i,j}^n - \phi_{i-1,j}^n}{h}\right)^2 + \left(\frac{\phi_{i-1,j+1}^n - \phi_{i-1,j}^n}{h}\right)^2}}, \\ C_3 &= \frac{1}{\sqrt{\left(\frac{\phi_{i+1,j}^n - \phi_{i,j}^n}{h}\right)^2 + \left(\frac{\phi_{i,j+1}^n - \phi_{i,j}^n}{h}\right)^2}}, \\ C_4 &= \frac{1}{\sqrt{\left(\frac{\phi_{i+1,j-1}^n - \phi_{i,j-1}^n}{h}\right)^2 + \left(\frac{\phi_{i,j}^n - \phi_{i,j-1}^n}{h}\right)^2}} \end{aligned}$$

4. Let $m_1 = \frac{\Delta t}{h^2} (\delta_\varepsilon(\phi_{i,j}^n) + \delta_\varepsilon(\phi_{i,j}^n - l)) v_0$, $C = 1 + m_1(C_1 + C_2 + C_3 + C_4)$.
The main update equation for ϕ becomes

$$\begin{aligned} \phi_{i,j}^{n+1} &= \frac{1}{C} \left[\phi_{i,j}^n + m_1 \left(C_1 \phi_{i+1,j}^n + C_2 \phi_{i-1,j}^n + C_3 \phi_{i,j+1}^n + C_4 \phi_{i,j-1}^n \right) \right. \\ &\quad + \Delta t \delta_\varepsilon(\phi_{i,j}^n) (-g_{i,j} - c_1)^2 (1 - H_\varepsilon(\phi_{i,j}^n - l)) \\ &\quad \left. + (g_{i,j} - c_0)^2 + \Delta t \delta_\varepsilon(\phi_{i,j}^n - l) \left(-(g_{i,j} - c_2)^2 + (g_{i,j} - c_1)^2 H_\varepsilon(\phi_{i,j}^n) \right) \right], \end{aligned}$$

5. And repeat, until steady state is reached.

This section is concluded with several experimental results obtained using the models presented here that act as denoising, segmentation, and active contours. In Fig. 4, an experimental result is shown taken from [31] obtained using the binary piecewise-constant model (12); we notice how interior contours can be automatically detected. In Fig. 5, we show an experimental result using the multilayer model (15), with $m = 2$ and two levels l_1, l_2 , applied to the segmentation of a brain image.

The work in [35, 79] also shows how the previous Mumford-Shah level set approaches can be extended to piecewise-constant segmentation of images with triple junctions, several non-nested regions, or with other complex topologies, by using two or more level set functions that form a perfect partition of the domain Ω .

11 Piecewise-Smooth Mumford and Shah Segmentation Using Level Sets

Considered first is the corresponding two-dimensional case under the assumption that the edges denoted by K in the image can be represented by one-level set function ϕ , i.e., $K = \{x \in \Omega | \phi(x) = 0\}$, and followed are the approaches developed in parallel by Chan and Vese [32, 79] and by Tsai et al. [78], in order to minimize

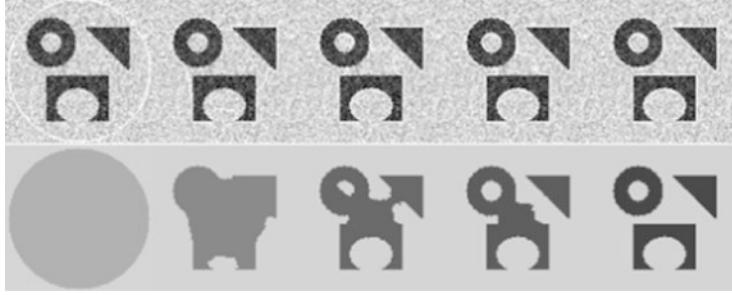

Fig. 4 Detection of different objects in a noisy image, with various convexities and with an interior contour which is automatically detected, using only one initial curve. After a short time, an interior contour appears inside the torus, and then it expands. *Top:* g and the evolving contours. *Bottom:* the piecewise-constant approximations u of g over time, given by $u = c_1 H(\phi) + c_2 (1 - H(\phi))$

the general Mumford and Shah model. As in [79], the link between the unknowns u and ϕ can be expressed by introducing two functions u^+ and u^- (see Fig. 6) such that

$$u(x) = \begin{cases} u^+(x) & \text{if } \phi(x) \geq 0, \\ u^-(x) & \text{if } \phi(x) \leq 0. \end{cases}$$

Assume that u^+ and u^- are H^1 functions on $\phi \geq 0$ and on $\phi \leq 0$, respectively (with Sobolev traces up to all boundary points, i.e., up to the boundary $\{\phi = 0\}$). The following minimization problem can be written

$$\inf_{u^+, u^-, \phi} E(u^+, u^-, \phi),$$

where

$$E(u^+, u^-, \phi) = \mu^2 \int_{\Omega} |u^+ - g|^2 H(\phi) dx + \mu^2 \int_{\Omega} |u^- - g|^2 (1 - H(\phi)) dx + \int_{\Omega} |\nabla u^+|^2 H(\phi) dx + \int_{\Omega} |\nabla u^-|^2 (1 - H(\phi)) dx + v \int_{\Omega} |DH(\phi)|$$

is the Mumford-Shah functional restricted to $u(x) = u^+(x)H(\phi(x)) + u^-(x)(1 - H(\phi(x)))$. Minimizing $E(u^+, u^-, \phi)$ with respect to u^+ , u^- , and ϕ , we obtain the following Euler-Lagrange equations (embedded in a time-dependent dynamical scheme for ϕ):

$$\mu^2(u^+ - g) = \Delta u^+ \text{ in } \{x : \phi(t, x) > 0\}, \quad \frac{\partial u^+}{\partial \vec{n}} = 0 \text{ on } \{x : \phi(t, x) = 0\} \cup \partial \Omega, \quad (17)$$

$$\mu^2(u^- - g) = \Delta u^- \text{ in } \{x : \phi(t, x) < 0\}, \quad \frac{\partial u^-}{\partial \vec{n}} = 0 \text{ on } \{x : \phi(t, x) = 0\} \cup \partial \Omega, \quad (18)$$

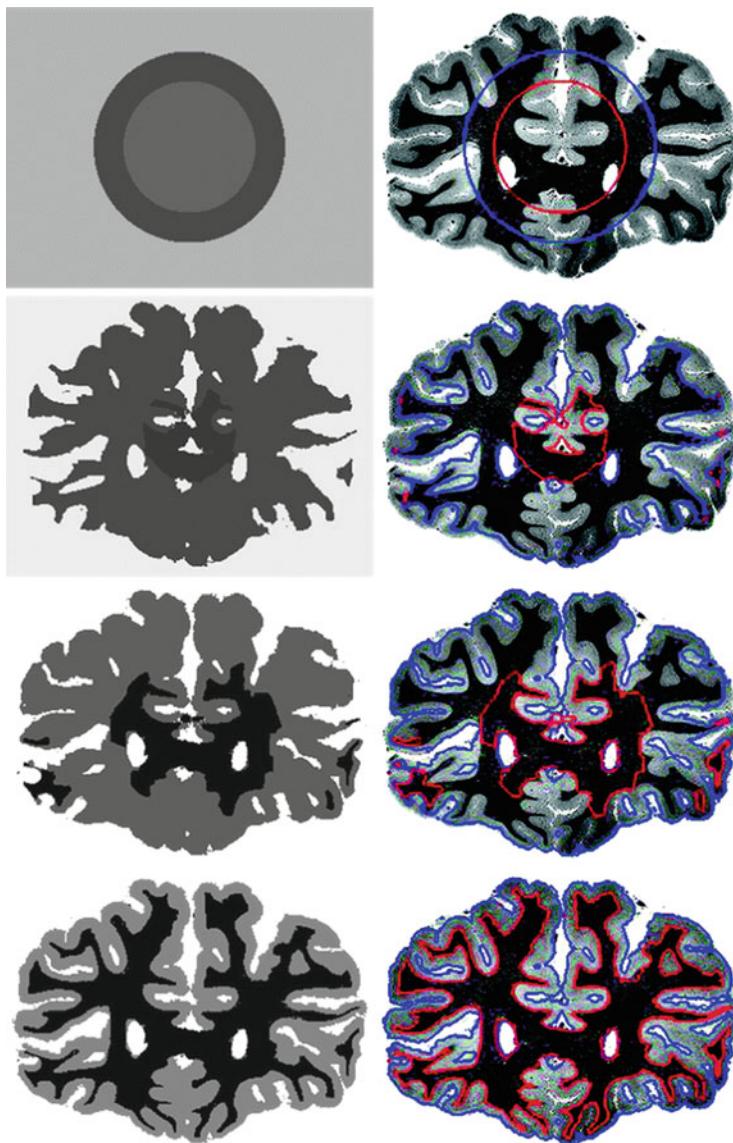

Fig. 5 Segmentation of a brain image using one-level set function with two levels. Parameters: $l_1 = 0$, $l_2 = 25$, $\Delta t = 0.1$, $v_0 = 0.1 \cdot 255^2$, 1,500 iterations

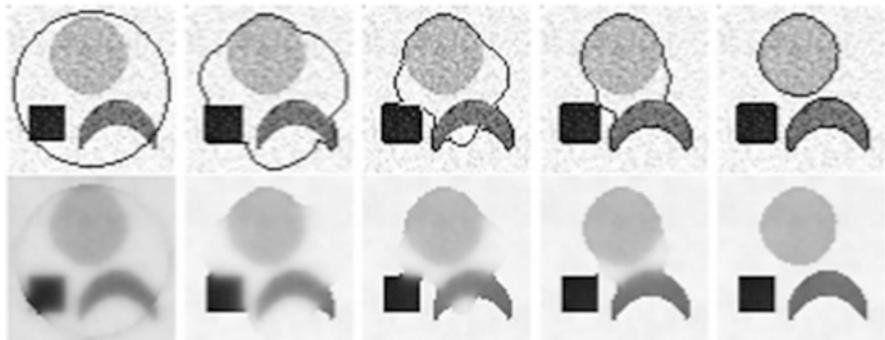

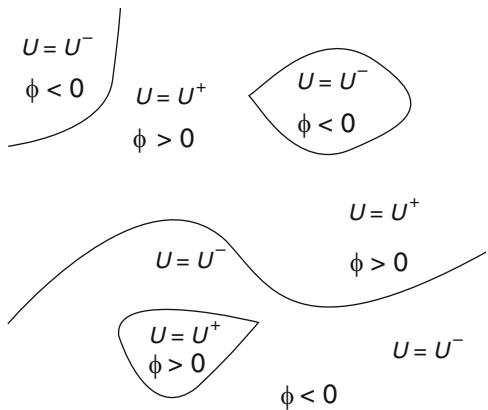

Fig. 7 Results on a noisy image, using the level set algorithm for the piecewise-smooth Mumford-Shah model with one-level set function. The algorithm performs as active contours, denoising, and edge detection

$$\frac{\partial \phi}{\partial t} = \delta_\varepsilon(\phi) \left[v \nabla \left(\frac{\nabla \phi}{|\nabla \phi|} \right) - \mu^2 |u^+ - g|^2 - |\nabla u^+|^2 + \mu^2 |u^- - g|^2 + |\nabla u^-|^2 \right], \quad (19)$$

where $\partial/\partial\vec{n}$ denotes the partial derivative in the normal direction \vec{n} at the corresponding boundary. We also associate the boundary condition $\frac{\partial \phi}{\partial \vec{n}} = 0$ on $\partial\Omega$ to Eq. (19).

Shown in Figs. 7 and 8 are experimental results taken from [79] obtained with the piecewise-smooth two-phase model.

There are cases when the boundaries K of regions forming a partition of the image could not be represented by the boundary of an open domain. To overcome this, several solutions have been proposed in this framework, and mentioned here are two of them: (1) in the work by Tsai et al. [78], the minimization of $E(u^+, u^-, \phi)$ is repeated inside each of the two regions previously computed, and (2) in the work of Chan and Vese [79], two or more level set functions are used. For example, in

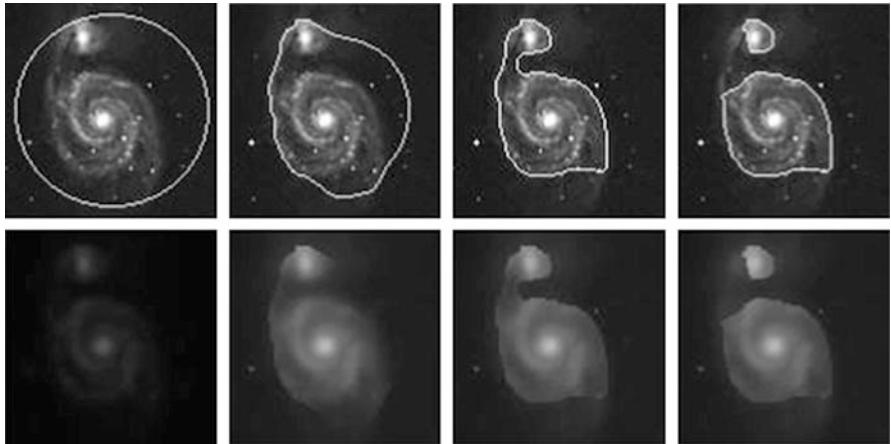

Fig. 8 Numerical result using the piecewise-smooth Mumford-Shah level set algorithm with one-level set function, on a piecewise-smooth real galaxy image

two dimensions, the problem can be solved using only two-level set functions, and we do not have to know a priori how many gray levels the image has (or how many segments). The idea is based on the four-color theorem. Based on this observation, we can “color” all the regions in a partition using only four “colors,” such that any two adjacent regions have different “colors.” Therefore, using two-level set functions, we can identify the four “colors” by the following (disjoint) sets: $\{\phi_1 > 0, \phi_2 > 0\}$, $\{\phi_1 < 0, \phi_2 < 0\}$, $\{\phi_1 < 0, \phi_2 > 0\}$, $\{\phi_1 > 0, \phi_2 < 0\}$. The boundaries of the regions forming the partition will be given by $\{\phi_1 = 0\} \cup \{\phi_2 = 0\}$, and this will be the set of curves K . Note that, in this particular multiphase formulation of the problem, we do not have the problems of “overlapping” or “vacuum” (i.e., the phases are disjoint, and their union is the entire domain Ω , by definition).

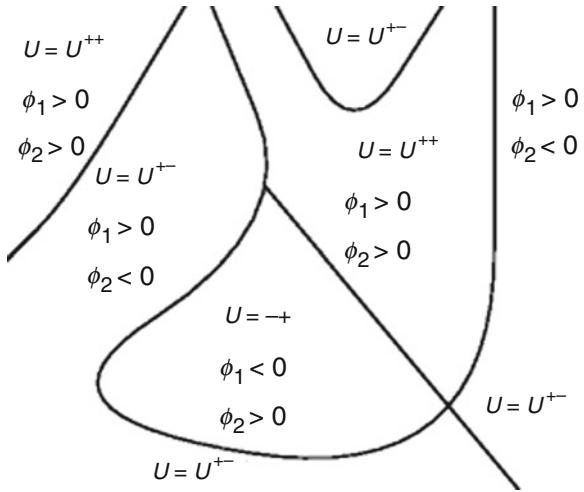

As before, the link between the function u and the four regions can be made by introducing four functions $u^{++}, u^{+-}, u^{-+}, u^{--}$, which are in fact the restrictions of u to each of the four phases, as follows (see Fig. 9):

$$u(x) = \begin{cases} u^{++}(x), & \text{if } \phi_1(x) > 0 \text{ and } \phi_2(x) > 0, \\ u^{+-}(x), & \text{if } \phi_1(x) > 0 \text{ and } \phi_2(x) < 0, \\ u^{-+}(x), & \text{if } \phi_1(x) < 0 \text{ and } \phi_2(x) > 0, \\ u^{--}(x), & \text{if } \phi_1(x) < 0 \text{ and } \phi_2(x) < 0. \end{cases}$$

Again, using the Heaviside function, the relation between u ; the four functions $u^{++}, u^{+-}, u^{-+}, u^{--}$; and the level set functions ϕ_1 and ϕ_2 can be expressed by

$$u = u^{++}H(\phi_1)H(\phi_2) + u^{+-}H(\phi_1)(1 - H(\phi_2)) + u^{-+}(1 - H(\phi_1))H(\phi_2) + u^{--}(1 - H(\phi_1))(1 - H(\phi_2))$$

Fig. 9 The functions u^{++} , u^{+-} , u^{-+} , u^{--} , and the zero-level lines of the level set functions ϕ_1, ϕ_2 for piecewise-smooth image partition

Introduced here is an energy in level set formulation based on the Mumford-Shah functional:

$$\begin{aligned} E(u, \phi_1, \phi_2) = & \mu^2 \int_{\Omega} |u^{++} - g|^2 H(\phi_1) H(\phi_2) dx \\ & + \int_{\Omega} |\nabla u^{++}|^2 H(\phi_1) H(\phi_2) dx \\ & + \mu^2 \int_{\Omega} |u^{+-} - g|^2 H(\phi_1)(1 - H(\phi_2)) dx \\ & + \int_{\Omega} |\nabla u^{+-}|^2 H(\phi_1)(1 - H(\phi_2)) dx \\ & + \mu^2 \int_{\Omega} |u^{-+} - g|^2 (1 - H(\phi_1)) H(\phi_2) dx \\ & + \int_{\Omega} |\nabla u^{-+}|^2 (1 - H(\phi_1)) H(\phi_2) dx \\ & + \mu^2 \int_{\Omega} |u^{--} - g|^2 (1 - H(\phi_1))(1 - H(\phi_2)) dx \\ & + \int_{\Omega} |\nabla u^{--}|^2 (1 - H(\phi_1))(1 - H(\phi_2)) dx \\ & + v \int_{\Omega} |DH(\phi_1)| + v \int_{\Omega} |DH(\phi_2)| \end{aligned}$$

Note that the expression $\int_{\Omega} |DH(\phi_1)| + \int_{\Omega} |DH(\phi_2)|$ is not exactly the length term of $K = \{x \in \Omega : \phi_1(x) = 0 \text{ and } \phi_2(x) = 0\}$; it is just an approximation and simplification. In practice, satisfactory results using the above formula are obtained, and the associated Euler-Lagrange equations are simplified.

The associated Euler-Lagrange equations are obtained as in the previous cases, embedded in a dynamic scheme, assuming $(t, x, y) \mapsto \phi_i(t, x, y)$: minimizing the energy with respect to the functions $u^{++}, u^{+-}, u^{-+}, u^{--}$, we have, for each fixed t :

$$\mu^2(u^{++} - g) = \Delta u^{++} \text{ in } \{\phi_1 > 0, \phi_2 > 0\}, \frac{\partial u^{++}}{\partial \vec{n}} = 0 \text{ on } \{\phi_1 = 0, \phi_2 \geq 0\},$$

$$\{\phi_1 \geq 0, \phi_2 = 0\};$$

$$\mu^2(u^{+-} - g) = \Delta u^{+-} \text{ in } \{\phi_1 > 0, \phi_2 < 0\}, \frac{\partial u^{+-}}{\partial \vec{n}} = 0 \text{ on } \{\phi_1 = 0, \phi_2 \leq 0\},$$

$$\{\phi_1 \geq 0, \phi_2 = 0\};$$

$$\mu^2(u^{-+} - g) = \Delta u^{-+} \text{ in } \{\phi_1 < 0, \phi_2 > 0\}, \frac{\partial u^{-+}}{\partial \vec{n}} = 0 \text{ on } \{\phi_1 = 0, \phi_2 \geq 0\},$$

$$\{\phi_1 \leq 0, \phi_2 = 0\};$$

$$\mu^2(u^{--} - g) = \Delta u^{--} \text{ in } \{\phi_1 < 0, \phi_2 < 0\}, \frac{\partial u^{--}}{\partial \vec{n}} = 0 \text{ on } \{\phi_1 = 0, \phi_2 \leq 0\},$$

$$\{\phi_1 \leq 0, \phi_2 = 0\}$$

The Euler-Lagrange equations evolving ϕ_1 and ϕ_2 , embedded in a dynamic scheme, are formally:

$$\begin{aligned} \frac{\partial \phi_1}{\partial t} &= \delta_\varepsilon(\phi_1) \left[v \nabla \left(\frac{\nabla \phi_1}{|\nabla \phi_1|} \right) - \mu^2 |u^{++} - g|^2 H(\phi_2) - |\nabla u^{++}|^2 H(\phi_2) \right. \\ &\quad - \mu^2 |u^{+-} - g|^2 (1 - H(\phi_2)) - |\nabla u^{+-}|^2 (1 - H(\phi_2)) + \mu^2 |u^{-+} - g|^2 \\ &\quad - g|^2 H(\phi_2) + |\nabla u^{-+}|^2 H(\phi_2) + \mu^2 |u^{--} - g|^2 (1 - H(\phi_2)) + \\ &\quad \left. |\nabla u^{--}|^2 (1 - H(\phi_2)) \right] = 0, \\ \frac{\partial \phi_2}{\partial t} &= \delta_\varepsilon(\phi_2) \left[v \nabla \left(\frac{\nabla \phi_2}{|\nabla \phi_2|} \right) - \mu^2 |u^{++} - g|^2 H(\phi_1) - |\nabla u^{++}|^2 H(\phi_1) \right. \\ &\quad - \mu^2 |u^{+-} - g|^2 H(\phi_2) + |\nabla u^{+-}|^2 H(\phi_1) - \mu^2 |u^{-+} - g|^2 (1 - H(\phi_1)) - \\ &\quad \left. |\nabla u^{-+}|^2 (1 - H(\phi_1)) - \mu^2 |u^{--} - g|^2 (1 - H(\phi_1)) + |\nabla u^{--}|^2 (1 - H(\phi_1)) \right] \end{aligned}$$

It can be shown, by standard techniques of the calculus of variations on the space $\text{SBV}(\Omega)$ (special functions of bounded variations), and a compactness result due to Ambrosio [3], that the proposed minimization problems from this section, in the level set formulation, have a minimizer. Finally, because there is no uniqueness of minimizers, and because the problems are nonconvex, the numerical results may depend on the initial choice of the curves and may compute only a local minimum. We think that, using the seed initialization (see [79]), the algorithms have the tendency of computing a global minimum, most of the times. Additional experimental results are shown in [79].

12 Case Examples: Variational Image Restoration with Segmentation-Based Regularization

This section focuses on the challenging task of edge-preserving variational image restoration. In this context, restoration is referred to as image deblurring and denoising, dealing with Gaussian and impulsive noise models. Terms from the Mumford-Shah segmentation functional are used as regularizers, reflecting the model of piecewise-constant or piecewise-smooth images.

In the standard model of degradation, the underlying assumptions are the linearity and shift invariance of the blur process and the additivity and normal

distribution of the noise. Formally, let Ω be an open-bounded subset of \mathbb{R}^n . The observed image $g: \Omega \rightarrow \mathbb{R}^N \in L^\infty$ is given by

$$g = h * u + n, \quad (20)$$

where g is normalized to the hypercube $[0, 1]^N$, h is the blur kernel such that $h(x) > 0$ and $\int h(x)dx = 1$, $u: \Omega \rightarrow \mathbb{R}^N$ is the (“ideal”) original image, $n \sim N(0, \sigma^2)$ stands for a white Gaussian noise, and $*$ denotes the convolution operator. The restoration problem is the recovery of the original image u given Eq. (20). Non-blind image restoration is the problem whenever the blur kernel is known, while blind restoration refers to the case of unknown kernel [49, 50]. The recovery process in the non-blind case is a typical inverse problem where the image u is the minimizer of an objective functional of the form

$$F(u) = \Phi(g - h * u) + J(\nabla u). \quad (21)$$

The functional consists of fidelity term and a regularizer. The fidelity term ϕ forces the smoothed image $h * u$ to be close to the observed image g . The commonly used model of a white Gaussian noise $n \sim N(0, \sigma^2)$ leads by the maximum likelihood estimation to the minimization of the L^2 norm of the noise

$$\Phi_{L^2} = \|g - h * u\|_{L^2(\Omega)}^2. \quad (22)$$

However, in the case of impulsive noise, some amount of pixels do not obey the Gaussian noise model. Minimization of outlier effects can be accomplished by replacing the quadratic form (22) with a robust ρ -function [44], e.g.,

$$\Phi_{L^1} = \|g - h * u\|_{L^1(\Omega)}. \quad (23)$$

The minimization of (22) or (23) alone with respect to u is an inverse problem which is known to be ill-posed: small perturbations in the data g may produce unbounded variations in the solution. To alleviate this problem, a regularization term can be added. The Tikhonov L^2 stabilizer [77]

$$J_{L^2} = \int_{\Omega} |\nabla u|^2 dx,$$

leads to over smoothing and loss of important edge information. A better edge preservation regularizer, the total variation (TV) term, was introduced by Rudin et al. [69, 70], where the L^2 norm was replaced by the L^1 norm of the image gradients

$$J_{L^1} = \int_{\Omega} |\nabla u| dx.$$

Still, although the total variation regularization outperforms the L^2 norm, the image features – the edges – are not explicitly extracted. The edges are implicitly preserved only by the image gradients.

An alternative regularizer is the one used in the Mumford-Shah functional [61, 63]. Recall that this is accomplished by searching for a pair (u, K) where $K \subset \Omega$ denotes the set of discontinuities of u , the unknown image, such that $u \in H^1(\Omega \setminus K)$, $K \subset \Omega$ closed in Ω , and

$$G(u, K) = \beta \int_{\Omega \setminus K} |\nabla u|^2 dx + \alpha H^{n-1}(K) < \infty. \quad (24)$$

In our study, the regularizer to the restoration problem (21) is given by

$$J_{\text{MS}} = G(u, K),$$

its L^1 variant [2, 74], and elliptic or level set approximations of these, as presented next. This enables the explicit extraction and preservation of the image edges in the course of the restoration process. We show the advantages of this regularizer in several applications and noise models (Gaussian and impulsive).

As has been mentioned, Ambrosio and Tortorelli [6] introduced an elliptic approximation $G_\varepsilon(u, v)$ to $G(u, K)$, as $\varepsilon \rightarrow 0^+$, that is recalled here,

$$G_\varepsilon(u, v) = \beta \int_{\Omega} v^2 |\nabla u|^2 dx + \alpha \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{(v - 1)^2}{4\varepsilon} \right) dx. \quad (25)$$

Replacing the Mumford-Shah regularization term (24) by $G_\varepsilon(u, v)$ yields the proposed restoration model

$$F_\varepsilon(u, v) = \Phi(g - h * u) + \beta \int_{\Omega} v^2 |\nabla u|^2 dx + \alpha \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{(v - 1)^2}{4\varepsilon} \right) dx \quad (26)$$

The functional (26) can also be understood from a generalized robust statistics viewpoint. This is beyond the scope of this chapter, and the interested reader can find the details in [12].

The rest of the chapter considers the non-blind restoration problem presented in [13] and its generalizations to several more realistic situations. Consider the problem of (semi-) blind deconvolution, the case of impulsive noise, the color restoration problem, and the case of space-variant blur. Also consider the problem of restoration of piecewise-constant images from noisy-blurry data using the level set form of the Mumford-Shah regularizer and image restoration using nonlocal Mumford-Shah-Ambrosio-Tortorelli regularizers.

13 Non-blind Restoration

Addressed first is the restoration problem with a known blur kernel h and additive Gaussian noise [10, 13]. In this case, the fidelity term is the L^2 norm of the noise (22), and the regularizer $\vartheta_{\text{MS}} = G_f(u, v)$ (25). The objective functional is therefore

$$F_\varepsilon(u, v) = \frac{1}{2} \int_{\Omega} (g - h * u)^2 dx + \beta \int_{\Omega} v^2 |\nabla u|^2 dx + \alpha \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{(v - 1)^2}{4\varepsilon} \right) \quad (27)$$

The functional (27) is strictly convex, bounded from below and coercive with respect to the functions u and v if the other one is fixed. Following [33], the alternate minimization (AM) approach is applied: in each step of the iterative procedure, we minimize with respect to one function and keep the other one fixed. The minimization is carried out using the Euler-Lagrange (E-L) equations with Neumann boundary conditions where u is initialized as the blurred image g and v is initialized to 1.

$$\frac{\delta F_\varepsilon}{\delta v} = 2\beta v |\nabla u|^2 + \alpha \frac{v - 1}{2\varepsilon} - 2\varepsilon\alpha \Delta v = 0 \quad (28)$$

$$\frac{\delta F_\varepsilon}{\delta u} = (h * u - g) * h(-x, -y) - 2\beta \nabla \cdot (v^2 \nabla u) = 0 \quad (29)$$

Equation (28) is linear with respect to v and can be easily solved after discretization by the minimal residual algorithm [81]. The integrodifferential equation (29) can be solved by the conjugate-gradient method [13]. The iterative process is stopped whenever some convergence criterion is satisfied (e.g., $\|u^{n+1} - u^n\| < \varepsilon \|u^n\|$). Figure 10 demonstrates the outcome of the algorithm. The top-left image is the blurred image g . The kernel corresponds to horizontal motion blur. The top-right image is the reconstruction obtained using total variation (TV) regularization [70, 80]. The bottom-left image is the outcome of the MS regularizer, with a known blur kernel. The bottom-right image shows the associated edge map v determined by the algorithm. Acceptable restoration is obtained with both methods. Nevertheless, the MS method yields a sharper result and is almost free of “ghosts” (white replications of notes) that can be seen in the top-right image (e.g., between the C notes in the right part of the top stave). The algorithm can be also applied to 3D images as shown in Fig. 11. In this example, the blur kernel was anisotropic 3D Gaussian kernel.

14 Semi-blind Restoration

Blind restoration refers to the case when the blur kernel h is not known in advance. In addition to being ill-posed with respect to the image, the blind restoration problem is ill-posed in the kernel as well. Blind image restoration with joint recovery of the image and the kernel, and regularization of both, was presented by You and Kaveh

Fig. 10 The case of a known (nine-pixel horizontal motion) blur kernel. *Top left*: corrupted image. *Top-right*: restoration using the TV method [70, 80]. *Bottom left*: restoration using the MS method. *Bottom right*: edge map produced by the MS method

Fig. 11 3D restoration of MR image. *Left*: blurred ($\sigma_x = 1.0, \sigma_y = 1.0, \sigma_z = 0.2$) image. *Middle*: recovered image. *Right*: edge map

[82], followed by Chan and Wong [33]. Chan and Wong suggested to minimize a functional consisting of a fidelity term and total variation (L^1 norm) regularization for both the image and the kernel:

$$F(u, h) = \frac{1}{2} \|h * u - g\|_{L^2(\Omega)}^2 + \alpha_1 \int_{\Omega} |\nabla u| dx + \alpha_2 \int_{\Omega} |\nabla h| dx. \quad (30)$$

By this approach, the recovered kernel is highly dependent on the image characteristics. It allows the distribution of edge directions in the image to have an influence on the shape of the recovered kernel which may lead to inaccurate restoration [13]. Facing the ill-posedness of blind restoration with a general kernel, two approaches can be taken. One is to add relevant data; the other is to constrain the solution. In many practical situations, the blurring kernel can be modeled by the physics/optics of the imaging device and the setup. The blurring kernel can then be constrained and described as a member in a class of parametric functions. The blind restoration problem is then reduced to a semi-blind one. Let us consider the case of isotropic Gaussian blur parameterized by the width σ ,

$$h_{\sigma}(x) = \frac{1}{2\pi\sigma^2} e^{-\frac{x^2}{2\sigma^2}}, x \in \mathbb{R}^n.$$

The semi-blind objective functional then takes the form [13]

$$F_{\varepsilon}(v, u, \sigma) = \frac{1}{2} \int_{\Omega} (h_{\sigma} * u - g)^2 dx + G_{\varepsilon}(u, v) + \gamma \int_{\Omega} |\nabla h_{\sigma}|^2 dx. \quad (31)$$

The last term in Eq. (31) stands for the regularization of the kernel, necessary to resolve the fundamental ambiguity in the division of the apparent blur between the recovered image and the blur kernel. This means that we prefer to reject the hypothesis that the blur originates from u , and assume that it is due to the convolution with the blur kernel. From the range of possible kernels, we thus select a wide one. This preference is represented by the kernel smoothness term: the width of the Gaussian corresponds to its smoothness, measured by the L^2 norm of its gradient. The optimization is carried out by using the alternate minimization approach. The recovered image u is initialized with g , the edge indicator function v is initialized with 1, and σ with a small number ε which reflects a delta function kernel. The Euler-Lagrange equations with respect to v and u are given by (28) and (29), respectively. The parameter σ is the solution of

$$\frac{\partial F_{\varepsilon}}{\partial \sigma} = \int_{\Omega} \left[(h_{\sigma} * u - g) \left(\frac{\partial h_{\sigma}}{\partial \sigma} * u \right) + \gamma \frac{\partial}{\partial \sigma} |\nabla h_{\sigma}|^2 \right] dx = 0, \quad (32)$$

which can be calculated by the bisection method. The functional (31) is not generally convex. Nevertheless, in practical numerical simulations, the algorithm converges to visually appealing restoration results as can be seen in the second row of Fig. 12.

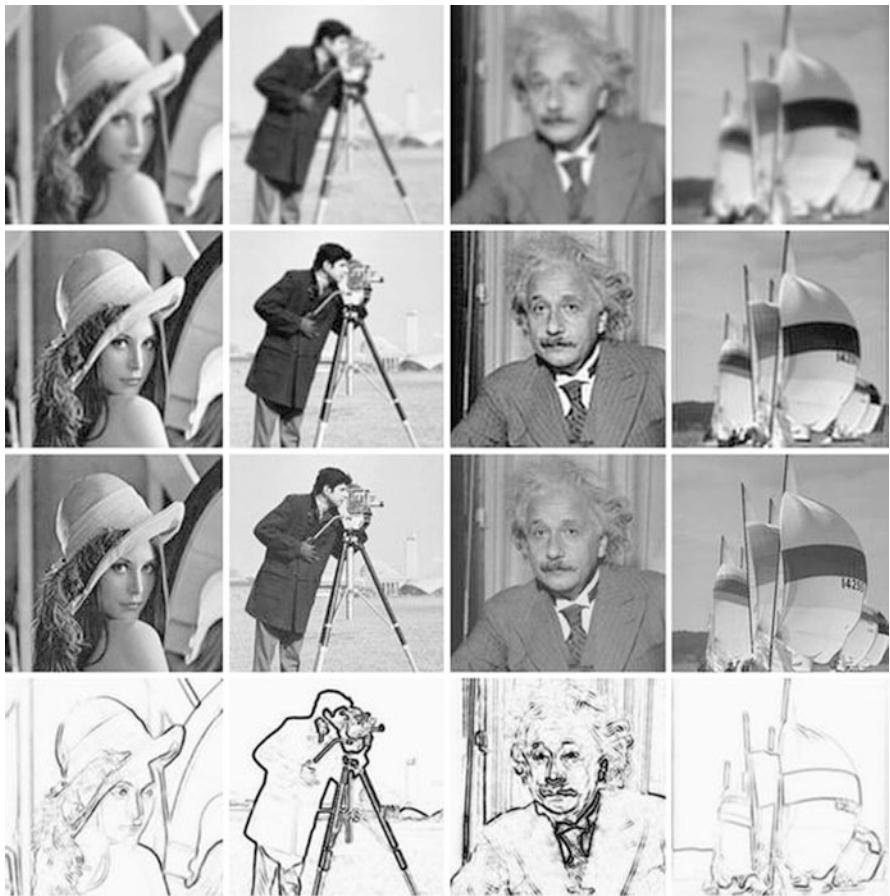

Fig. 12 Semi-blind restoration. *Top row*: blurred images. *Second row*: restoration using the semi-blind method. *Third row*: original images. *Bottom row*: edge maps produced by the semi-blind method

15 Image Restoration with Impulsive Noise

Consider an image that has been blurred with a known blur kernel h and contaminated by impulsive noise. Salt-and-pepper noise, for instance, is a common model for the effects of bit errors in transmission, malfunctioning pixels, and faulty memory locations. Image deblurring algorithms that were designed for Gaussian noise produce inadequate results with impulsive noise.

The left image of Fig. 13 is a blurred image contaminated by salt-and-pepper noise, and the right image is the outcome of the total variation restoration method [80]. A straightforward sequential approach is to first denoise the image and then to deblur it. This two-stage method is however prone to failure, especially at high

Fig. 13 Current image deblurring algorithms fail in the presence of salt-and-pepper noise. *Left*: blurred image with salt-and-pepper noise. *Right*: restoration using the TV method [80]

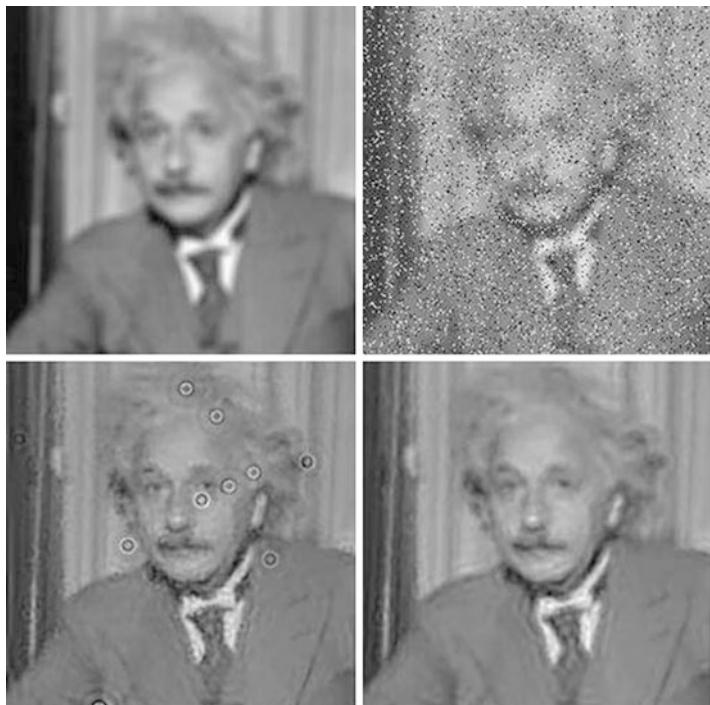

Fig. 14 The failure of the two-stage approach to salt-and-pepper noise removal and image deblurring. *Top-left*: blurred image. *Top-right*: blurred image contaminated by salt-and-pepper noise. *Bottom-left*: the outcome of 3×3 median filtering, followed by deblurring. *Bottom-right*: the outcome of 5×5 median filtering, followed by deblurring

noise density. Image denoising using median-type filtering creates distortion that depends on the neighborhood size; this error can be strongly amplified by the deblurring process. This is illustrated in Fig. 14. The top-left and top-right images are the blurred and blurred-noisy images, respectively. The outcome of 3×3 median filtering followed by total variation deblurring [80] is shown in the bottom left. At this noise level, the 3×3 neighborhood size of the median filter is insufficient, the noise is not entirely removed, and the residual noise is greatly amplified by the deblurring process. If the neighborhood size of the median filter increases to 5×5 , the noise is fully removed, but the distortion leads to inadequate deblurring (bottom right).

In a unified variational framework, the “ideal” image u can be approximated as the minimizer of the objective functional [12, 14]

$$F_\varepsilon(u, v) = \int_{\Omega} \sqrt{(h * u - g)^2 + \eta} dx + G_\varepsilon(u, v). \quad (33)$$

The quadratic data-fidelity term is now replaced by the modified L^1 norm [64] which is robust to outliers, i.e., to impulse noise. The parameter $\eta = 1$ enforces the differentiability of (33) with respect to u . Optimization of the functional is carried out using the Euler-Lagrange equations subject to Neumann boundary conditions:

$$\frac{\delta F_\varepsilon}{\delta v} = 2\beta v |\nabla u|^2 + \alpha \left(\frac{v-1}{2\varepsilon} \right) - 2\varepsilon\alpha \Delta v = 0, \quad (34)$$

$$\frac{\delta F_\varepsilon}{\delta u} = \frac{(h * u - g)}{\sqrt{(h * u - g)^2 + \eta}} * h(-x, -y) - 2\beta \nabla \cdot (v^2 \nabla u) = 0. \quad (35)$$

The alternate minimization technique can be applied here as well since the functional (33) is convex, bounded from below and coercive with respect to either function u or v if the other one is fixed. Equation (34) is obviously linear with respect to v . In contrast, (35) is a nonlinear integrodifferential equation. Linearization of this equation is carried out using the fixed-point iteration scheme as in [33, 80]. In this method, additional iteration index l serves as intermediate stage calculating u^{n+1} . $u = u^l$ is set in the denominator, and $u = u^{l+1}$ elsewhere, where l is the current iteration number. Equation (35) can thus be rewritten as

$$H(v, u^l) u^{l+1} = G(u^l), l = 0, 1, \dots \quad (36)$$

where H is the linear integrodifferential operator

$$H(v, u^l) u^{l+1} = \frac{h * u^{l+1}}{\sqrt{(h * u^l - g)^2 + \eta}} * h(-x, -y) - 2\beta \nabla \cdot (v^2 \nabla u^{l+1})$$

and

$$G(u^l) = \frac{g}{\sqrt{(h * u^l - g)^2 + \eta}} * h(-x, -y). \quad (37)$$

Note that (36) is now a *linear* integrodifferential equation in u^{l+1} .

The discretization of Eqs. (34) and (36) yields two systems of linear algebraic equations. These systems are solved in alternation, leading to the following iterative algorithm [12]:

Initialization: $u^0 = g$, $v^0 = 1$.

1. Solve for v^{n+1}

$$\left(2\beta |\nabla u^n|^2 + \frac{\alpha}{2\varepsilon} - 2\alpha\varepsilon \Delta\right) v^{n+1} = \frac{\alpha}{2\varepsilon}. \quad (38)$$

2. Set $u^{n+1,0} = u^n$ and solve for u^{n+1} (iterating on l)

$$H(v^{n+1}, u^{n+1,l}) u^{n+1,l+1} = G(u^{n+1,l}). \quad (39)$$

3. If $\|u^{n+1} - u^n\|_{L_2} < \varepsilon_1 \|u^n\|_{L_2}$, stop.

The convergence of the algorithm was proved in [14]. Figure 15 demonstrates the performance of the algorithm. The top row shows the blurred images with increasing salt-and-pepper noise level. The outcome of the restoration algorithm is shown in the bottom row.

A variant of the Mumford-Shah functional in its Γ -convergence approximation was suggested by Shah [74]. In this version, the L^2 norm of $|\nabla u|$ in (25) was replaced by its L^1 norm in the first term of G_ε

$$J_{\text{MSTV}}(u, v) = \beta \int_{\Omega} v^2 |\nabla u| dx + \alpha \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{(v-1)^2}{4\varepsilon} \right) dx.$$

Alicandro et al. [2] proved the Γ -convergence of this functional to

$$J_{\text{MSTV}}(u) = \beta \int_{\Omega/K} |\nabla u| dx + \alpha \int_K \frac{|u^+ - u^-|}{1 + |u^+ - u^-|} dH^1 + |D^c u|(\Omega),$$

where u^+ and u^- denote the image values on two sides of the edge set K , H^1 is the one-dimensional Hausdorff measure, and $D^c u$ is the Cantor part of the measure-valued derivative Du . The Mumford-Shah and Shah regularizers are compared in Fig. 16. The blurred and noisy images are shown in the left column. The results of the restoration using the Mumford-Shah stabilizer (MS) are presented in the middle column, and the images recovered using the Shah regularizer (MSTV) are shown in the right column.

Fig. 15 Top row: the *Lena* image blurred with a pillbox kernel of radius 3 and contaminated by salt-and-pepper noise. The noise density is (left to right) 0.01, 0.1, and 0.3. Bottom row: the corresponding recovered images

The recovery using both methods is satisfactory, but it can be clearly seen that while the Mumford-Shah restoration performs better in the high-frequency image content (see the shades, for instance), the Shah restoration attracts the image toward the piecewise constant or cartoon limit which yields images much closer to the “ideal.” This can be explained by the fact that the Shah regularizer is more robust to image gradients and hence eliminates high-frequency contributions.

The special case of pure impulse denoising (no blur) is demonstrated in Fig. 17. The image on the left shows the outcome of the algorithm of [65] with L^1 norm for both the fidelity and regularization, while the recovery using the L^1 fidelity and MS regularizer is shown on the right. It can be observed that the better robustness of the MS regularizer leads to better performance in the presence of salt-and-pepper noise.

16 Color Image Restoration

The restoration problem is now extended to vector-valued images [9]. In the case of color images, the image intensity is defined as $u: \Omega \rightarrow [0, 1]^3$. Here g^v denotes the observed image at channel $v \in \{r, g, b\}$ such that $g^v = h * u^v + n^v$. The underlying assumption here is that the blur kernel h is common to all of the channels. If the noise is randomly located in a random color channel, the fidelity term can be

Fig. 16 *Left column:* the window image blurred with a pillbox kernel of radius 3 and contaminated by salt-and-pepper noise. The noise density is (top to bottom) 0.01 and 0.1. *Middle column:* the corresponding recovered images with Mumford-Shah (MS) regularization. *Right column:* the corresponding recovered images with Shah (MSTV) regularization

Fig. 17 Pure impulse denoising. *Left column:* restoration using the L^1 regularization [65]. *Right column:* restoration using the MS regularizer

modeled as

$$\Phi_{L^2} = \int_{\Omega} \sum_v (h * u^v - g^v)^2 dx$$

in the case of Gaussian noise, and

$$\Phi_{L^1} = \int_{\Omega} \sqrt{(h * u^v - g^v)^2 + \eta} dx, \quad \eta \ll 1, \quad (40)$$

in the case of impulsive noise. The TV regularization can be generalized to

$$\mathcal{J}_{TV}(u) = \int_{\Omega} \|\nabla u\| dx, \quad (41)$$

where

$$\|\nabla u\| = \sqrt{\sum_{v \in \{r,g,b\}} |\nabla u^v|^2 + \mu}, \quad \mu \ll 1. \quad (42)$$

The color MS regularizer thus takes the form

$$\mathcal{J}_{MS}(u, v) = \beta \int_{\Omega} v^2 \|\nabla u\|^2 dx + \alpha \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{(v - 1)^2}{4\varepsilon} \right) dx. \quad (43)$$

Note that in this regularizer the edge map v is common for the three channels and provides the necessary coupling between colors. In the same fashion, the color MSTV regularizer is given by

$$\mathcal{J}_{MSTV}(u, v) = \beta \int_{\Omega} v^2 \|\nabla u\| dx + \alpha \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{(v - 1)^2}{4\varepsilon} \right) dx. \quad (44)$$

Once again, the optimization technique is alternate minimization with respect to u^v and v [9]. Figure 18 demonstrates the outcome of the different regularizers for an image blurred by Gaussian kernel and corrupted by both Gaussian and salt-and-pepper noise. The fidelity term in all cases was selected as Φ_L^1 (40).

The methods based on Mumford-Shah regularizer are superior to the TV stabilizers, where MSTV provides a result slightly closer to the “ideal” with little loss of details.

17 Space-Variant Restoration

The assumption of space-invariant blur kernel is sometimes inaccurate in real photographic images. For example, when multiple objects move at different velocities and in different directions in a scene, one gets space-variant motion blur. Likewise, when a camera lens is focused on one specific object, other objects nearer or farther away from the lens are not as sharp. In such situations, different blur kernels degrade different areas of the image. In some cases, it can be assumed that the blur kernel is a piecewise space-variant function. This means that every sub-domain in the image is blurred by a different kernel. In the full blind restoration, several operations have to be simultaneously applied: (1) segmentation of the subregions, (2) estimation of the blur kernels, and (3) recovery of the “ideal” image. Presented here is the simplest case where it is assumed that the subregions and blur kernels are known in advance. The segmentation procedure in a semi-blind restoration problem can be found in

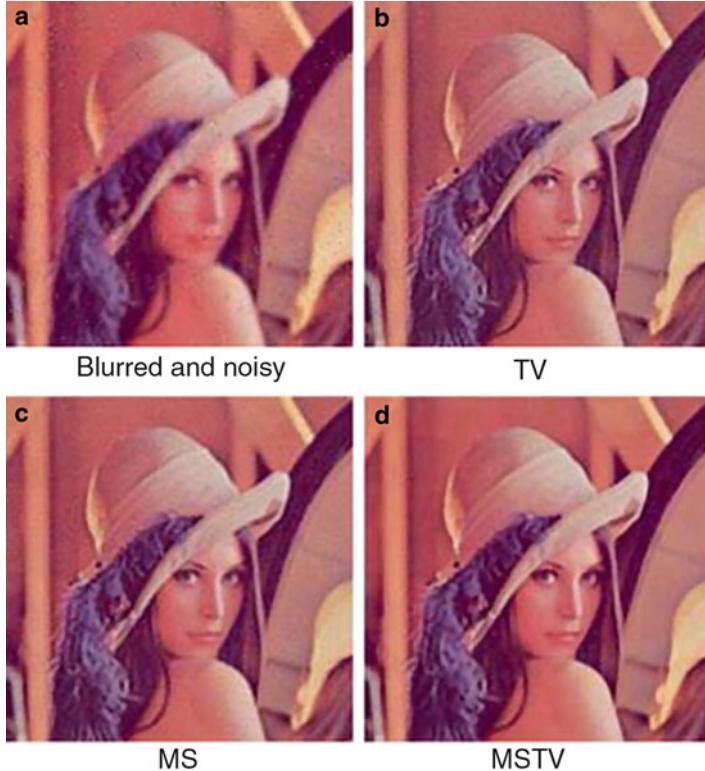

Fig. 18 Recovery of the *Lena* image blurred by 7×7 out-of-focus kernel contaminated by mixture of Gaussian and salt-and-pepper noise

[15]. The non-blind space-variant restoration approach relies on the use of a global regularizer, which eliminates the requirement of dealing with region boundaries. As a result, the continuity of the gray levels in the recovered image is inherent. This method does not limit the number of subregions, their geometrical shape, and the kernel support size.

Let the open nonoverlapping subsets $w_i \subset \Omega$ denote regions that are blurred by kernels h_i , respectively. In addition, $\Omega/\cup\bar{w_i}$ denotes the background region blurred by the background kernel h_b , and $\bar{w_i}$ stands for the closure of w_i . The region boundaries are denoted by ∂w_i . The recovered image u is the minimizer of the objective functional

$$\mathcal{F}(u, v) = \frac{1}{2} \sum_i \eta_i \int_{w_i} (h_i * u - g)^2 dx + \frac{\eta_b}{2} \int_{\Omega/(\cup\bar{w_i})} (h_b * u - g)^2 dx + \mathcal{J}_M. \quad (45)$$

where η_i and η_b are positive scalars and $\vartheta_{\text{MS}}(u, v)$ is the Mumford-Shah regularizer (25). Following the formulation of Chan and Vese [31], the domains w_i can be

Fig. 19 Non-blind space-variant restoration. *Left column:* spatially variant motion blurred images. *Right column:* the corresponding recovered images using the suggested method

replaced by the Heaviside function $H(\phi_i)$, where

$$H(\phi_i) = \begin{cases} 1, & \phi_i > 0, \\ 0, & \phi_i \leq 0, \end{cases} \quad (46)$$

and $\phi_i : \Omega \rightarrow \mathbb{R}$ is a level set function such that

$$\partial\omega_i = \{x \in \Omega : \phi_i(x) = 0\}.$$

The functional then takes the form

$$\mathcal{F}(u, v) = \frac{1}{2} \sum_i \eta_i \int_{\Omega} (h_i * u - g)^2 H(\phi_i) dx + \frac{\eta_p}{2} \int_{\Omega} (h_b * u - g)^2 (1 - \sum_i H(\phi_i)) dx + \mathcal{J}_{MS}(u, v). \quad (47)$$

Figure 19 demonstrates the performance of the suggested algorithm. The two images in the left column were synthetically blurred by different blur kernels within the marked shapes. The corresponding recovered images are shown in the right column. Special handling of the region boundaries was not necessary because the

MS regularizer was applied globally to the whole image, enforcing the piecewise-smoothness constraint. This means that the boundaries of the blurred regions were smoothed within the restoration process while edges were preserved.

18 Level Set Formulations for Joint Restoration and Segmentation

Presented here are other joint formulations for denoising, deblurring, and piecewise-constant segmentation introduced in [45] that can be seen as applications and modifications of the piecewise-constant Mumford-Shah model in level set formulation presented in Sect. 10. For related discussion, the reader is referred to [11–13, 47, 53]. A minimization approach is used, and the gradient descent method is considered. Let $g = h * u + n$ be a given blurred-noisy image, where h is a known blurring kernel (such as the Gaussian kernel) and n represents Gaussian additive noise of zero mean. We assume that the contours or jumps in the image u can be represented by the m distinct levels $\{-\infty = l_0 < l_1 < l_2 < \dots < l_m < l_{m+1} = \infty\}$ of the same implicit (Lipschitz-continuous) function $\phi: \Omega \rightarrow \mathbb{R}$ partitioning Ω into $m + 1$ disjoint open regions $R_j = \{x \in \Omega: l_{j-1} < \phi(x) < l_j\}$, $1 \leq j \leq m + 1$. Thus, the denoised-deblurred image $u = c_1 H(\phi - l_m) + \sum_{j=2}^m c_j H(\phi - l_{m-j+1})H(l_{m-j+2} - \phi) + c_{m+1} H(l_1 - \phi)$ is recovered by minimizing the following energy functional ($v_0 > 0$):

$$E(c_1, c_2, \dots, c_{m+1}, \phi) = \int_{\Omega} |g - h * (c_1 H(\phi - l_m) + \sum_{j=2}^m c_j H(\phi - l_{m-j+1})H(l_{m-j+2} - \phi) + c_{m+1} H(l_1 - \phi))|^2 dx + v_0 \sum_{j=1}^m \int_{\Omega} |\nabla H(\phi - l_j)|$$

In the binary case (one level $m = 1, l_1 = 0$), we assume the degradation model $g = h * c_1 H(\phi) + c_2 (1 - H(\phi)) + n$, and we wish to recover $u = c_1 H(\phi) + c_2 (1 - H(\phi))$ in Ω together with a segmentation of g . The modified binary segmentation model incorporating the blur becomes

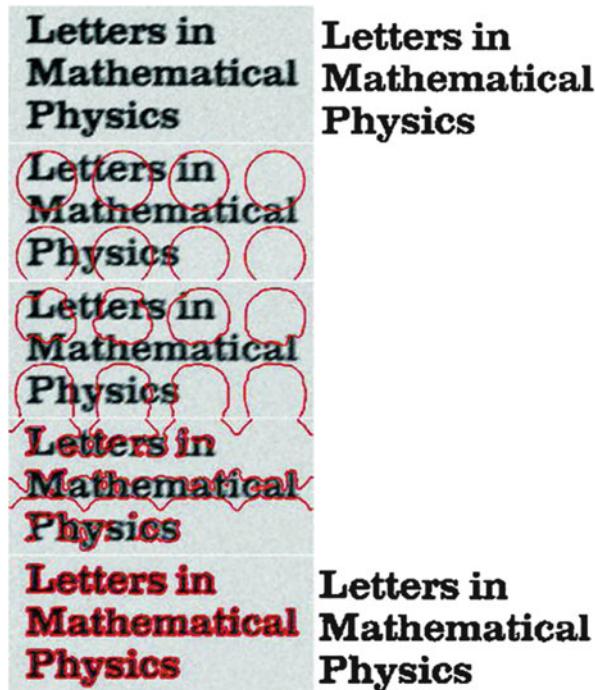

$$\begin{aligned} \inf_{c_1, c_2, \phi} \{E(c_1, c_2, \phi) &= \int_{\Omega} |g - h * (c_1 H(\phi) + c_2 (1 - H(\phi)))|^2 dx \\ &+ v_0 \int_{\Omega} |\nabla H(\phi)| dx\}. \end{aligned} \quad (48)$$

The Euler-Lagrange equations are computed minimizing this energy with respect to c_1, c_2 , and ϕ . Using alternating minimization, keeping first ϕ fixed and minimizing the energy with respect to the unknown constants c_1 and c_2 , the following linear system of equations are obtained:

$$\begin{aligned} c_1 \int_{\Omega} h_1^2 dx + c_2 \int_{\Omega} h_1 h_2 dx &= \int g h_1 dx, \\ c_1 \int_{\Omega} h_1 h_2 dx + c_2 \int_{\Omega} h_2^2 dx &= \int g h_2 dx \end{aligned}$$

with the notations $h_1 = h * H(\phi)$ and $h_2 = h * (1 - H(\phi))$. Note that the linear system has a unique solution because the determinant of the coefficient matrix is not

Fig. 20 Joint segmentation, denoising, and deblurring using the binary level set model. Top row: (from left to right) degraded image g (blurred with motion blur kernel of length 10, oriented at an angle $\theta = 25^\circ$ w.r.t. the horizon and contaminated by Gaussian noise with $\sigma_n = 10$), original image. Rows 2–5: initial curves, curve evolution using (48) at iterations 50, 100, and 300 with $v_0 = 5 \cdot 255^2$ and the restored image $u(\text{SNR} = 28.1827)$. (c_1, c_2): original image $\approx (62.7525, 259.8939)$, restored u , $(61.9194, 262.7795)$

zero due to the Cauchy-Schwartz inequality $\int_{\Omega} h_1 h_2 \, dx^2 \leq \int_{\Omega} h_1^2 \, dx \int_{\Omega} h_2^2 \, dx$, where the equality holds if and only if $h_1 = h_2$ for a.e. $x \in \Omega$. But clearly, $h_1 = h * H(\phi)$ and $h_2 = h * (1 - H(\phi))$ are distinct; thus, we have strict inequality.

Keeping now the constants c_1 and c_2 fixed and minimizing the energy with respect to ϕ , the evolution equation is obtained by introducing an artificial time for the gradient descent in $\phi(t, x)$, $t > 0$, $x \in \Omega$

$$\frac{\partial \phi}{\partial t}(t, x) = \delta(\phi) \left[\left(\tilde{h} * g - c_1 \tilde{h} * (h * H(\phi)) - c_2 \tilde{h} * (h * (1 - H(\phi))) \right) (c_1 - c_2) + v_0 \operatorname{div} \left(\frac{\nabla \phi}{|\nabla \phi|} \right) \right],$$

where $\tilde{h}(x) = h(-x)$.

Figure 20 shows a numerical result for joint denoising, deblurring, and segmentation of a synthetic image, in a binary level set approach.

In the case of two distinct levels $l_1 < l_2$ of the level set function $\phi(m = 2)$, we wish to recover a piecewise-constant image of the form $u = c_1 H(\phi - l_2) + c_2 H(l_2 - \phi) H(\phi - l_1) + c_3 H(l_1 - \phi)$ and a segmentation of g , assuming the degradation model $g = h * c_1 H(\phi - l_2) + c_2 H(l_2 - \phi) H(\phi - l_1) + c_3 H(l_1 - \phi) + n$, by minimizing

$$\inf_{c_1, c_2, c_3, \phi} E(c_1, c_2, c_3, \phi) = \int_{\Omega} |g - h * (c_1 H(\phi - l_2) + c_2 H(l_2 - \phi) H(\phi - l_1) + c_3 H(l_1 - \phi))|^2 \, dx + v_0 \sum_{j=1}^2 \int_{\Omega} |\nabla H(\phi - l_j)| \, dx. \quad (49)$$

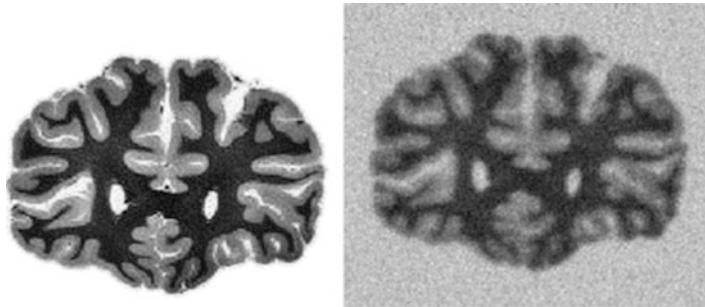

Fig. 21 Original image (*left*) and its noisy, blurry version (*right*) blurred with Gaussian kernel with $\sigma_b = 1$ and contaminated by Gaussian noise $\sigma_n = 20$

Similar to the previous binary model with blur, for fixed ϕ , the unknown constants are computed by solving the linear system of three equations:

$$\begin{aligned} c_1 \int h_1^2 dx + c_2 \int h_1 h_2 dx + c_3 \int h_1 h_3 dx &= \int g h_1 dx \\ c_1 \int h_1 h_2 dx + c_2 \int h_2^2 dx + c_3 \int h_2 h_3 dx &= \int g h_2 dx \\ c_1 \int h_1 h_3 dx + c_2 \int h_2 h_3 dx + c_3 \int h_3^2 dx &= \int g h_3 dx \end{aligned}$$

where $h_1 = h * H(\phi - l_2)$, $h_2 = h * H(l_2 - \phi)H(\phi - l_1)$, and $h_3 = h * H(l_1 - \phi)$.

For fixed c_1 , c_2 , and c_3 , by minimizing the functional E with respect to ϕ , the gradient descent is obtained for $\phi(t, x)$, $t > 0$, $x \in \Omega$:

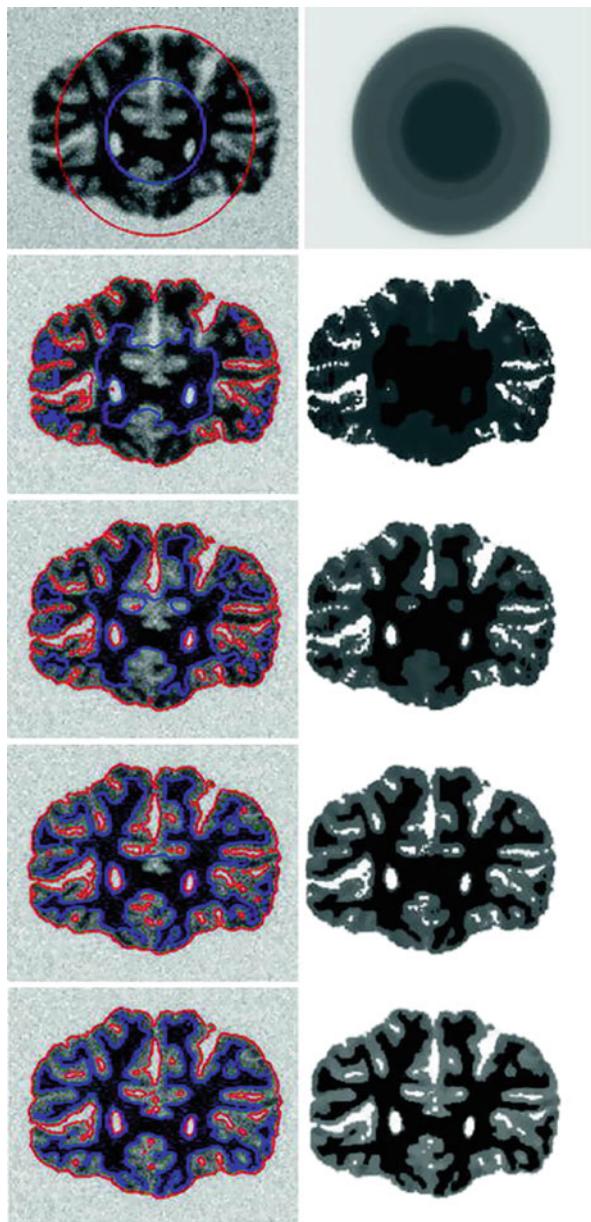

$$\begin{aligned} \frac{\partial \phi}{\partial t}(t, x) &= \tilde{h} * (g - h * (c_1 H(\phi - l_2) + c_2 H(l_2 - \phi) H(\phi - l_2) \\ &\quad + c_3 H(l_1 - \phi)) (c_1 \delta(\phi - l_2) \\ &\quad + c_2 H(l_2 - \phi) \delta(\phi - l_1) - c_2 H(\phi - l_1) \delta(l_2 - \phi) - c_3 \delta(l_1 - \phi))) \\ &\quad + v_0 \operatorname{div} \left(\frac{\nabla \phi}{|\nabla \phi|} \right) (\delta(\phi - l_1) + \delta(\phi - l_2)). \end{aligned} \quad (50)$$

Figures 21 and 22 show a numerical result for joint denoising, deblurring, and segmentation of the brain image in a multilayer level set approach.

19 Image Restoration by Nonlocal Mumford-Shah Regularizers

The traditional regularization terms discussed in the previous sections (depending on the image gradient) are based on local image operators, which denoise and preserve edges very well, but may induce loss of fine structures like texture during the restoration process. Recently, Buades et al. [22] introduced the nonlocal means filter, which produces excellent denoising results. Gilboa and Osher [42, 43] formulated the variational framework of NL means by proposing nonlocal regularizing functionals and the nonlocal operators such as the nonlocal gradient and

Fig. 22 Curve evolution and restored u using (51),
 $v_0 = 0.02 \cdot 255^2$, (c_1, c_2, c_3) :
original image \approx
 $(12.7501, 125.3610, 255.6453)$,
restored $u \approx$
 $(22.4797, 136.9884, 255.0074)$

divergence. Following Jung et al. [46], presented here are nonlocal versions of the Mumford-Shah-Ambrosio-Tortorelli regularizing functionals, called NL/MSH¹ and NL/MSTV, by applying the nonlocal operators proposed by Gilboa-Osher to MSH¹ and MSTV, respectively, for image restoration in the presence of blur and Gaussian or impulse noise. In addition, for the impulse noise model, use of a preprocessed

image is proposed to compute the weights w (the weights w defined in the NL means filter are more appropriate for the additive Gaussian noise case).

First recall the Ambrosio-Tortorelli regularizer,

$$\Psi_{\varepsilon}^{\text{MSH}^1}(u, v) = \beta \int_{\Omega} v^2 |\nabla u|^2 dx + \alpha \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{(v - 1)^2}{4\varepsilon} \right) dx, \quad (51)$$

where $0 \leq v(x) \leq 1$ represents the edges: $v(x) \approx 0$ if $x \in K$ and $v(x) \approx 1$ otherwise, ε is a small positive constant, and α, β are positive weights.

Shah [74] suggested a modified version of the approximation (51) to the MS functional by replacing the norm square of $|\nabla u|$ by the norm in the first term:

$$\Psi_{\varepsilon}^{\text{MSTV}}(u, v) = \beta \int_{\Omega} v^2 |\nabla u| dx + \alpha \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{(v - 1)^2}{4\varepsilon} \right) dx.$$

This functional Γ converges to the other ψ^{MSTV} functional [2]:

$$\Psi^{\text{MSTV}}(u) = \beta \int_{\Omega/K} |\nabla u| dx + \alpha \int_K \frac{|u^+ - u^-|}{1 + |u^+ - u^-|} dH^1 + |D_c u|(\Omega),$$

where u^+ and u^- denote the image values on two sides of the jump set $K = J_u$ of u and $D_c u$ is the Cantor part of the measure-valued derivative Du .

Nonlocal methods in image processing have been explored in many papers because they are well adapted to texture denoising, while the standard denoising models working with local image information seem to consider texture as noise, which results in losing texture. Nonlocal methods are generalized from the neighborhood filters and patch-based methods. The idea of neighborhood filter is to restore a pixel by averaging the values of neighboring pixels with a similar gray level value.

Buades et al. [22] generalized this idea by applying the patch-based methods, proposing a famous neighborhood filter called nonlocal means (or NL means):

$$NLu(x) = \frac{1}{C(x)} \int_{\Omega} e^{-\frac{d_a(u(x), u(y))}{h^2}} u(y) dy$$

$$d_a(u(x), u(y)) = \int_{\mathbb{R}^2} G_a(t) |u(x + t) - u(y + t)|^2 dt$$

where d_a is the patch distance, G_a is the Gaussian kernel with standard deviation a determining the patch size, $C(x) = \int_{\Omega} e^{-\frac{d_a(u(x), u(y))}{h^2}} dy$ is the normalization factor, and h is the filtering parameter which corresponds to the noise level; it is usually set to be the standard deviation of the noise. The NL means not only compares the gray level at a single point but the geometrical configuration in a whole neighborhood (patch). Thus, to denoise a pixel, it is better to average the nearby pixels with similar structures rather than just with similar intensities.

In practice, the search window $\Omega_w = \{y \in \Omega : |y - x| \leq r\}$ is used instead of Ω (semi-local) and the weight function at $(x, y) \in \Omega \times \Omega$ depending on a function $u: \Omega \rightarrow \mathbb{R}$

$$w(x, y) = \exp\left(-\frac{d_a(u(x), u(y))}{h^2}\right).$$

The weight function $w(x, y)$ gives the similarity of image features between two pixels x and y , which is normally computed based on the blurry-noisy image g .

Based on the gradient and divergence definitions on graphs in the context of machine learning, Gilboa and Osher [43] derived the nonlocal operators. Let $u: \Omega \rightarrow \mathbb{R}$ be a function, and $w: \Omega \times \Omega \rightarrow \mathbb{R}$ is a weight function assumed to be nonnegative and symmetric. The nonlocal gradient $\nabla_w u: \Omega \times \Omega \rightarrow \mathbb{R}$ is defined as the vector $(\nabla_w u)(x, y) := (u(y) - u(x)) \sqrt{w(x, y)}$. Hence, the norm of the nonlocal gradient of u at $x \in \Omega$ is defined as

$$|\nabla_w u|(x) = \sqrt{\int_{\Omega} (u(y) - u(x))^2 w(x, y) dy}.$$

The nonlocal divergence $\operatorname{div}_w \vec{v}: \Omega \rightarrow \mathbb{R}$ of the vector $\vec{v}: \Omega \times \Omega \rightarrow \mathbb{R}$ is defined as the adjoint of the nonlocal gradient

$$(\operatorname{div}_w \vec{v})(x) := \int_{\Omega} (v(x, y) - v(y, x)) \sqrt{w(x, y)} dy.$$

Based on these nonlocal operators, they introduced nonlocal regularizing functionals of the general form

$$\Psi(u) = \int_{\Omega} \phi(|\nabla_w u|^2) dx,$$

where $\phi(s)$ is a positive function, convex in \sqrt{s} with $\phi(0) = 0$. Inspired by these ideas, nonlocal versions of Ambrosio-Tortorelli and Shah approximations to the MS regularizer for image denoising-deblurring are presented. This is also continuation of work by Bar et al. [11–13], as presented in the first part of this section.

Proposed are the following nonlocal approximated Mumford-Shah and Ambrosio-Tortorelli regularizing functionals (NL/MS) by applying the nonlocal operators to the approximations of the MS regularizer,

$$\Psi^{\text{NL/MS}}(u, v) = \beta \int_{\Omega} v^2 \phi(|\nabla_w u|^2) dx + \alpha \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{(v - 1)^2}{4\varepsilon} \right) dx,$$

where $\phi(s) = s$ and $\phi(s) = \sqrt{s}$ correspond to the nonlocal version of MSH¹ and MSTV regularizers, called here NL/MSH¹ and NL/MSTV, respectively:

$$\begin{aligned}\Psi^{\text{NL/MSH}^1}(u, v) &= \beta \int_{\Omega} v^2 |\nabla_w u|^2 dx + \alpha \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{(v-1)^2}{4\varepsilon} \right) dx \\ \Psi^{\text{NL/MSTV}}(u, v) &= \beta \int_{\Omega} v^2 |\nabla_w u| dx + \alpha \int_{\Omega} \left(\varepsilon |\nabla v|^2 + \frac{(v-1)^2}{4\varepsilon} \right) dx.\end{aligned}$$

In addition, these nonlocal regularizers are used to deblur images in the presence of Gaussian or impulse noise. Thus, by incorporating the proper fidelity term depending on the noise model, two types of total energies as Gaussian noise model:

$$E^G(u, v) = \int_{\Omega} (g - h * u)^2 dx + \Psi^{\text{NL/MS}}(u, v),$$

Impulse noise model:

$$E^{\text{Im}}(u, v) = \int_{\Omega} |g - h * u| dx + \Psi^{\text{NL/MS}}(u, v).$$

Minimizing these functionals in u and v , the Euler-Lagrange equations: Gaussian noise model:

$$\begin{aligned}\frac{\partial E^G}{\partial v} &= 2\beta v \phi(|\nabla_w u|^2) - 2\varepsilon \alpha \Delta v + \alpha \left(\frac{v-1}{2\varepsilon}\right) = 0, \\ \frac{\partial E^G}{\partial u} &= h^* * (h * u - g) + L^{\text{NL/MS}} u = 0\end{aligned}$$

Impulse noise model:

$$\begin{aligned}\frac{\partial E^{\text{Im}}}{\partial v} &= 2\beta v \phi(|\nabla_w u|^2) - 2\varepsilon \alpha \Delta v + \alpha \left(\frac{v-1}{2\varepsilon}\right) = 0, \\ \frac{\partial E^{\text{Im}}}{\partial u} &= h^* * \text{sign}(h * u - g) + L^{\text{NL/MS}} u = 0,\end{aligned}$$

where $h^*(x) = h(-x)$ and

$$\begin{aligned}L^{\text{NL/MS}} u &= -2 \int_{\Omega} (u(y) - u(x)) w(x, y) \\ &\quad \left[\left(v^2(y) \phi'(|\nabla_w(u)|^2(y)) \right) \right. \\ &\quad \left. + v^2(x) \phi'(|\nabla_w(u)|^2(x)) \right] dy\end{aligned}$$

More specifically, the NL/MSH¹ and NL/MSTV regularizers give

$$\begin{aligned} L^{\text{NL/MSH}^1} u &= -2 \nabla_w \cdot (v^2(x) \nabla_w u(x)) \\ &= -2 \int_{\Omega} (u(y) - u(x)) w(x, y) \\ &\quad [v^2(y) + v^2(x)] dy, \end{aligned}$$

$$\begin{aligned} L^{\text{NL/MSTV}} u &= -\nabla_w \cdot \left(v^2(x) \frac{\nabla_w u(x)}{|\nabla_w u(x)|} \right) \\ &= -\int_{\Omega} (u(y) - u(x)) w(x, y) \left[\frac{v^2(y)}{|\nabla_w u(y)|} + \frac{v^2(x)}{|\nabla_w u(x)|} \right] dy \end{aligned}$$

The energy functionals $E^G(u, v)$ and $E^{\text{Im}}(u, v)$ are convex in each variable and bounded from below. Therefore, to solve two Euler-Lagrange equations simultaneously, the alternate minimization (AM) approach is applied: in each step of the iterative procedure, we minimize with respect to one function while keeping the other one fixed. Due to its simplicity, the explicit scheme for u based on the gradient descent method and the Gauss-Seidel scheme for v is used. Note that since both energy functionals are not convex in the joint variable, only a local minimizer may be computed. However, this is not a drawback in practice, since the initial guess for u in our algorithm is the data g .

Furthermore, to extend the nonlocal methods to the impulse noise case, a preprocessing step is needed for the weight function $w(x, y)$ since it is not possible to directly use the data g to compute w . In other words, in the presence of impulse noise, the noisy pixels tend to have larger weights than the other neighboring points, so it is likely to keep the noise value at such pixel. Thus, a simple algorithm is proposed to obtain first a preprocessed image f , which removes the impulse noise (outliers) as well as preserves the textures as much as possible. Basically, the median filter is used, well known for removing impulse noise. However, if one step of the median filter is applied, then the output may be too smoothed out. In order to preserve the fine structures as well as to remove the noise properly, the idea of Bregman

Fig. 23 Original and noisy-blurry images (noisy-blurry image using the pillbox kernel of radius 2 and Gaussian noise with $\sigma_n = 5$)

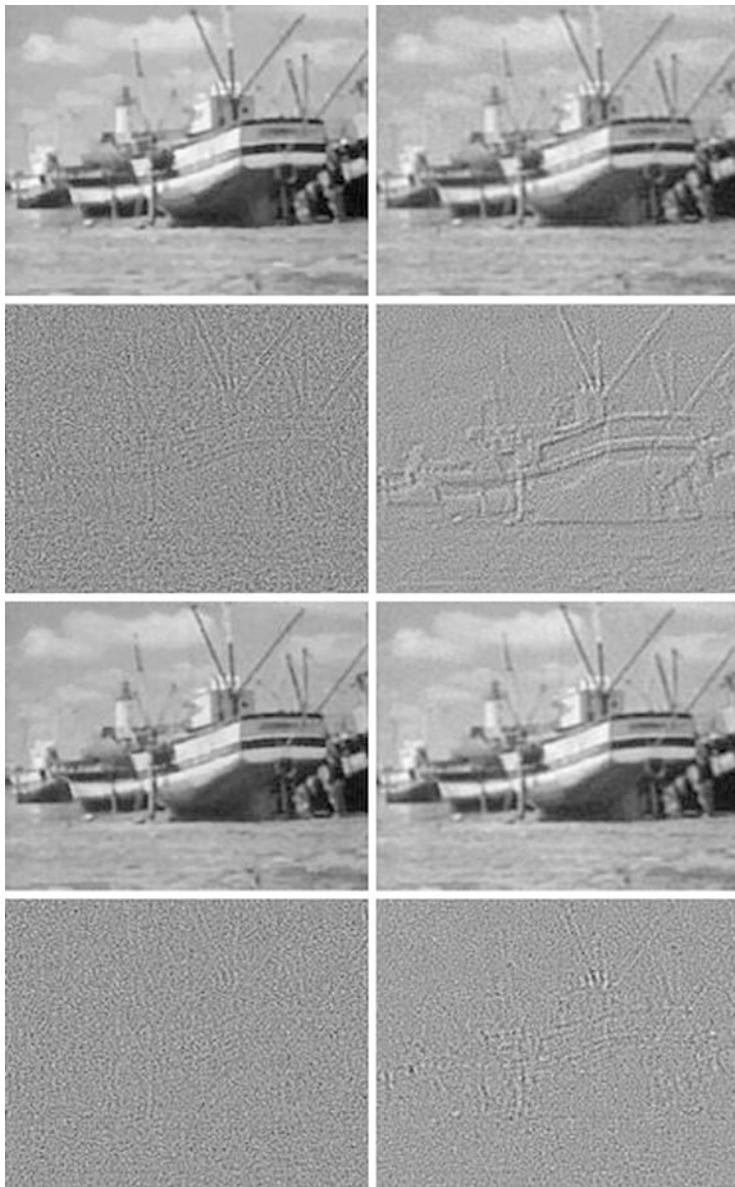

Fig. 24 Recovery of noisy-blurry image from Figs. 21–23. *Top row:* recovered image u using MSTV ($\text{SNR} = 25.1968$), MSH^1 ($\text{SNR} = 23.1324$). *Third row:* recovered image u using NL/MSTV ($\text{SNR} = 26.4696$), NL/MSH 1 ($\text{SNR} = 24.7164$). *Second, bottom rows:* corresponding residuals $g - h \ast u$. $\beta = 0.0045$ (MSTV), 0.001 (NL/MSTV), 0.06 (MSH 1), 0.006 (NL/MSH 1), $\alpha = 0.00000001$, $\varepsilon = 0.00002$

Fig. 25 Recovery of noisy-blurry image with Gaussian kernel with $\sigma = 1$ and salt-and-pepper noise with $d = 0.3$. *Top row:* original image, blurry image, noisy-blurry image. *Middle row:* recovered images using MSTV (SNR = 27.8336), MSH¹ (SNR = 23.2052). *Bottom row:* recovered images using NL/MSTV (SNR = 29.3503), NL/MSH¹ (SNR = 27.1477). *Parameters:* $\beta = 0.25$ (MSTV), 0.1 (NL/MSTV), $\alpha = 0.01$, $\varepsilon = 0.002$. *Parameters:* $\beta = 2$ (MSH¹), 0.55 (NL/MSH¹), $\alpha = 0.001$, $\varepsilon = 0.0001$

iteration is used [21, 66], and the following algorithm is proposed to obtain a preprocessed image f that will be used only in the computation of the weight function:

- Initialize: $r_0 = 0$, $f_0 = 0$.
- do (iterate $n = 0, 1, 2, \dots$)
- $f_{n+1} = \text{median}(g + r_n, [aa])$
- $r_{n+1} = r_n + g - h * f_{n+1}$
- while $\|g - h_* f_n\|_1 > \|g - h_* f_{n+1}\|_1$
- Optional $f_m = \text{median}(f_m, [bb])$

where g is the given noisy-blurry data and $\text{median}(u, [aa])$ is the median filter of size $a \times a$ with input u ; the optional step is needed in the case when the final f_m still has some salt-and-pepper-like noise. This algorithm is simple and requires a few iterations only, so it takes less than 1 s for a 256×256 size image. The preprocessed

Fig. 26 Edge map v using the MS regularizers in the recovery of the Lena image blurred with Gaussian blur kernel with $\sigma_b = 1$ and contaminated by salt-and-pepper noise with density $d = 0.3$. Top: (left) MSTV, (right) NL/MSTV. Bottom: (left) MSH^1 , (right) NL/ MSH^1

image f will be used only in the computation of the weights w while keeping g in the data-fidelity term; thus, artifacts are not introduced by the median filter.

Figures 23 and 24 show an experimental result for image restoration of a boat image degraded by the pillbox kernel blur of radius 2 and additive Gaussian noise. The nonlocal methods give better reconstruction.

Figures 25 and 26 show an experimental result for image restoration of a woman image degraded by Gaussian kernel blur and salt-and-pepper noise. Figure 26 shows the edge set v for the four results. The nonlocal methods give better reconstruction.

Figure 27 shows an experimental result for restoration of the Einstein image degraded by motion kernel blur and random-valued impulse noise. The nonlocal methods give better reconstruction.

20 Conclusion

This chapter is concluded by first summarizing its main results. The Mumford-Shah model for image segmentation has been presented, together with its main properties. Several approximations to the Mumford and Shah energy have been discussed, with an emphasis on phase-field approximations and level set approximations. Several numerical results for image segmentation by these methods have been presented. In the last section of the chapter, several restoration problems were addressed in a variational framework. The fidelity term was formulated according to the noise

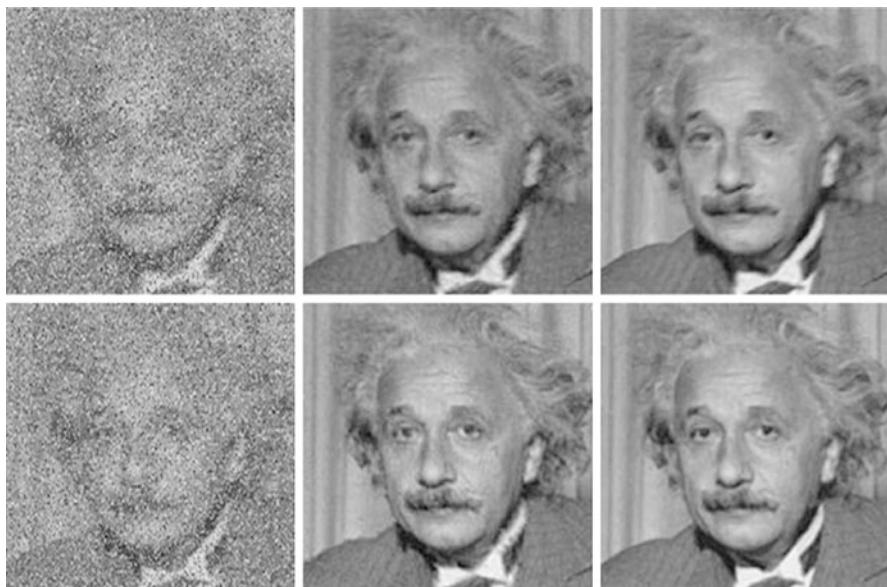

Fig. 27 Comparison between MSH^1 and NL/MSH^1 with the image blurred and contaminated by high density ($d = 0.4$) of random-valued impulse noise. *Top*: noisy-blurry image blurred with the motion blur in recovered images using MSH^1 (left, SNR = 17.9608) and NL/MSH^1 (right, SNR = 20.7563). *Bottom*: noisy blurry image blurred with the Gaussian blur in recovered images using MSH^1 (left, SNR = 16.6960) and NL/MSH^1 (right, SNR = 24.2500). *Top*: $\beta = 1.5$ (MSH^1), 0.5 (NL/MSH^1), $\alpha = 0.0001$, $\varepsilon = 0.002$. *Bottom*: $\beta = 2.5$ (MSH^1), 0.65 (NL/MSH^1), $\alpha = 0.000001$, $\varepsilon = 0.002$

model (Gaussian, impulse, multichannel impulse). First, the a priori piecewise-smooth image model was mathematically integrated into the functional as an approximation of the Mumford-Shah segmentation elements by the Γ -convergence formulation. Comparative experimental results show the superiority of this regularizer with respect to modern state-of-the-art restoration techniques. Also, the piecewise-constant level set formulations of the Mumford-Shah energy have been applied to image restoration (related to relevant work by Kim et al. [47]), joint with segmentation. Finally, in the last section, the Ambrosio-Tortorelli approximations and Bar et al. restoration models have been extended to nonlocal regularizers, inspired by the work of Gilboa et al. These models produce much improved restoration results for images with texture and fine details.

21 Recommended Reading

Many more topics on the Mumford-Shah model and its applications have been explored in image processing, computer vision, and more generally inverse problems. This chapter contains only a small sample of results and methods. As

mentioned before, detailed monographs on the Mumford-Shah problem and related theoretical and application topics by Blake and Zisserman [16], by Morel and Solimini [60], by Chambolle [26], by Ambrosio et al. [4], by David [38], and by Braides [19] are recommended. Also, the monographs by Aubert and Kornprobst [8] and by Chan and Shen [28] contain chapters presenting the Mumford and Shah problem and its main properties.

The authors would like to mention the work by Cohen et al. [36, 37] on using curve evolution approach and the Mumford-Shah functional for detecting the boundary of a lake. The work by Aubert et al. [7] also proposes an interesting approximation of the Mumford-Shah energy by a family of discrete edge-preserving functionals, with Γ -convergence result.

Abstract

Denoising images can be achieved by a spatial averaging of nearby pixels. However, although this method removes noise, it creates blur. Hence, neighborhood filters are usually preferred. These filters perform an average of neighboring pixels, but only under the condition that their gray level is close enough to the one of the pixel in restoration. This very popular method unfortunately creates shocks and staircasing effects. It also excessively blurs texture and fine structures when noise dominates the signal.

In this chapter, we perform an asymptotic analysis of neighborhood filters as the size of the neighborhood shrinks to zero. We prove that these filters are asymptotically equivalent to the Perona-Malik equation, one of the first nonlinear PDEs proposed for image restoration. As a solution to the shock effect, we propose an extremely simple variant of the neighborhood filter using a linear regression instead of an average. By analyzing its subjacent PDE, we prove that this variant does not create shocks: it is actually related to the mean curvature motion.

We also present a generalization of neighborhood filters, the nonlocal means (NL-means) algorithm, addressing the preservation of structure in a digital image. The NL-means algorithm tries to take advantage of the high degree of redundancy of any natural image. By this, we simply mean that every small window in a natural image has many similar windows in the same image. Now in a very general sense inspired by the neighborhood filters, one can define as “neighborhood of a pixel” any set of pixels with a similar window around. All pixels in that neighborhood can be used for predicting its denoised value.

We finally analyze the recently introduced variational formulations of neighborhood filters and their application to segmentation and seed diffusion.

1 Introduction

The *neighborhood filter or sigma filter* is attributed to J.S. Lee [48] (in 1983) but goes back to L. Yaroslavsky and the Sovietic image-processing theory [75]. This filter is introduced in a denoising framework for the removal of additive white noise:

$$v(x) = u(x) + n(x),$$

where \mathbf{x} indicates a pixel site, $v(\mathbf{x})$ is the noisy value, $u(\mathbf{x})$ is the “true” value at pixel \mathbf{x} , and $n(\mathbf{x})$ is the noise perturbation. When the noise values $n(\mathbf{x})$ and $n(\mathbf{y})$ at different pixels are assumed to be independent random variables and independent of the image value $u(\mathbf{x})$, one talks about “white noise.” Generally, $n(\mathbf{x})$ is supposed to follow a Gaussian distribution of zero mean and standard deviation σ .

Lee and Yaroslavsky proposed to smooth the noisy image by averaging only those neighboring pixels that have a similar intensity. Averaging is the principle of most denoising methods. The variance law in probability theory ensures that if N

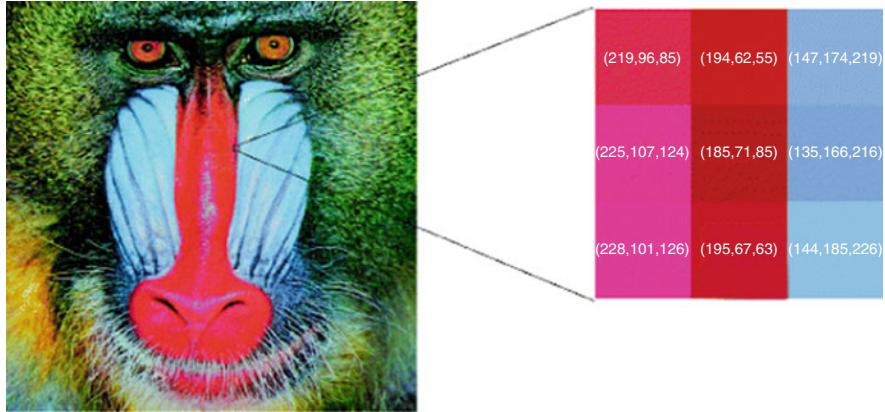

Fig. 1 The nine pixels in the baboon image on the right have been enlarged. They present a high red-blue contrast. In the red pixels, the first (red) component is stronger. In the blue pixels, the third component, blue, dominates

noise values are averaged, the noise standard deviation is divided by \sqrt{N} . Thus, one should, for example, find for each pixel nine other pixels in the image with the same color (up to the fluctuations due to noise) in order to reduce the noise by a factor 3. A first idea might be to choose the closest ones. Now, the closest pixels have not necessarily the same color as illustrated in Fig. 1. Look at the red pixel placed in the middle of Fig. 1. This pixel has five red neighbors and three blue ones. If the color of this pixel is replaced by the average of the colors of its neighbors, it turns blue. The same process would likewise reddens the blue pixels of this figure. Thus, the red and blue border would be blurred. It is clear that in order to denoise the central red pixel, it is better to average the color of this pixel with the nearby red pixels and only them, excluding the blue ones. This is exactly the technique proposed by neighborhood filters.

The original sigma and neighborhood filter were proposed as an average of the spatially close pixels with a gray level difference lower than a certain threshold h . Thus, for a certain pixel \mathbf{x} , the denoised value is the average of pixels in the spatial and intensity neighborhood:

$$\{y \in \Omega \mid \|x - y\| < \rho \text{ and } |u(x) - u(y)| < h\}.$$

However, in order to make it coherent with further extensions and facilitate the mathematical development of this chapter, we will write the filter in a continuous framework under a weighted average form. We will denote the neighborhood or sigma filter by NF and define it for a pixel \mathbf{x} as

$$NF_{h,\rho}u(x) = \frac{1}{C(x)} \int_{B_\rho(x)} u(y) e^{-\frac{|u(y)-u(x)|^2}{h^2}} dy, \quad (1)$$

where $B_\rho(\mathbf{x})$ is a ball of center \mathbf{x} and radius $\rho > 0$, $h > 0$ is the filtering parameter, and $C(x) = \int_{B_\rho(x)} e^{-\frac{|u(y)-u(x)|^2}{h^2}} dy$ is the normalization factor. The parameter h controls the degree of color similarity needed to be taken into account in the average. This value depends on the noise standard deviation σ , and it was set to 2.5σ in [48] and [75].

The Yaroslavsky and Lee's filter (1) is less known than more recent versions, namely, the *SUSAN filter* [68] and the *bilateral filter* [70]. Both algorithms, instead of considering a fixed spatial neighborhood $B_\rho(\mathbf{x})$, weigh the distance to the reference pixel \mathbf{x} :

$$\text{SF}_{h,\rho} u(x) = \frac{1}{C(x)} \int_{\Omega} u(y) e^{-\frac{|y-x|^2}{\rho^2}} e^{-\frac{|u(y)-u(x)|^2}{h^2}} dy, \quad (2)$$

where $C(x) = \int_{\Omega} e^{-\frac{|y-x|^2}{\rho^2}} e^{-\frac{|u(y)-u(x)|^2}{h^2}} dy$ is the normalization factor and $\rho > 0$ is now a spatial filtering parameter. Even if the SUSAN algorithm was previously introduced, the whole literature refers to it as the bilateral filter. Therefore, we shall call this filter by the latter name in subsequent sections.

The only difference between the neighborhood filter and the bilateral or SUSAN filter is the way the spatial component is treated. While for the neighborhood filter all pixels within a certain spatial distance are treated uniformly, for the bilateral or SUSAN filter, pixels closer to the reference one are considered more important. We display in Fig. 2 a denoising experience where a Gaussian white noise of standard deviation 10 has been added to a non-noisy image. We display the denoised image by both the neighborhood and bilateral filters. We observe that both filters avoid the excessive blurring caused by a Gaussian convolution and preserve all contrasted edges in the image.

Fig. 2 From left to right: noise image, Gaussian convolution, neighborhood filter, and bilateral filter. The neighborhood and bilateral filters avoid the excessive blurring caused by a Gaussian convolution and preserve all contrasted edges in the image

The above denoising experience was applied to color images. In order to clarify how the neighborhood filters are implemented in this case, we remind that each pixel \mathbf{x} is a triplet of values $u(\mathbf{x}) = (u_1(\mathbf{x}), u_2(\mathbf{x}), u_3(\mathbf{x}))$, denoting the red, green, and blue components. Then, the filter rewrites

$$\text{NF}_{h,\rho} u_i(x) = \frac{1}{C(x)} \int_{B_\rho(x)} u_i(y) e^{-\frac{\|u(y)-u(x)\|^2}{h^2}} dy,$$

$\|u(\mathbf{y}) - u(\mathbf{x})\|^2$ being the average of the distances of the three channels:

$$\|u(y) - u(x)\|^2 = \frac{1}{3} \sum_{i=1}^3 |u_i(y) - u_i(x)|.$$

The same definition applies for the SUSAN or bilateral filter by incorporating the spatial weighting term. The above definition naturally extends to multispectral images with an arbitrary number of channels. Bennett et al. [7] applied it to multispectral data with an infrared channel and Peng et al. [56] for general multispectral data.

The evaluation of the denoising performance of neighborhood filters and comparison with state-of-the-art algorithms are postponed to Sect. 2. In the same section, we present a natural extension of the neighborhood filter, the NL-means algorithm, proposed in [12]. This algorithm evaluates the similarity between two pixels \mathbf{x} and \mathbf{y} not only by the intensity or color difference of \mathbf{x} and \mathbf{y} but by the difference of intensities in a whole spatial neighborhood.

The bilateral filter was also proposed as a filtering algorithm with a filtering scale depending on both parameters h and ρ . Thus, taking several values for these parameters, we obtain different filtered images and corresponding residuals in a multi-scale framework. In Fig. 3, we display several applications of the bilateral filter for different values of the parameters h and ρ . We also display the differences between the original and filtered images in Fig. 4. For moderated values of h , this residual contains details and texture, but it does not contain contrasted edges. This contrasted information is removed by the bilateral filter only for large values of h . In that case, all pixels are judged as having a similar intensity level and the weight is set taking into account only the spatial component. It is well known that the residual by such an average is proportional to the Laplacian of the image. In Sect. 2, we will mathematically analyze the asymptotical expansion of the neighborhood residual image.

This detail removal of the bilateral while conserving very contrasted edges is the key in many image and video processing algorithms. Durand and Dorsey [28] use this property in the context of tone mapping whose goal is to compress the intensity values of a high-dynamic-range image. The authors isolate the details before compressing the range of the image. Filtered details and texture are added back at the final stage. Similar approaches for image editing are presented by Bae et al. [5], which transfer the visual look of an artist picture onto a casual photograph. Eisemann and Durand [32] and Petschnigg et al. [58] combine the filtered and

Fig. 3 Several applications of the bilateral filter for increasing values of parameters ρ and h . The parameter ρ increases from top to bottom taking values $\{2, 5, 10\}$ and h increases from left to right taking values $\{5, 10, 25, 100\}$

residual image of a flash and non-flash image of the same scene. These two last algorithms, in addition, compute the weight configuration in one image of the pair and average the intensity values of the other image. As we will see, this is a common feature with iterative versions of neighborhood filters. However, for these applications, both images of the pair must be correctly and precisely registered.

The iteration of the neighborhood filter was not originally considered by the pioneering works of Lee and Yaroslavsky. However, recent applications have shown its interest. The iteration of the filter as a local smoothing operator tends to piecewise

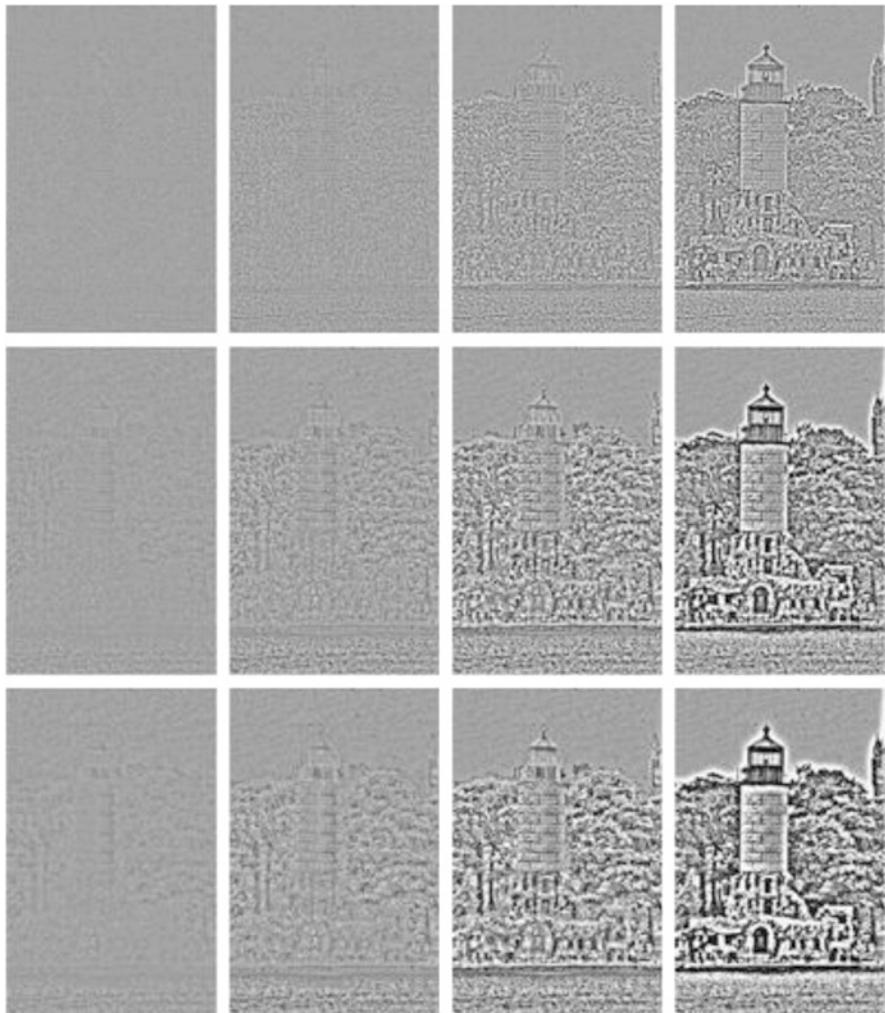

Fig. 4 Residual differences between original and filtered images in Fig. 3. For moderated values of h this residual contains details and texture but it doesn't contain contrasted edges. These contrasted information is removed by the bilateral filter only for large values of h

constant images by creating artificial discontinuities in regular zones. Barash et al. [6] showed that an iteration of the neighborhood filter was equivalent to a step of a certain numerical scheme of the classical Perona-Malik equation [57]. A complete proof of the equivalence between the neighborhood filter and the Perona-Malik equation was presented in [13] including a modification of the filter to avoid the creation of shocks inside regular parts of the image. Another theoretical explanation of the shock effect of the neighborhood filters can be found in Van de Weijer and van den Boomgaard [71] and Comaniciu [20]. Both papers show that the iteration of the

neighborhood filter process makes points tend to the local modes of the histogram but in a different framework: the first for images and the second for any dimensional clouds of points. This discontinuity or shock creation in regular zones of the image is not desirable for filtering or denoising applications. However, it can be used for image or video editing as proposed by Winnemoller et al. [73] in order to simplify video content and achieve a cartoon look.

Even if it may seem paradoxical, linear schemes have showed to be more useful than nonlinear ones for iterating the neighborhood filter; that is, the weight distribution for each pixel is computed once and is maintained during the whole iteration process. We will show in Sect. 4 that by computing the weights on an image and keeping them constant during the iteration process, a histogram concentration phenomenon makes the filter a powerful segmentation algorithm. The same iteration is useful to linearly diffuse or filter any initial data or seeds as proposed by Grady et al. [38] for medical image segmentation or [11] for colorization (see Fig. 5 for an example). The main hypothesis for this seed diffusion algorithm is that pixels having a similar gray level value should be related and are likely to belong to the same object. Thus, pixels of different sites are related as in a graph with a weight depending on the gray level distance. The iteration of the neighborhood filter on the graph is equivalent to the solution of the heat equation on the graph by taking the graph Laplacian. Eigenvalues and eigenvectors of such a graph Laplacian can be computed allowing the design of Wiener and thresholding filters on the graph (see [69] and [59, 60] for more details).

Both the neighborhood filter and the NL-means have been adapted and extended for other types of data and other image-processing tasks: for 3D data set points [17, 26, 35, 43, 79], and [42]; *demosaicking*, the operation which transforms the ‘‘R

or G or B” raw image in each camera into an “R and G and B” image [15, 51, 63]; *movie colorization*, [34] and [49]; *image inpainting* by proposing a nonlocal image inpainting variational framework with a unified treatment of geometry and texture [2] (see also [74]); *zooming* by a fractal-like technique where examples are taken from the image itself at different scales [29]; *movie flicker stabilization* [24], compensating spurious oscillations in the colors of successive frames; and *super-resolution*, an image zooming method by which several frames from a video, or several low-resolution photographs, can be fused into a larger image [62]. The main point of this super-resolution technique is that it gives up an explicit estimate of the motion, allowing actually for a multiple motion, since a block can look like several other blocks in the same frame. The very same observation is made in [30] for devising a super-resolution algorithm and in [22, 33].

2 Denoising

Analysis of Neighborhood Filter as a Denoising Algorithm

In this section, we will further investigate the neighborhood filter behavior as a denoising algorithm. We will consider the simplest neighborhood filter version which averages spatially close pixels with an intensity difference lower than a certain threshold h . By classical probability theory, the average of N random and i.i.d values has a variance N times smaller than the variance of the original values. However, this theoretical reduction is not observed when applying neighborhood filters.

In order to evaluate the noise reduction capability of the neighborhood filter, we apply it to a noise sample and evaluate the variance of the filtered sample. Let us suppose that we observe the realization of a white noise at a pixel \mathbf{x} , $n(\mathbf{x}) = a$. The nearby pixels with an intensity difference lower than h will be independent and identically distributed with the probability distribution function the restriction of the Gaussian to the interval $(a - h, a + h)$. If the research zone is large enough, then the average value will tend to the expectation of such a variable. Thus, the increase of the research zone and therefore of the number of pixels being averaged does not increase the noise reduction capability of the filter. Such a noise reduction factor is computed in the next result.

Theorem 1. *Assume that the $n(i)$ are i.i.d. with zero mean and variance σ^2 . Then, the filtered noise by the neighborhood filter NF_h satisfies the following:*

- *The noise reduction depends only on the value of h ,*

$$\text{Var } \text{NF}_h n(x) = f\left(\frac{h}{\sigma}\right) \sigma^2,$$

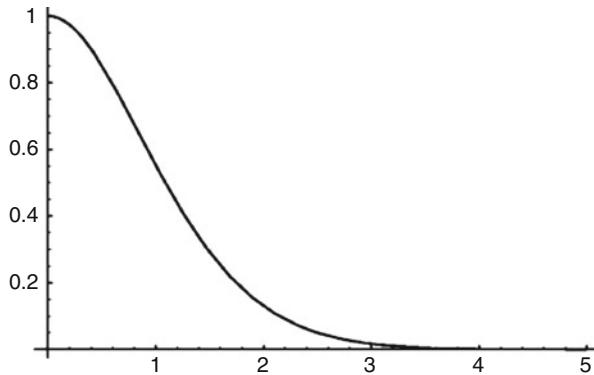

Fig. 6 Noise reduction function $f(x)$ given by Theorem 1

where

$$f(x) = \frac{1}{(2\pi)^{3/2}} \int_{\mathbb{R}} \frac{1}{\beta^2(a, x)} (e^{2xa} - 1)^2 e^{(a+x)^2} e^{-\frac{a^2}{2}} da$$

is a decreasing function with $f(0) = 1$ and $\lim_{x \rightarrow \infty} f(x) = 0$.

- The values $\text{NF}_h n(\mathbf{x})$ and $\text{NF}_h n(\mathbf{y})$ are uncorrelated for $\mathbf{x} \neq \mathbf{y}$.

The function $f(x)$ is plotted in Fig. 6. The noise reduction increases as the ratio h/σ also does. We see that $f(x)$ is near zero for values of x over 2.5 or 3, that is, values of h over 2.5σ or 3σ , which justifies the values proposed in the original papers by Lee and Yaroslavsky. However, for a Gaussian variable, the probability of observing values at a distance of the average larger than 2.5 or 3 times the standard deviation is very small. Thus, by taking these values, we excessively increase the probability of mismatching pixels of different objects. Thus, close objects with an intensity contrast lower than 3σ will not be correctly denoised. This explains the decreasing performance of the neighborhood filter as the noise standard deviation increases.

The previous theorem also tells us that the denoised noise values are still uncorrelated once the filter has been applied. This is easily justified since we showed that as the size ρ of the neighborhood increases, the filtered value tends to the expectation of the Gauss distribution restricted to the interval $(n(\mathbf{x}) - h, n(\mathbf{x}) + h)$. The filtered value is therefore a deterministic function of $n(\mathbf{x})$ and h . Independent random variables are mapped by a deterministic function on independent variables.

This property may seem anecdotic since noise is what we wish to get rid of. Now, it is impossible to totally remove noise. The question is how the remnants of noise look like. The transformation of a white noise into any correlated signal creates structure and artifacts. Only white noise is perceptually devoid of structure, as was pointed out by Attneave [3].

The only difference between the neighborhood filter and the bilateral or SUSAN filter is the way the spatial component is treated. While for the classical neighborhood all pixels within a certain distance are treated equally, for the bilateral filter, pixels closer to the reference pixel are more important. Even if this can seem a slight difference, this is crucial from a qualitative point of view, that is, the creation of artifacts.

It is easily shown that introducing the weighting function on the intensity difference instead of a non-weighted average does not modify the second property of Theorem 1, and the denoised noise values are still uncorrelated if ρ is large enough. However, the introduction of the spatial kernel by the bilateral or SUSAN filter affects this property. Indeed, the introduction of a spatial decay of the weights makes denoised values at close positions to be correlated.

There are two ways to show how denoising algorithms behave when they are applied to a noise sample. One of them is to find a mathematical proof that the pixels remain independent (or at least uncorrelated) and identically distributed random variables. The experimental device simply is to observe the effect of denoising on the simulated realization of a white noise. Figure 7 displays the filtered noises for the neighborhood filter, the bilateral filter, and other state-of-the-art denoising algorithms.

Neighborhood Filter Extension: The NL-Means Algorithm

Now in a very general sense inspired by the neighborhood filter, one can define as “neighborhood of a pixel \mathbf{x} ” any set of pixels \mathbf{y} in the image such that a window around \mathbf{y} looks like a window around \mathbf{x} . All pixels in that neighborhood can be used for predicting the value at \mathbf{x} , as was shown in [23, 31] for texture synthesis and in [21, 80] for inpainting purposes. The fact that such a self-similarity exists is a regularity assumption, actually more general and more accurate than all regularity assumptions we consider when dealing with local smoothing filters, and it also generalizes a periodicity assumption of the image.

Let v be the noisy image observation defined on a bounded domain $\Omega \subset \mathbb{R}^2$, and let $\mathbf{x} \in \Omega$. The NL-means algorithm estimates the value of \mathbf{x} as an average of the values of all the pixels whose Gaussian neighborhood looks like the neighborhood of \mathbf{x} :

$$\text{NL}(v)(x) = \frac{1}{C(x)} \int_{\Omega} e^{-\frac{(G_a * |v(x + \cdot) - v(y + \cdot)|^2)(0)}{h^2}} v(y) dy, \quad (3)$$

where G_a is a Gaussian kernel with standard deviation a , h acts as a filtering parameter, and $C(x) = \int_{\Omega} e^{-\frac{(G_a * |v(x + \cdot) - v(z + \cdot)|^2)(0)}{h^2}} dz$ is the normalizing factor. We recall that

$$(G_a * |v(x + \cdot) - v(y + \cdot)|^2)(0) = \int_{\mathbb{R}^2} G_a(t) |v(x + t) - v(y + t)|^2 dt.$$

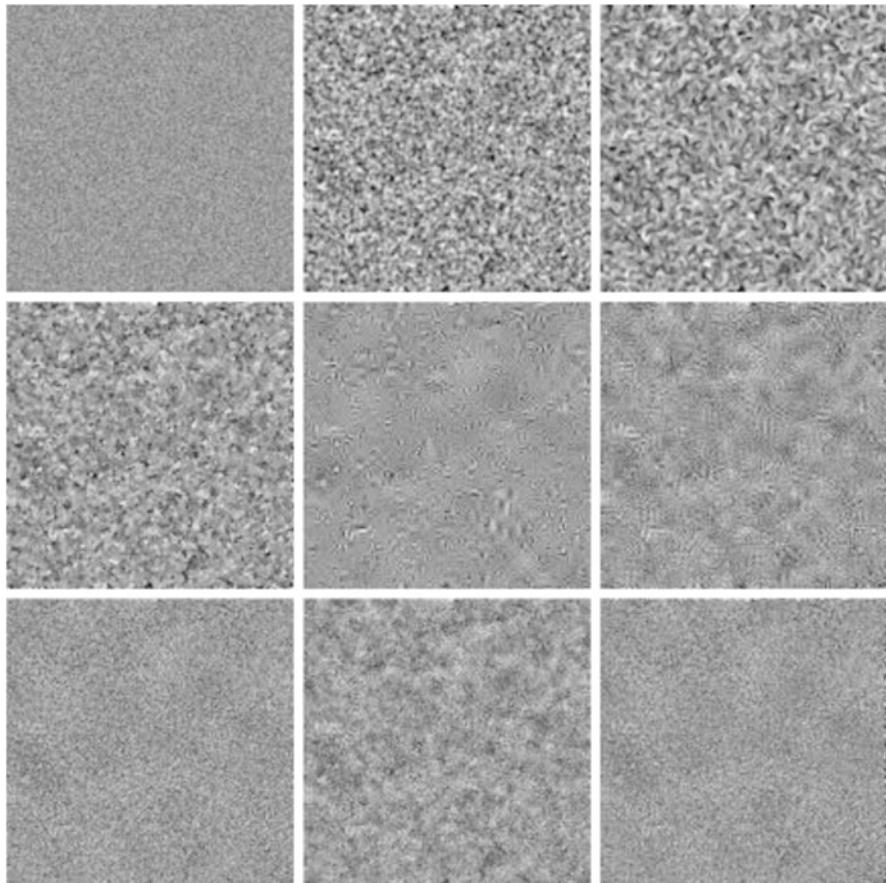

Fig. 7 The noise to noise criterion. From left to right and from top to bottom: original noise image of standard deviation 20, Gaussian convolution, anisotropic filtering, total variation, TIHWT, DCT empirical Wiener filter, neighborhood filter, bilateral filter, and the NL-means. Parameters have been fixed for each method so that the noise standard deviation is reduced by a factor 4. The filtered noise by the Gaussian filter and the total variation minimization are quite similar, even if the first one is totally blurred and the second one has created many high frequency details. The filtered noise by the hard wavelet thresholding looks like a constant image with superposed wavelets. The filtered noise by the neighborhood filter and the NL-means algorithm looks like a white noise. This is not the case for the bilateral filter, where low frequencies of noise are enhanced because of the spatial decay

We will see that the use of an entire window around the compared points makes this comparison more robust to noise. For the moment, we will compare the weighting distributions of both filters. Figure 8 illustrates how the NL-means algorithm chooses in each case a weight configuration adapted to the local geometry of the image. Then, the NL-means algorithm seems to provide a feasible and rational method to automatically take the best of all classical denoising algorithms, reducing for every possible geometric configuration the mismatched averaged pixels. It

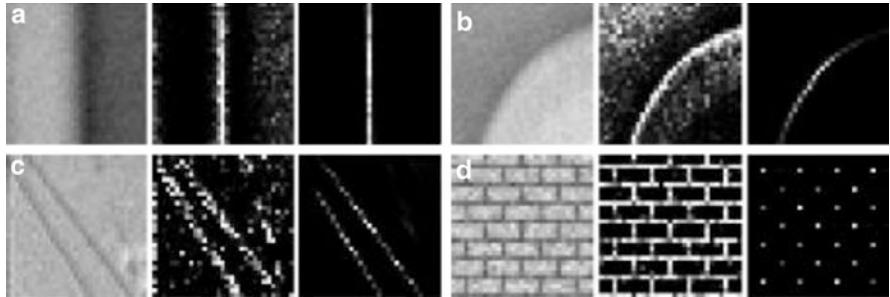

Fig. 8 Weight distribution of NL-means, the bilateral filter, and the anisotropic filter used to estimate the central pixel in four detail images. On the two right-hand-side images of each triplet, we display the weight distribution used to estimate the central pixel of the left image by the neighborhood and the NL-means algorithm. **(a)** In straight edges, the weights are distributed in the direction of the level line (as the mean curvature motion). **(b)** On curved edges, the weights favor pixels belonging to the same contour or level line, which is a strong improvement with respect to the mean curvature motion. In the cases of **(c)** and **(d)**, the weights are distributed across the more similar configurations, even though they are far away from the observed pixel. This shows a behavior similar to a nonlocal neighborhood filter or to an ideal Wiener filter

preserves flat zones as the Gaussian convolution and straight edges as the anisotropic filtering while still restoring corners or curved edges and texture.

Due to the nature of the algorithm, one of the most favorable cases is the textural case. Texture images have a large redundancy. For each pixel, many similar samples can be found in the image with a very similar configuration, leading to a noise reduction and a preservation of the original image. In Fig. 9, one can see an example with a Brodatz texture. The Fourier transform of the noisy and restored images shows the ability of the algorithm to preserve the main features even in the case of high frequencies.

The NL-means seems to naturally extend the Gaussian, anisotropic, and neighborhood filtering. But it is not easily related to other state-of-the-art denoising methods as the total variation minimization [64], the wavelet thresholding [19, 27], or the local DCT empirical Wiener filters [76]. For this reason, we compare these methods visually in artificial denoising experiences (see [12] for a more comprehensive comparison).

Figure 10 illustrates the fact that a nonlocal algorithm is needed for the correct reconstruction of periodic images. Local smoothing filters and Wiener and thresholding methods are not able to reconstruct the wall pattern. Only NL-means and the global Fourier-Wiener filter reconstruct the original texture. The Fourier-Wiener filter is based on a global Fourier transform, which is able to capture the periodic structure of the image in a few coefficients. But this only is an ideal filter: the Fourier transform of the original image is being used. Figure 8d shows how NL-means chooses the correct weight configuration and explains the correct reconstruction of the wall pattern.

The NL-means algorithm is not only able to restore periodic or texture Images; natural images also have enough redundancy to be restored. For example, in a

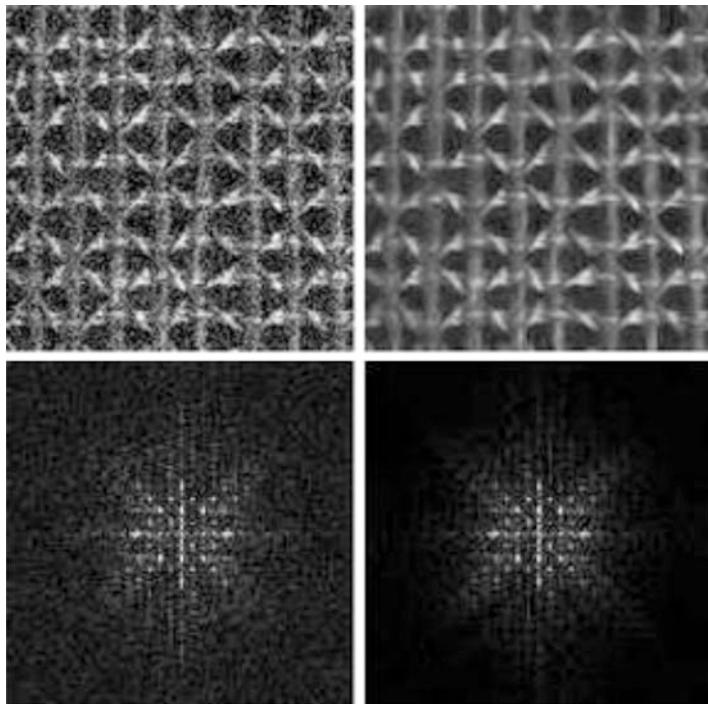

Fig. 9 NL-means denoising experiment with a Brodatz texture image. *Left:* noisy image with standard deviation 30. *Right:* NL-means restored image. The Fourier transforms of the noisy and restored images show how main features are preserved even at high frequencies

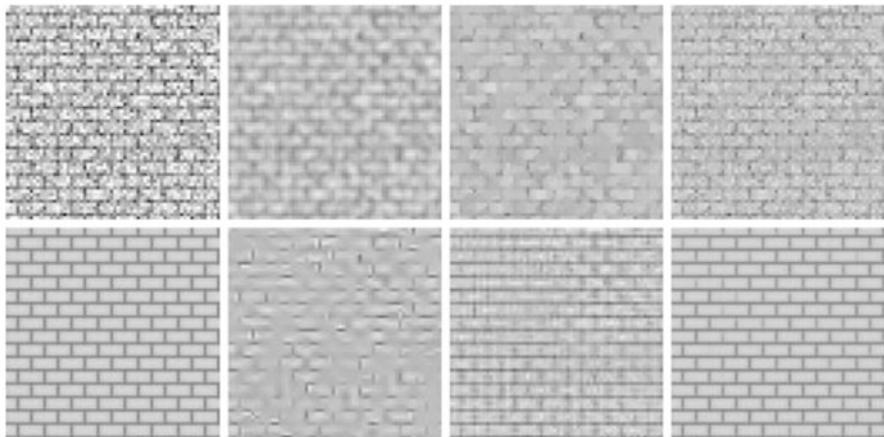

Fig. 10 Denoising experience on a periodic image. From left to right and from top to bottom: noisy image (standard deviation 35), Gauss filtering, total variation, neighborhood filter, Wiener filter (ideal filter), TIHWWT (translation invariant hard thresholding), DCT empirical Wiener filtering, and NL-means

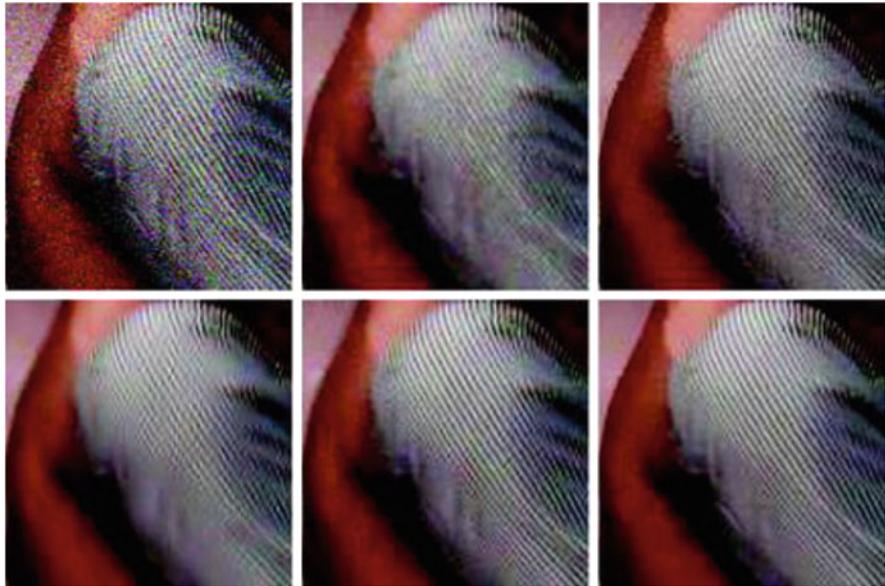

Fig. 11 Denoising experience on a natural image. From left to right and from top to bottom: noisy image (standard deviation 35), total variation, neighborhood filter, translation invariant hard thresholding (TIHWT), empirical Wiener, and NL-means

flat zone, one can find many pixels lying in the same region and with similar configurations. In a straight or curved edge, a complete line of pixels with a similar configuration is found. In addition, the redundancy of natural images allows us to find many similar configurations in faraway pixels.

Figure 11 shows that wavelet and DCT thresholding are well adapted to the recovery of oscillatory patterns. Although some artifacts are noticeable in both solutions, the stripes are well reconstructed. The DCT transform seems to be more adapted to this type of texture, and stripes are a little better reconstructed. For a much more detailed comparison between sliding window transform domain filtering methods and wavelet threshold methods, we refer the reader to [77]. NL-means also performs well on this type of texture, due to its high degree of redundancy.

The above description of movie denoising algorithms and its juxtaposition to the NL-means principle shows how the main problem, motion estimation, can be circumvented. In denoising, the more samples we have the happier we are. The *aperture problem* is just a name for the fact that there are many blocks in the next frame similar to a given one in the current frame. Thus, singling out one of them in the next frame to perform the motion compensation is an unnecessary and probably harmful step. A much simpler strategy that takes advantage of the aperture problem is to denoise a movie pixel by involving indiscriminately spatial and temporal similarities (see [14] for more details on this discussion). The algorithm favors pixels with a similar local configuration, as the similar configurations move, so do

the weights. Thus, the algorithm is able to follow the similar configurations when they move without any explicit motion computation (see Fig. 12).

Extension to Movies

Averaging filters are easily extended to the denoising of image sequences and video. The denoising algorithms involve indiscriminately pixels not belonging only to the same frame but also the previous and posterior ones.

In many cases, this straightforward extension cannot correctly deal with moving objects. For that reason, state-of-the-art movie filters are motion compensated (see [10] for a comprehensive review). The underlying idea is the existence of a “ground true” physical motion, which motion estimation algorithms should be able to estimate. Legitimate information should exist only along these physical trajectories. The *motion compensated filters* estimate explicitly the motion of the sequence by a motion estimation algorithm. The motion compensated movie yields a new stationary data on which an averaging filter can be applied. The motion compensation movie yields a new stationary data on which an averaging filter can be applied. The motion compensation neighborhood filter was proposed by Ozkan et al. [55]. We illustrate in Fig. 13 the improvement obtained with the proposed compensation.

One of the major difficulties in motion estimation is the ambiguity of trajectories, the so-called aperture problem. This problem is illustrated in Fig. 14. At most pixels, there are several options for the displacement vector. All of these options have a similar gray level value and a similar block around them. Now, motion estimators have to select one by some additional criterion.

3 Asymptotic

PDE Models and Local Smoothing Filters

According to Shannon’s theory, a signal can be correctly represented by a discrete set of values, the “samples,” only if it has been previously smoothed. Let us start with u_0 the physical image, a real function defined on a bounded domain $\Omega \subset \mathbb{R}^2$. Then a blur optical kernel k is applied, i.e., u_0 is convolved with k to obtain an observable signal k^*u_0 . Gabor remarked in 1960 that the difference between the original and the blurred images is roughly proportional to its Laplacian, $\Delta u = u_{xx} + u_{yy}$. In order to formalize this remark, we have to notice that k is spatially concentrated and that we may introduce a scale parameter for k , namely, $k_h(x) = h^{-1}k(h^{-\frac{1}{2}}x)$. If, for instance, u is C^2 and bounded and if k is a radial function in the Schwartz class, then

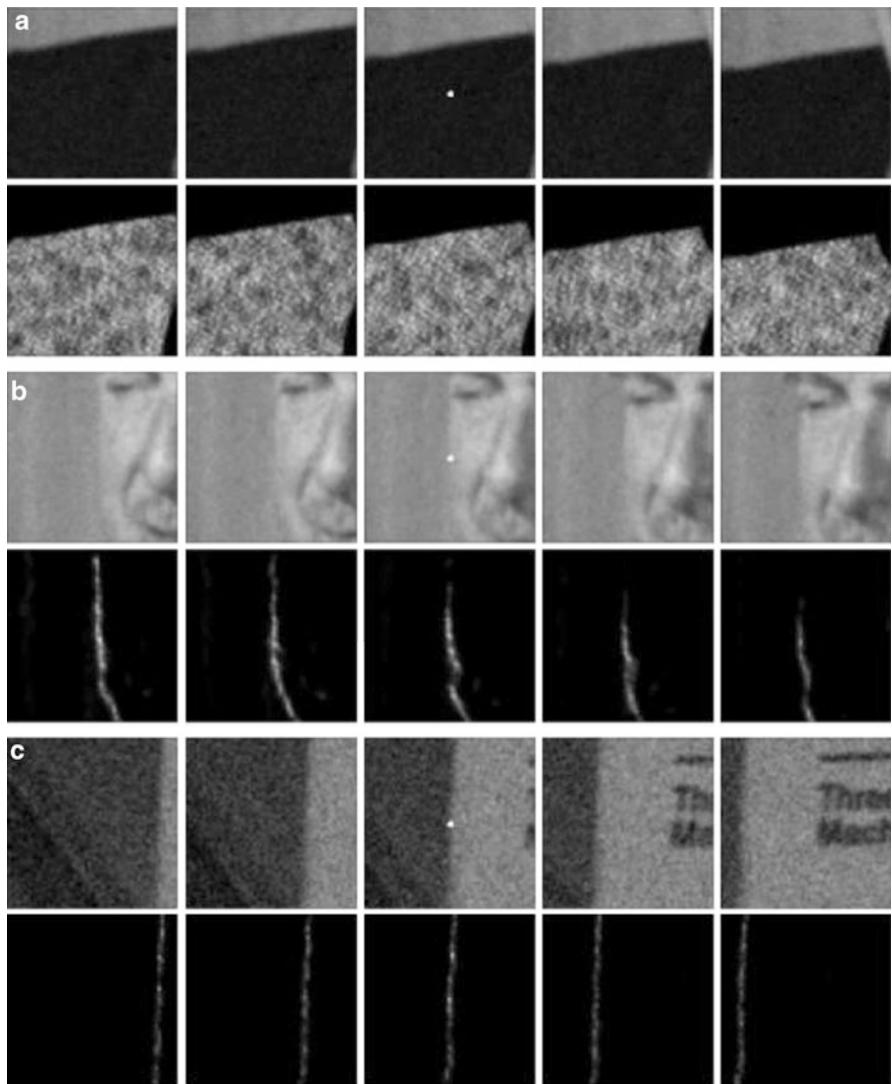

Fig. 12 Weight distribution of NL-means applied to a movie. In (a), (b), and (c), the first row shows a five frames image sequence. In the second row, the weight distribution used to estimate the central pixel (in white) of the middle frame is shown. The weights are equally distributed over the successive frames, including the current one. They actually involve all the candidates for the motion estimation instead of picking just one per frame. The aperture problem can be taken advantage of for a better denoising performance by involving more pixels in the average Fig. 7 displays the application of the denoising methods to a white noise. We display the filtered noise

Fig. 13 Comparison of static filters, motion compensated filters, and NL-means applied to an image sequence. *Top*: three frames of the sequence are displayed. *Middle* and *left to right*: neighborhood filter, motion compensated neighborhood filter, and the NL-means. (AWA). *Bottom*: the noise removed by each method (difference between the noisy and filtered frame). Motion compensation improves the static algorithms by better preserving the details and creating less blur. We can read the titles of the books in the noise removed by AWA. Therefore, that much information has been removed from the original. Finally, the NL-means algorithm (*bottom row*) has almost no noticeable structure in its removed noise. As a consequence, the filtered sequence has kept more details and is less blurred

$$\frac{u_0 * k_h(x) - u_0(x)}{h} \rightarrow c \Delta u_0(x).$$

Hence, when h gets smaller, the blur process looks more and more like the heat equation

$$u_t = c \Delta u, \quad u(0) = u_0.$$

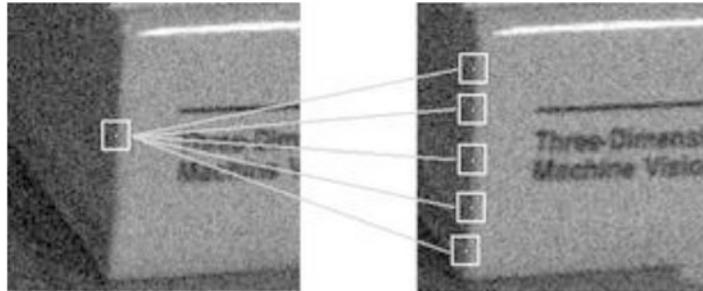

Fig. 14 Aperture problem and the ambiguity of trajectories are the most difficult problems in motion estimation: There can be many good matches. The motion estimation algorithms must pick one

Thus, Gabor established a first relationship between local smoothing operators and PDEs. The classical choice for k is the Gaussian kernel.

Remarking that the optical blur is equivalent to one step of the heat equation, Gabor deduced that we can, to some extent, deblur an image by reversing the time in the heat equation, $u_t = -\Delta u$. Numerically, this amounts to subtracting the filtered version from the original image:

$$u - G_h * u = -h^2 \Delta u + o(h^2).$$

This leads to considering the reverse heat equation as an image restoration, ill-posed though it is. The time-reversed heat equation was stabilized in the Osher-Rudin shock filter [54] who proposed

$$u_t = -\text{sign}(\mathcal{L}(u)) |Du|,$$

where the propagation term $|Du|$ is tuned by the sign of an edge detector $\Lambda(u)$. The function $\Lambda(u)$ changes sign across the edges where the sharpening effect therefore occurs. In practice, $\Lambda(u) = \Delta u$ and the equation is related to a reverse heat equation.

The early Perona-Malik “anisotropic diffusion” [57] is directly inspired from the Gabor remark. It reads

$$u_t = \text{div} \left(g(|Du|^2) Du \right),$$

where $g : [0, +\infty) \rightarrow [0, +\infty)$ is a smooth decreasing function satisfying $g(0) = 1$, $\lim_{s \rightarrow +\infty} g(s) = 0$. This model is actually related to the preceding ones. Let us consider the second derivatives of u in the directions of Du and Du^\perp :

$$u_{\eta\eta} = D^2 u \left(\frac{Du}{|Du|}, \frac{Du}{|Du|} \right), \quad u_{\xi\xi} = D^2 u \left(\frac{Du^\perp}{|Du|}, \frac{Du^\perp}{|Du|} \right).$$

Then, Eq. (5) can be rewritten as

$$u_t = g(|Du|^2) u_{\xi\xi} + h(|Du|^2) u_{\eta\eta},$$

where $h(s) = g(s) + 2sg'(s)$. Perona and Malik proposed the function $g(s) = \frac{1}{1+s/k}$. In this case, the coefficient of the first term is always positive and this term therefore appears as a one-dimensional diffusion term in the orthogonal direction to the gradient. The sign of the second coefficient, however, depends on the value of the gradient. When $|Du|^2 < k$, this second term appears as a one-dimensional diffusion in the gradient direction. It leads to a reverse heat equation term when $|Du|^2 > k$.

The Perona-Malik model has got many variants and extensions. Tannenbaum and Zucker [45] proposed, endowed in a more general shape analysis framework, the simplest equation of the list:

$$u_t = |Du| \operatorname{div} \left(\frac{Du}{|Du|} \right) = u_{\xi\xi}.$$

This equation had been proposed some time before in another context by Sethian [66] as a tool for front propagation algorithms. This equation is a “pure” diffusion in the direction orthogonal to the gradient and is equivalent to the anisotropic filter AF [40]:

$$\operatorname{AF}_h u(x) = \int G_h(t) u(x + t\xi) dt,$$

where $\xi = Du(\mathbf{x})^\perp / |Du(\mathbf{x})|$ and $G_h(t)$ denotes the one-dimensional Gauss function with variance h^2 .

This diffusion is also related to two models proposed in image restoration. The Rudin-Osher-Fatemi [64] total variation model leads to the minimization of the total variation of the image $TV(u) = \int |Du|$, subject to some constraints. The steepest descent of this energy reads, at least formally,

$$\frac{\partial u}{\partial t} = \operatorname{div} \left(\frac{Du}{|Du|} \right) \quad (4)$$

which is related to the mean curvature motion and to the Perona-Malik equation when $g(|Du|^2) = \frac{1}{|Du|}$. This particular case, which is not considered in [57], yields again (4). An existence and uniqueness theory is available for this equation [1].

Asymptotic Behavior of Neighborhood Filters (Dimension 1)

Let u denote a one-dimensional signal defined on an interval $I \subset \mathbb{R}$ and consider the neighborhood filter

$$\text{NF}_{h,\rho} u(x) = \frac{1}{C(x)} \int_{x-\rho}^{x+\rho} u(y) e^{-\frac{|u(y)-u(x)|^2}{h^2}} dy,$$

$$\text{where } C(x) = \int_{x-\rho}^{x+\rho} e^{-\frac{|u(y)-u(x)|^2}{h^2}} dy.$$

The following theorem describes the asymptotical behavior of the neighborhood filter in 1D. The proof of this theorem and next ones in this section can be found in [13].

Theorem 2. Suppose $u \in C^2(I)$, and let $\rho, h, \alpha > 0$ such that $\rho, h \rightarrow 0$ and $h = O(\rho^\alpha)$. Consider the continuous function $g(t) = \frac{te^{-t^2}}{E(t)}$, for $t \neq 0$, $g(0) = \frac{1}{2}$, where $E(t) = 2 \int_0^t e^{-s^2} ds$. Let f be the continuous function

$$f(t) = \frac{g(t)}{t^2} + g(t) - \frac{1}{2t^2}, \quad f(0) = \frac{1}{6}.$$

Then, for $x \in \mathbb{R}$,

1. If $\alpha < 1$, $\text{NF}_{h,\rho} u(x) - u(x) \simeq \frac{u''(x)}{6} \rho^2$.
2. If $\alpha = 1$, $\text{NF}_{h,\rho} u(x) - u(x) \simeq f\left(\frac{\rho}{h} |u'(x)|\right) u''(x) \rho^2$.
3. If $1 < \alpha < \frac{3}{2}$, $\text{NF}_{h,\rho} u(x) - u(x) \simeq g\left(\rho^{1-\alpha} |u'(x)|\right) u''(x) \rho^2$.

According to Theorem 2, the neighborhood filter makes the signal evolve proportionally to its second derivative. The equation $u_t = cu'$ acts as a smoothing or enhancing model depending on the sign of c . Following the previous theorem, we can distinguish three cases depending on the values of h and ρ . First, if h is much larger than ρ , the second derivative is weighted by a positive constant and the signal is therefore filtered by a heat equation. Second, if h and ρ have the same order, the sign and magnitude of the weight is given by $f\left(\frac{\rho}{h} |u'(x)|\right)$. As the function f takes positive and negative values (see Fig. 15), the filter behaves as a filtering/enhancing algorithm depending on the magnitude of $|u'(x)|$. If B denotes the zero of f , then a filtering model is applied wherever $|u'| < B \frac{h}{\rho}$ and an enhancing model wherever $|u'| > B \frac{h}{\rho}$. The intensity of the enhancement tends to zero when the derivative tends to infinity. Thus, points x where $|u'(x)|$ is large are not altered. The transition of the filtering to the enhancement model creates a singularity in the filtered signal. In the last case, ρ is much larger than h and the sign and magnitude of the weight is given by $g\left(\frac{\rho}{h} |u'(x)|\right)$. Function g is positive and decreases to zero. If the derivative of u is bounded, then $\frac{\rho}{h} |u'(x)|$ tends to infinity and the intensity of the filtering to zero. In this case, the signal is hardly modified.

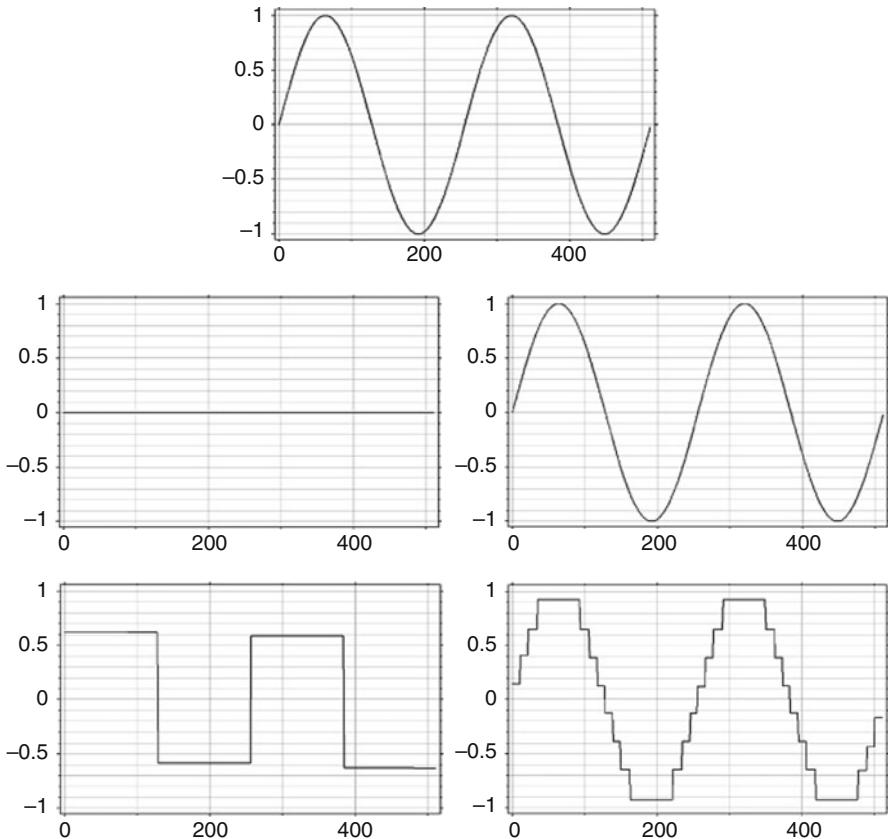

Fig. 15 One dimensional neighborhood filter experiment. The neighborhood filter is iterated until the steady state is attained for different values of the ratio ρ/h . *Top:* Original sine signal. *Middle left:* filtered signal with $\rho/h = 10^{-8}$. *Middle right:* filtered signal with $\rho/h = 10^8$. *Bottom left:* filtered signal with $\rho/h = 2$. *Bottom right:* filtered signal with $\rho/h = 5$. The examples corroborate the results of Theorem 2. If ρ/h tends to zero the algorithm behaves like a heat equation and the filtered signal tends to a constant. If, instead, ρ/h tends to infinity the signal is hardly modified. If ρ and h have the same order, the algorithm presents a filtering/enhancing dynamic. Singularities are created due to the transition of smoothing to enhancement. The number of enhanced regions strongly depends upon the ratio $\frac{\rho}{h}$ as illustrated in the *bottom figures*

In summary, a neighborhood filter in dimension 1 shows interesting behavior only if ρ and h have the same order of magnitude, in which case the neighborhood filter behaves like a Perona-Malik equation. It enhances edges with a gradient above a certain threshold and smoothes the rest.

Figure 16 illustrates the behavior of the one-dimensional neighborhood filter. The algorithm is iterated until the steady state is attained on a sine signal for different values of the ratio ρ/h . The results of the experiment corroborate the asymptotical expansion of Theorem 2. In the first experiment, $\rho/h = 10^{-8}$ and the neighborhood

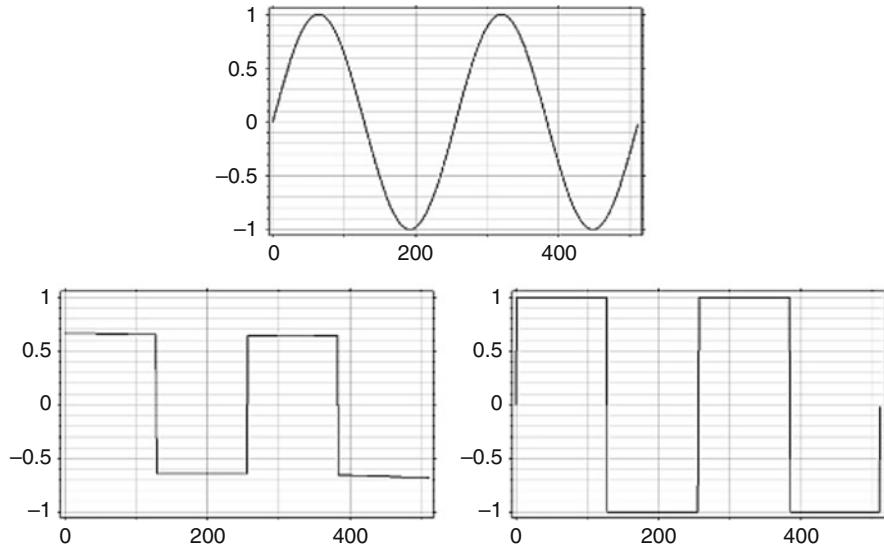

Fig. 16 One-dimensional neighborhood filter experiment. The examples corroborate the results of Theorem 2. If ρ/h tends to zero, the algorithm behaves like a heat equation and the filtered signal tends to a constant. If, instead, ρ/h tends to infinity, the signal is hardly modified. If ρ and h have the same order, the algorithm presents a filtering/enhancing dynamic. Singularities are created due to the transition of smoothing to enhancement. The number of enhanced regions strongly depends upon the ratio $\frac{\rho}{h}$, as illustrated in the bottom figures

filter is equivalent to a heat equation. The filtered signal tends to a constant. In the second experiment, $\rho/h = 10^8$ and the value $g\left(\frac{\rho}{h} |u'| \right)$ is nearly zero. As predicted by the theorem, the filtered signal is nearly identical to the original one. The last two experiments illustrate the filtering/enhancing behavior of the algorithm when h and ρ have similar values. As predicted, an enhancing model is applied where the derivative is large. Many singularities are being created because of the transition of the filtering to the enhancing model. Unfortunately, the number of singularities and their position depend upon the value of ρ/h . This behavior is explained by Theorem 2(2). Figure 22 illustrates the same effect in the 2D case.

The filtering/enhancing character of the neighborhood filter is very different from a pure enhancing algorithm like the Osher-Rudin shock filter. Figures 17 and 18 illustrate these differences. In Fig. 17, the minimum and the maximum of the signal have been preserved by the shock filter, while these two values have been significantly reduced by the neighborhood filter. This filtering/enhancing effect is optimal when the signal is noisy. Figure 18 shows how the shock filter creates artificial steps due to the fluctuations of noise, while the neighborhood filter reduces the noise avoiding any spurious shock. Parameter h has been chosen larger than

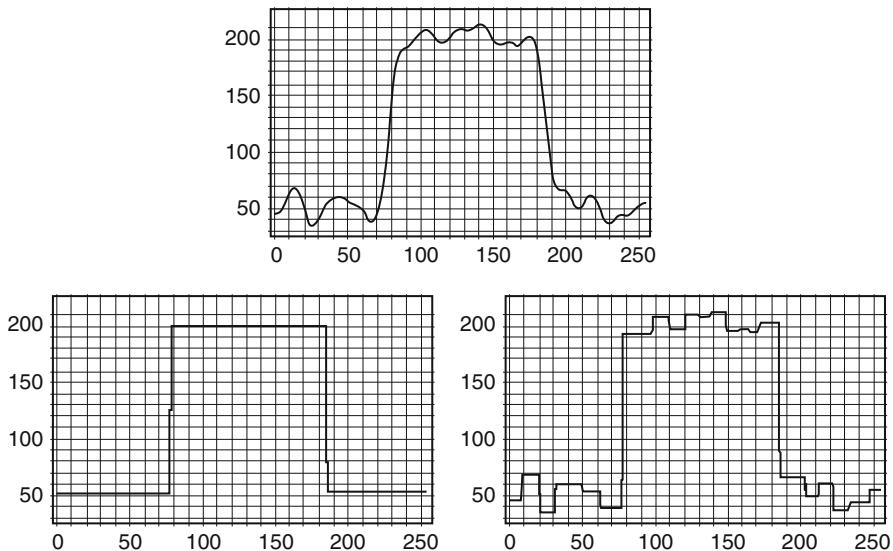

Fig. 17 Comparison between the neighborhood filter and the shock filter. *Top:* original signal. *Bottom left:* application of the neighborhood filter. *Bottom right:* application of the shock filter. The minimum and the maximum of the signal have been preserved by the shock filter and reduced by the neighborhood filter. This fact illustrates the filtering/enhancing character of the neighborhood filter compared with a pure enhancing filter

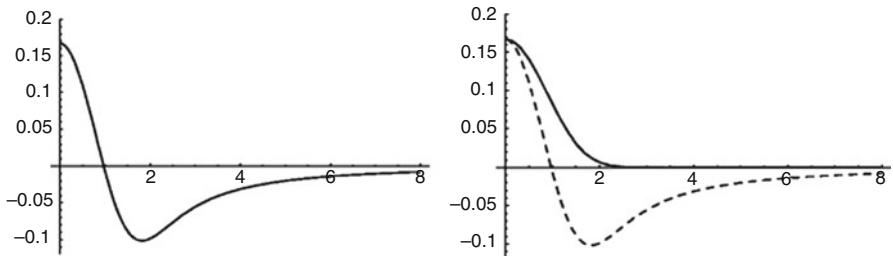

Fig. 18 Comparison between the neighborhood filter and the shock filter. *Top:* original signal. *Bottom left:* application of the neighborhood filter. *Bottom right:* application of the shock filter. The shock filter is sensitive to noise and creates spurious steps. The filtering/enhancing character of the neighborhood filter avoids this effect

the amplitude of noise in order to remove it. Choosing an intermediate value of h , artificial steps could also be generated on points where the noise amplitude is above this parameter value.

The Two-Dimensional Case

The following theorem extends the previous result to the two-dimensional case.

Theorem 3. Suppose $u \in C^2(\Omega)$, and let $\rho, h, \alpha > 0$ such that $\rho, h \rightarrow 0$ and $h = O(\rho^\alpha)$. Let us consider the continuous function \tilde{g} defined by $\tilde{g}(t) = \frac{1}{3} \frac{te^{-t^2}}{3E(t)}$, for $t \neq 0$, $\tilde{g}(0) = \frac{1}{6}$, where $E(t) = 2 \int_0^t e^{-s^2} ds$. Let \tilde{f} be the continuous function defined by

$$\tilde{f}(t) = 3\tilde{g}(t) + \frac{3\tilde{g}(t)}{t^2} - \frac{1}{2t^2}, \quad \tilde{f}(0) = \frac{1}{6}.$$

Then, for $\mathbf{x} \in \Omega$,

1. If $\alpha < 1$,

$$\text{NF}_{h,\rho} u(x) - u(x) \simeq \frac{\Delta u(x)}{6} \rho^2.$$

2. If $\alpha = 1$,

$$\text{NF}_{h,\rho} u(x) - u(x) \simeq \left[\tilde{g} \left(\frac{\rho}{h} |Du(x)| \right) u_{\xi\xi}(x) + \tilde{f} \left(\frac{\rho}{h} |Du(x)| \right) u_{\eta\eta}(x) \right] \rho^2.$$

3. If $1 < \alpha < \frac{3}{2}$,

$$\text{NF}_{h,\rho} u(x) - u(x) \simeq \tilde{g} \left(\rho^{1-\alpha} |Du(x)| \right) [u_{\xi\xi}(x) + 3u_{\eta\eta}(x)] \rho^2.$$

where $\xi = Du(\mathbf{x})^\perp / |Du(\mathbf{x})|$ and $\eta = Du(\mathbf{x}) / |Du(\mathbf{x})|$.

According to Theorem 3, the two-dimensional neighborhood filter acts as an evolution PDE with two terms. The first term is proportional to the second derivative of u in the direction $\xi = Du(\mathbf{x})^\perp / |Du(\mathbf{x})|$, which is tangent to the level line passing through \mathbf{x} . The second term is proportional to the second derivative of u in the direction $\eta = Du(\mathbf{x}) / |Du(\mathbf{x})|$, which is orthogonal to the level line passing through \mathbf{x} . Like in the one-dimensional case, the evolution equations $u_t = c_1 u_{\xi\xi}$ and $u_t = c_2 u_{\eta\eta}$ act as filtering or enhancing models depending on the signs of c_1 and c_2 . Following the previous theorem, we can distinguish three cases, depending on the values of h and ρ .

First, if h is much larger than ρ , both second derivatives are weighted by the same positive constant. Thus, the sum of both terms is equivalent to the Laplacian of u , Δu , and we get back to Gaussian filtering.

Second, if h and ρ have the same order of magnitude, the neighborhood filter behaves as a filtering/enhancing algorithm. The coefficient of the diffusion in the tangential direction, $u_{\xi\xi}$, is given by $\tilde{g} \left(\frac{\rho}{h} |Du| \right)$. The function \tilde{g} is positive and

decreasing. Thus, there is always diffusion in that direction. The weight of the normal diffusion, $u_{\eta\eta}$, is given by $\tilde{f}(\frac{\rho}{h}|Du|)$. As the function \tilde{f} takes positive and negative values (see Fig. 15), the filter behaves as a filtering/enhancing algorithm in the normal direction and depending on $|Du|$. If \tilde{B} denotes the zero of \tilde{f} , then a filtering model is applied wherever $|Du| < \tilde{B}\frac{h}{\rho}$ and an enhancing strategy wherever $|Du| > \tilde{B}\frac{h}{\rho}$. The intensity of the filtering in the tangent diffusion and the enhancing in the normal diffusion tend to zero when the gradient tends to infinity. Thus, points with a very large gradient are not altered.

Finally, if ρ is much larger than h , the value $\frac{\rho}{h}$ tends to infinity and then the filtering magnitude $\tilde{g}(\frac{\rho}{h}|Du|)$ tends to zero. Thus, the original image is hardly altered. Let us mention that similar calculations were performed in a particular case for the neighborhood median filter by Masnou [52].

We observe that when ρ and h have the same order, the neighborhood filter asymptotically behaves like a Perona-Malik model. Let us be more specific about this comparison. Taking $g(s) = \tilde{g}(s^{\frac{1}{2}})$ in the Perona-Malik Eq. (6), we obtain

$$u_t = \tilde{g}(|Du|) u_{\xi\xi} + \tilde{h}(|Du|) u_{\eta\eta}, \quad (5)$$

where $\tilde{h}(s) = \tilde{g}(s) + s\tilde{g}'(s)$. Thus, the Perona-Malik model and the neighborhood filter can be decomposed in the same way and with exactly the same weight in the tangent direction. Then the function \tilde{h} has the same behavior as \tilde{f} (Theorem 3), as can be observed in Fig. 19. Thus, in this case, a neighborhood filter has the same qualitative behavior as a Perona-Malik model, even if we cannot rewrite it exactly as such.

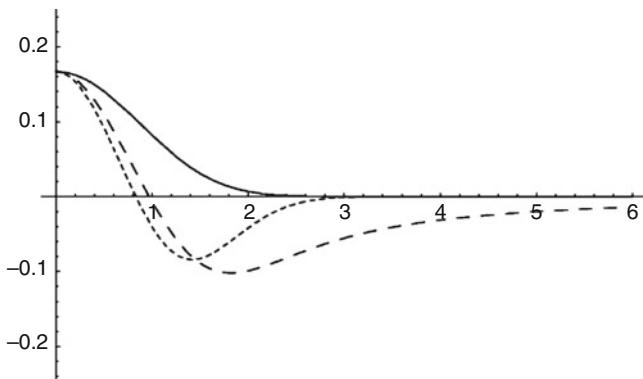

Fig. 19 Weight comparison of the neighborhood filter and the Perona-Malik equation. Magnitude of the tangent diffusion (continuous line, identical for both models) and normal diffusion (dashed line- -) of Theorem 3. Magnitude of the tangent diffusion (continuous line) and normal diffusion (dashed line- -) of the Perona-Malik model (5). Both models show nearly the same behavior

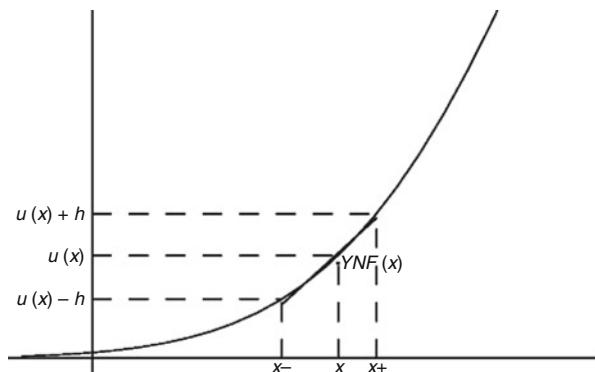

Figure 22 displays a comparison of the neighborhood filter and the Perona-Malik model. We display a natural image and the filtered images by both models. These solutions have a similar visual quality and tend to display flat zones and artificial contours inside the smooth regions. Figure 23 corroborates this visual impression. We display the level lines of both filtered solutions. As expected from the above consistency theorems, for both models the level lines of the original image tend to concentrate, thus creating large flat zones separated by edges. The solutions are very close, up to the obvious very different implementations. The neighborhood filter is implemented exactly as in its definition and the Perona-Malik model by the explicit difference scheme proposed in the original paper.

A Regression Correction of the Neighborhood Filter

In the previous sections, we have shown the enhancing character of the neighborhood filter. We have seen that the neighborhood filter, like the Perona-Malik model, can create large flat zones and spurious contours inside smooth regions. This effect depends upon a gradient threshold which is hard to fix in such a way as to always separate the visually smooth regions from edge regions. In order to avoid this undesirable effect, let us analyze in more detail what happens with the neighborhood filter in the one-dimensional case.

Figure 20 shows a simple illustration of this effect. For each x in the convex part of the signal, the filtered value is the average of the points y such that $u(x) - h < u(y) < u(x) + h$ for a certain threshold h . As it is illustrated in the figure, the number of points satisfying $u(x) - h < u(y) \leq u(x)$ is larger than the number of points satisfying $u(x) \leq u(y) < u(x) + h$. Thus, the average value $YNF(x)$ is smaller than $u(x)$, enhancing this part of the signal. A similar argument can be applied in the concave parts of the signal, dealing with the same enhancing effect. Therefore, shocks will be created inside smooth zones where concave and convex parts meet. Figure 20 also shows how the mean is not a good estimate of $u(x)$ in this case. In the same figure, we display the regression line approximating u

Fig. 20 Illustration of the shock effect of the YNF on the convex of a signal. The number of points y satisfying $u(x) - h < u(y) \leq u(x)$ is larger than the number satisfying $u(x) \leq u(y) < u(x) + h$. Thus, the average value $YNF(x)$ is smaller than $u(x)$, enhancing that part of the signal. The regression line of u inside (x_-, x_+) better approximates the signal at x

inside $(u^{-1}(u(x) - h), u^{-1}(u(x) + h))$. We see how the value of the regression line at x better approximates the signal. In the sequel, we propose to correct the neighborhood filter with this better estimate.

In the general case, this linear regression strategy amounts to finding for every point \mathbf{x} the plane locally approximating u in the following sense:

$$\min_{a_0, a_1} \int_{B_\rho(x)} w(x, y)(u(y) - a_1 y_1 - a_0)^2 dy, \quad w(x, y) = e^{-\frac{|u(y)-|}{h^2}}$$

and then replacing $u(\mathbf{x})$ by the filtered value $a_1 x_1 + a_0$. The weights used to define the minimization problem are the same as the ones used by the neighborhood filter. Thus, the points with a gray level value close to $u(x)$ will have a larger influence in the minimization process than those with a further gray level value. We denote the above linear regression correction by $\text{LNF}_{h,\rho}$. Taking $a_1 = 0$ and then approximating u by a constant function, the minimization (5) goes back to the neighborhood filter.

This minimization was originally proposed by Cleveland [18] with a weight family not depending on the function u but only on the spatial distance of \mathbf{x} and \mathbf{y} . A similar scheme incorporating u in the weight computation has been statistically studied in [61]. The authors propose an iterative procedure that describes for every point the largest possible neighborhood in which the initial data can be well approximated by a parametric function.

Another similar strategy is the interpolation by ENO schemes [41]. The goal of ENO interpolation is to obtain a better adapted prediction near the singularities of the data. For each point it selects different stencils of fixed size M and for each stencil reconstructs the associated interpolation polynomial of degree M . Then the *least oscillatory* polynomial is selected by some prescribed numerical criterion. The selected stencils tend to escape from large gradients and discontinuities.

The regression strategy also tends to select the right points in order to approximate the function. Instead of choosing a certain interval, all the points are used in the polynomial reconstruction, but weighted by the gray level differences.

As in the previous sections, let us analyze the asymptotic behavior of the linear regression correction. We compute the asymptotic expansion of the filter when $0 < \alpha \leq 1$. We showed that when $\alpha > 1$, the signal is hardly modified.

For the sake of completeness, we first compute the asymptotic expansion in the one-dimensional case.

Theorem 4. *Suppose $u \in C^2(I)$, and let $\rho, h, \alpha > 0$ such that $\rho, h \rightarrow 0$ and $h = O(\rho^\alpha)$. Let \tilde{f} be the continuous function defined as $\tilde{f}(0) = \frac{1}{6}$,*

$$\tilde{f}(t) = \frac{1}{4t^2} \left(1 - \frac{2te^{-t^2}}{E(t)} \right),$$

for $t \neq 0$, where $E(t) = 2 \int_0^t e^{-s^2} ds$. Then, for $x \in \mathbb{R}$,

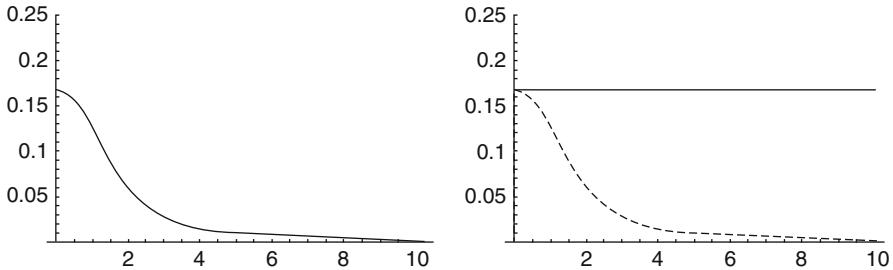

Fig. 21 Weighting functions of Theorems 4 and 5. *Left:* function \tilde{f} of Theorem 4. *Right:* constant $1/6$ (*continuous line*) and function \tilde{f} (*dashed line*) of Theorem 5

1. If $\alpha < 1$, $\text{LNF}_{h,\rho}u(x) - u(x) \simeq \frac{u''(x)}{6}\rho^2$.
2. If $\alpha = 1$, $\text{NF}_{h,\rho}u(x) - u(x) \simeq \tilde{f}\left(\frac{\rho}{h}|u'(x)|\right)u''(x)\rho^2$.

Theorem 4 shows that the $\text{LNF}_{h,\rho}$ filter lets the signal evolve proportionally to its second derivative, as the neighborhood filter does. When h is larger than ρ , the filter is equivalent to the original neighborhood filter and the signal is filtered by a heat equation. When ρ and h have the same order, the sign and magnitude of the filtering process is given by $\tilde{f}\left(\frac{\rho}{h}|u'(x)|\right)$ (see Fig. 21). This function is positive and quickly decreases to zero. Thus, the signal is filtered by a heat equation of decreasing magnitude and is not altered wherever the derivative is very large.

The same asymptotic expansion can be computed in the two-dimensional case.

Theorem 5. Suppose $u \in C^2(\Omega)$, and let $\rho, h, \alpha > 0$ such that $\rho, h \rightarrow 0$ and $h = O(\rho^\alpha)$. Let \tilde{f} be the continuous function defined as $\tilde{f}(0) = \frac{1}{6}$,

$$\tilde{f}(t) = \frac{1}{4t^2} \left(1 - \frac{2te^{-t^2}}{E(t)} \right),$$

for $t \neq 0$, where $E(t) = 2 \int_0^t e^{-s^2} ds$. Then, for $\mathbf{x} \in \Omega$,

1. If $\alpha < 1$,

$$\text{LNF}_{h,\rho}u(x) - u(x) \simeq \frac{\Delta u(x)}{6}\rho^2.$$

2. If $\alpha = 1$,

$$\text{LNF}_{h,\rho}u(x) - u(x) \simeq \left[\tilde{f}\left(\frac{\rho}{h}|Du(x)|\right)u_{\eta\eta}(x)(x) + \frac{1}{6}u_{\xi\xi}(x) \right]\rho^2.$$

According to the previous theorem, the filter can be written as the sum of two diffusion terms in the direction of ξ and η . When h is much larger than ρ , the linear regression correction is equivalent to the heat equation like the original neighborhood filter. When ρ and h have the same order, the behavior of the linear regression algorithm is very different from the original neighborhood filter. The function weighting the tangent diffusion is a positive constant. The function weighting the normal diffusion is positive and decreasing (see Fig. 21), and therefore there is no enhancing effect. The algorithm combines the tangent and normal diffusion wherever the gradient is small. Wherever the gradient is larger, the normal diffusion is canceled and the image is filtered only in its tangent direction. This subjacent PDE was already proposed as a diffusion equation in [4]. This diffusion makes the level lines evolve proportionally to their curvature. In the Perona-Malik model, the diffusion is stopped near the edges. In this case, the edges are filtered by a mean curvature motion.

It may be asked whether the modified neighborhood filter still preserves signal discontinuities. The answer is yes. It is easily checked that for small enough h , all piecewise affine functions with smooth jump curves are steady. Thus, the behavior is the same as for the classical neighborhood filter. Our asymptotic analysis is of course not valid for such functions, but only for smooth functions.

As a numerical scheme, the linear regression neighborhood filter allows the implementation of a mean curvature motion without the computation of gradients and orientations. When the gradient is small, the linear regression filter naturally behaves like the heat equation. This effect is introduced on typical schemes implementing the mean curvature motion. In flat zones, the gradient is not well defined and some kind of isotropic diffusion must be applied. Therefore, the linear regression neighborhood filter naturally extends the mean curvature motion and yields a stable numerical scheme for its computation, independent of gradient orientations.

Figure 22 displays an experiment comparing the $\text{LNF}_{h,\rho}$ with the neighborhood filter and the Perona-Malik equation. The linear correction does not create any contour or flat zone inside the smooth regions. Figure 23 displays the level lines of the previous experiment. The level lines of the $\text{LNF}_{h,\rho}$ are filtered by a mean curvature motion, and they do not get grouped creating flat zones. The same effect is illustrated in Fig. 24.

The Vector-Valued Case

Let u be a vector-valued function defined on a bounded domain $\Omega \subset \mathbb{R}^2$, $u : \Omega \rightarrow \mathbb{R}^n$. The vector neighborhood filter can be written as

$$\text{NF}_{h,\rho} u(x) = \frac{1}{C(x)} \int_{B_\rho(x)} u(y) e^{-\frac{\|u(y)-u(x)\|^2}{h^2}} dy,$$

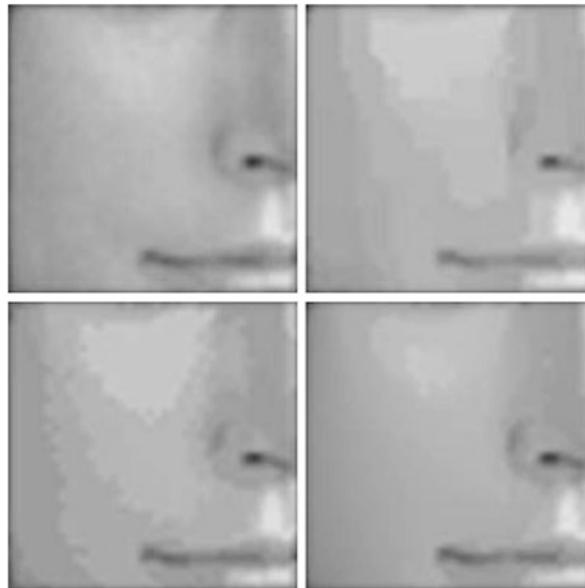

Fig. 22 Comparison experiment. *Top left:* original image. *Top right:* Perona-Malik filtered image. *Bottom left:* filtered image by the neighborhood filter. *Bottom right:* filtered image by the linear regression neighborhood filter. The neighborhood filter experiments are performed by iterating the discrete version of definitions (1) and (5). Both the neighborhood filter and its linear regression correction have been applied with the same value of h and ρ . The displayed images have been attained within the same number of iterations. The Perona-Malik equation is implemented by the explicit difference scheme proposed in the original paper. The Perona-Malik model and the neighborhood filter create artificial contours and flat zones. This effect is almost completely avoided by the linear regression neighborhood filter

where $\|u(\mathbf{y}) - u(\mathbf{x})\|^2$ is now the Euclidean vector norm and each component function u_i is filtered with the same weight distribution. The linear regression correction is defined as in the scalar case, and each component is locally approximated by a plane with the same weight distribution.

In order to compute the asymptotic expansion of the linear regression filter, we must fix a coordinate system for \mathbb{R}^2 . In the scalar case, we used the reference system given by the gradient of the image at \mathbf{x} and its orthogonal direction. In addition, this reference allows us to relate the obtained diffusion to the evolution of the level lines of the image and the mean curvature motion. Now, we cannot use the same reference and we need to define a new one. By analogy with the scalar case, we choose the directions of minimum and maximum variation of the vector function.

Definition 1. We define the normal direction η and the tangent direction ξ as the vectors that respectively maximize and minimize the following variation:

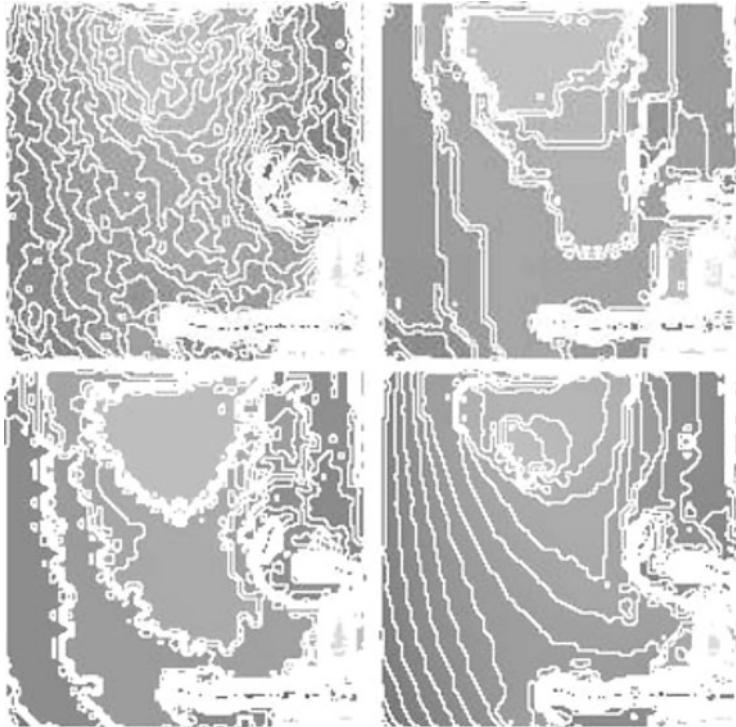

Fig. 23 Level lines of the images in Fig. 22. By the Perona-Malik filter and the neighborhood filter, the level lines tend to group, creating flat zones. The regression correction filters the level lines by a curvature motion without creating any flat zone

$$\sum_{i=1}^n \left\| \frac{\partial u_i}{\partial v}(x) \right\|^2$$

under the constraint $\|v\| = 1$.

It is easily seen that this constrained optimization leads to the computation of the eigenvectors of the matrix

$$A = \begin{pmatrix} \left\| \frac{\partial u}{\partial x} \right\|^2 & \left\langle \frac{\partial u}{\partial x}, \frac{\partial u}{\partial y} \right\rangle \\ \left\langle \frac{\partial u}{\partial x}, \frac{\partial u}{\partial y} \right\rangle & \left\| \frac{\partial u}{\partial y} \right\|^2 \end{pmatrix},$$

where $\frac{\partial u}{\partial x} = \left(\frac{\partial u_1}{\partial x}, \dots, \frac{\partial u_n}{\partial x} \right)$ and $\frac{\partial u}{\partial y} = \left(\frac{\partial u_1}{\partial y}, \dots, \frac{\partial u_n}{\partial y} \right)$. The two positive eigenvalues of A , λ_+ and λ_- , are the maximum and the minimum of the vector norm associated to A and the maximum and the minimum variations, as defined in Definition 1. The corresponding eigenvectors are orthogonal leading to the above-defined normal and tangent directions. This orthonormal system was first proposed for vector-valued

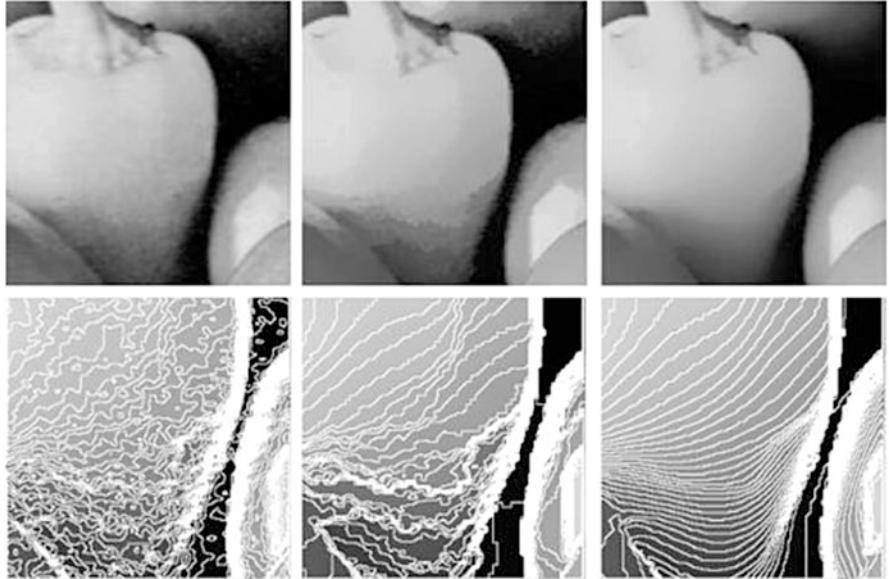

Fig. 24 Comparison of the neighborhood filter and the linear regression correction. *Top left:* original image. *Top middle:* filtered image by the neighborhood filter. *Top right:* filtered image by the regression neighborhood filter. *Bottom:* level lines of a part of the images on the above line. Both neighborhood filters have been performed with the same filtering parameters and the same number of iterations. The linear regression neighborhood algorithm has filtered the image while preserving the main boundaries as the original neighborhood filter. No enhancing has been applied by the linear correction avoiding the shock effect. The level lines of the neighborhood filter tend to group and create large flat zones. In addition, these level lines oscillate, while those of the linear regression algorithm have been correctly filtered

image analysis in [25]. Many PDE equations have been proposed for color image filtering using this system. We note the coherence-enhancing diffusion [72], the Beltrami flow [46], and an extension of the mean curvature motion [65].

Theorem 6. Suppose $u \in C^2(\Omega, \mathbb{R}^n)$, and let $\rho, h, \alpha > 0$ such that $\rho, h \rightarrow 0$ and $h = O(\rho^\alpha)$. Let \tilde{f} be the continuous function defined as $\tilde{f}(0) = \frac{1}{6}$,

$$\tilde{f}(t) = \frac{1}{4t^2} \left(1 - \frac{2te^{-t^2}}{E(t)} \right),$$

for $t \neq 0$, where $E(t) = 2 \int_0^t e^{-s^2} ds$. Then, for $\mathbf{x} \in \Omega$,

1. If $\alpha < 1$,

$$\text{LNF}_{h,\rho} u(x) - u(x) \simeq \frac{\Delta u(x)}{6} \rho^2.$$

2. If $\alpha = 1$,

$$\text{LNF}_{h,\rho} u(x) - u(x) \simeq \left[\tilde{f} \left(\frac{\rho}{h} \left\| \frac{\partial u}{\partial \xi}(x) \right\| \right) D^2 u(\xi, \xi)(x) + \tilde{f} \left(\frac{\rho}{h} \left\| \frac{\partial u}{\partial \eta}(x) \right\| \right) D^2 u(\eta, \eta) \right]$$

where $\Delta u(\mathbf{x}) = (\Delta u_i(\mathbf{x}))_{1 \leq i \leq n}$ and $D^2 u(v, v)(\mathbf{x}) = D^2 u_i(v, v)(\mathbf{x})_{1 \leq i \leq n}$ for $v \in \{\eta, \xi\}$.

Interpretation

When h is much larger than ρ , the linear regression neighborhood filter is equivalent to the heat equation applied independently to each component. When h and ρ have the same order, the subjacent PDE acts as an evolution equation with two terms. The first term is proportional to the second derivative of u in the tangent direction ξ . The second term is proportional to the second derivative of u in the normal direction η . The magnitude of each diffusion term depends on the variation in the respective direction, $\lambda_- = \left\| \frac{\partial u}{\partial \xi}(x) \right\|$ and $\lambda_+ = \left\| \frac{\partial u}{\partial \eta}(x) \right\|$. The weighting function \tilde{f} is positive and decreases to zero (see Fig. 21). We can distinguish the following cases depending on the values of λ_+ and λ_- .

- If $\lambda_+ \simeq \lambda_- \simeq 0$, then there are very few variations of the vector image u around \mathbf{x} . In this case, the linear regression neighborhood filter behaves like a heat equation with maximum diffusion coefficient $\tilde{f}(0)$.
- If $\lambda_+ \gg \lambda_-$, then there are strong variations of u around \mathbf{x} and the point may be located on an edge. In this case, the magnitude $\tilde{f} \left(\frac{\rho}{h} \lambda_+ \right)$ tends to zero and there is no diffusion in the direction of maximal variation. If $\lambda_- \gg 0$, then \mathbf{x} may be placed on an edge with different orientations depending on each component and the magnitude of the filtering in both directions tends to zero, so that the image is hardly altered. If $\lambda_- \simeq 0$, then the edges have similar orientations in all the components and the image is filtered by a directional Laplacian in the direction of minimal variation.
- If $\lambda_+ \simeq \lambda_- \gg 0$, then we may be located on a saddle point, and in this case the image is hardly modified. When dealing with multivalued images, one can think of the complementarity of the different channels leading to the perception of a corner.

In the scalar case, the theorem gives back the result studied in the previous sections. The normal and tangent directions are, respectively, the gradient direction and the level line direction. In this case, $\frac{\partial u}{\partial \xi}(x) = 0$ and $\frac{\partial u}{\partial \eta}(x) = |Du(x)|$, and we get back to

$$\text{LNF}_{h,\rho} u(x) - u(x) \simeq \left[\frac{1}{6} D^2 u(\xi, \xi)(x) + \tilde{f} \left(\frac{\rho}{h} |Du(x)| \right) D^2 u(\eta, \eta)(x) \right] \rho^2$$

4 Variational and Linear Diffusion

The relationship of neighborhood filters with classic local PDEs has been discussed in the previous section. Yet, the main interest has shifted to defining *nonlocal PDEs*. The extension of the neighborhood filter and the NL-means method to define nonlocal image-adapted differential operators and nonlocal variational methods starts with [47], which proposes to perform denoising and deblurring by nonlocal functionals.

The general goal of this development is actually to give a variational to all neighborhood filters and to give a nonlocal form to the total variation as well. More precisely, the neighborhood filters derive from the functional

$$J(u) = \int_{\Omega \times \Omega} g \left(\frac{|u(x) - u(y)|^2}{h^2} \right) w(|x - y|) dx dy,$$

where g and w have a Gaussian decay. In the same line, a functional yields a (variational) interpretation to NL-means:

$$\text{JNL}(u) = \int_{\Omega \times \Omega} \left(1 - e^{-\frac{G_\sigma * |u(x-) - u(y-)|^2(0)}{h^2}} \right) w(|x - y|) dx dy.$$

In a similar variational framework, Gilboa et al. [36] consider the general kind of quadratic nonlocal functional

$$J(u) := \int_{\Omega \times \Omega} (u(x) - u(y))^2 w(x - y) dx dy, \quad (6)$$

where $w(\mathbf{x}, \mathbf{y})$ is any fixed weight distribution, which in most applications writes as the neighborhood or NL-means weight distribution. The resolution of the graph heat equation or the variational minimization (6) is given by

$$u_{n+1}(x) = \frac{1}{C(x)} \int_{\Omega} u_n(y) w(x, y) dy,$$

where $C(\mathbf{x}) = \int_{\Omega} w(\mathbf{x}, \mathbf{y}) d\mathbf{y}$ is a normalizing factor. The freedom of having a totally decoupled weight distribution makes this formulation a linear and powerful tool for image processing. In fact, this formulation rewrites as the Dirichlet integral of the following nonlocal gradient: $\nabla_w u(x, y) = (u(\mathbf{x}) - u(\mathbf{y}))w(x, y)$. The whole process relates to a graph Laplacian where each pixel is considered as the node of a weighted graph, and the weights of the edge between two pixels x and y , respectively, are decreasing functions of the distances of patches around x and y , $w(x, y)$. Then a graph Laplacian can be calculated on this graph, seen as the sampling of a manifold, and the linear diffusion can be interpreted as the heat equation on the set of blocks endowed with these weights. The eigenvalues and

eigenvectors of such a Laplacian can be computed and used for designing spectral algorithms as Wiener and thresholding methods (see [69] and [59]).

The nonlocal term (6) has shown to be very useful as a regularization term for many image-processing tasks. The nonlocal differential operators permit to define a total variation or a Dirichlet integral. Several articles on deblurring have followed this variational line: [36, 44, 53] for image segmentation; [8] for fluorescence microscopy; [81], again, for nonlocal deconvolution; and [50] for deconvolution and tomographic reconstruction. In [33], a paper dedicated to another notoriously ill-posed problem, the super-resolution, the nonlocal variational principle, is viewed as “an emerging powerful family of regularization techniques,” and the paper “proposes to use the example-based approach as a new regularising principle in ill-posed image-processing problems such as image super-resolution from several low resolution photographs.” For all these methods, the weight distribution is computed in the first iteration and is maintained during the whole iteration process.

In this section, we will concentrate on the last nonlocal functional as a linear diffusion process and therefore the associated graph to the image as a heat equation; that is, no fidelity term will be added to the functional.

Linear Diffusion: Seed Growing

In [37,39], a novel method was proposed for performing multi-label, semiautomated medical image segmentation. The Grady segmentation method is a linearized sigma filter applied to propagate seed regions.

Given a small number of pixels with user-defined labels which are called seeds, this method computes the probability that a random walker starting at each unlabeled pixel will first reach one of the pre-labeled pixels. By assigning each pixel to the label for which the greatest probability is calculated, a high-quality image segmentation can be obtained.

With each unlabeled pixel, a K-tuple vector is assigned that represents the probability that a random walker starting from this unlabeled pixel first reaches each of the K seed points. A final segmentation may be derived from these K-tuples by selecting for each pixel the most probable seed destination for a random walker. By biasing the random walker to avoid crossing sharp intensity gradients, a quality segmentation is obtained that respects object boundaries (including weak boundaries). The image (or volume) is treated as a graph with a fixed number of vertices and edges. Each edge is assigned real-valued weight corresponding to the likelihood that a random walker will cross that edge (e.g., a weight of zero means that the walker may not move along that edge). By a classical result the probability that a random walker first reaches a seed point exactly equals the solution to the heat equation [9] with boundary Dirichlet conditions at the locations of the seed points, the seed point in question being fixed to unity, while the other seeds are set to zero.

This idea was not quite new. Region competition segmentation is an old concept [82]. One can also refer to an algorithm developed for machine learning by Zhu et al. [83], which also finds clusters based upon harmonic functions, using boundary

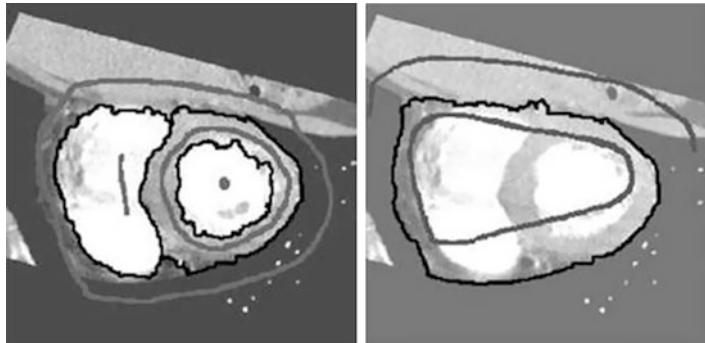

Fig. 25 (Taken from [38].) The Grady segmentation method is a linearized sigma filter applied to propagate seed regions. The *gray curves* are user-defined seed regions. A diffusion with sigma filter weights computed on the original image u_0 is applied until a steady state is attained. A threshold gives the black curves separating the regions of initial seeds

conditions set by a few seed points. Ref. [67] also involves weights in the image considered as a graph and takes seed points. The method is also directly related to the recent image-coloring method of Sapiro et al. by diffusion from seeds [78] (see also [65]).

Thus, the Grady segmentation method is a linearized sigma filter applied to propagate seed regions. Figure 25 taken from [38] illustrates the process on a two-chamber view of a cardiac image. The gray curves are user-defined seed regions roughly denoting the ventricles in the image. In that case, one of the seed regions is put to 1 and the other to 0. A diffusion with sigma filter weights computed on the original image u_0 is applied until a steady state is attained. This gives at each pixel y a value $p_1(y)$ between 0 and 1, which is interpreted as the probability for y to belong to the region of the first seed. In this binary case, a single threshold at 0.5 gives the black curves separating the regions of both seeds. Like the active contour method, this method is highly dependent on the initial seeds. It is, however, much less sensitive to noise than the snakes method [16] and permits to initialize fairly far from the desired contours. We will see that by the histogram concentration phenomenon, one can get similar or better results without any initialization.

The very same process as illustrated allows to diffuse initial chromatic information on an initial gray image as we exposed in the introduction. Figure 26 illustrates this application and compares the obtained solution by using the NL-means and the neighborhood filter.

Linear Diffusion: Histogram Concentration

The segmentation process can be accomplished by iterating the neighborhood filter and computing the weight distribution in the initial image, as displayed in Fig. 27. The top image shows one slice of a 3D CT image with interest area surrounded

Fig. 26 *Left* and from *top* to *bottom*: initial chromatic data on the gray image, linear diffused seeds by using neighborhood filter weights on the gray image, and the same for the NL-means weights. *Right*: details of left-hand images. The neighborhood filter weights are not robust since just a single point from different objects can be easily confused and iteration may lead to an incorrect colorization

by a parallelepiped. The next row shows several slices of this area of interest. It can be appreciated, first, that the background of arteries has a lot of oscillating clutter and, second, that the gray level value in arteries varies a lot, thus making an automatic threshold problematic. The best way actually to convince oneself that even in this small area a direct threshold would not do the job is to refer to the histograms of Fig. 29. The first histogram that is Gaussian-like and poorly concentrated corresponds to the background. The background mode decreases slowly. On the far right part of the histogram, one can see a small pick corresponding to very white arteries. The fixing of an accurate threshold in the slowly decreasing background mode is problematic. The top right histogram shows what happens after the application of a median iterative filtering (the mean curvature motion). The histogram does not concentrate at all. The bottom left histogram is obtained after

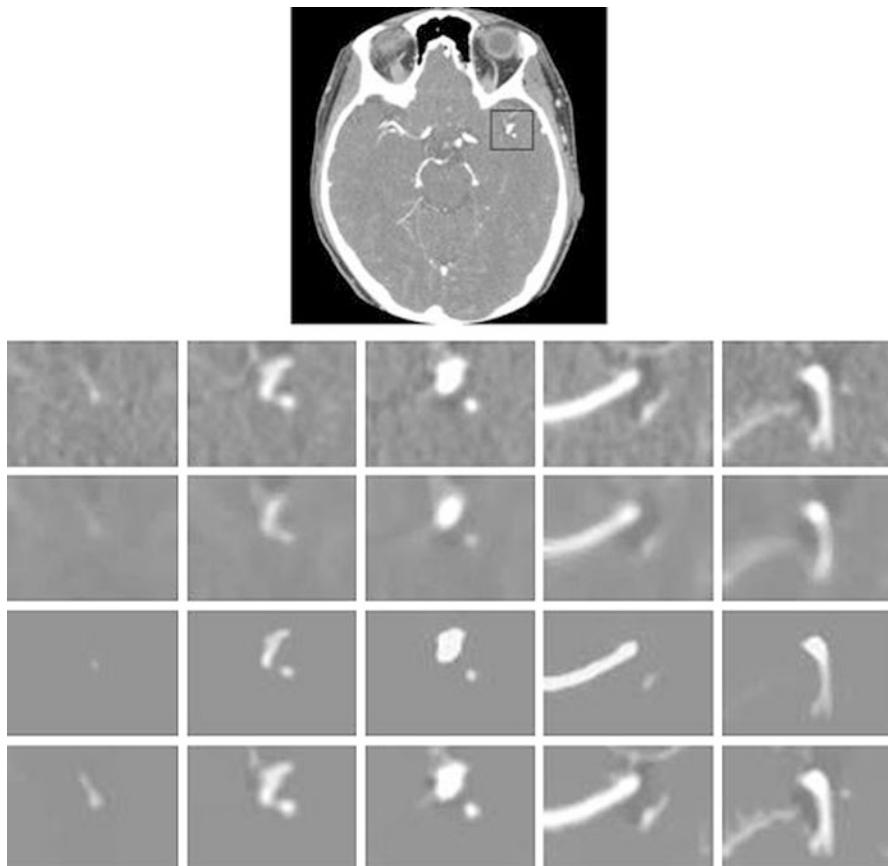

Fig. 27 Comparative behavior of discussed methods in 3D. Application to a 3D angiography CT image of the head where blood vessels should be segmented. *Top*: one slice image of the CT volume data with marked interested area. *Middle*: display of interest area for several slices of the 3D image. *Second row*: filtered slices by using median filter. *Third row*: sigma filter. *Fourth row*: 3D nonlocal heat equation. *Bottom*: filtered slices by using the linear method with 3D NL-means weights. The whole sequence has been treated as a 3D image with a weight support of $(5 \times 5 \times 3)$ and a comparison window of $3 \times 3 \times 3$. The background is flattened and blood vessels are enhanced. Thus, a better segmentation is possible by a simple threshold, as justified by Fig. 29

applying the linearized neighborhood filter. The bottom right histogram is the one obtained by the linearized NL-means described in the same section. In both cases, one observes that the background mode of the histogram is strongly concentrated on a few gray level values. An automatic threshold is easily fixed by taking the first local minimum after the main histogram peak. This histogram concentration is very similar to the obtained by the mean-shift approach [20] where the neighborhood filter is nonlinearly iterated. In that case, the authors show that clusters tend to its mean, yielding piecewise constant image.

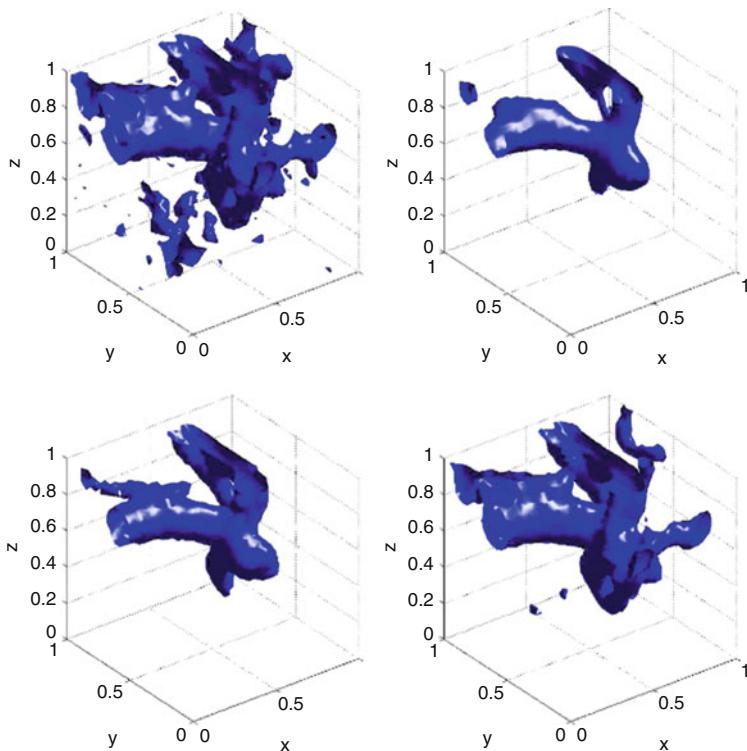

Fig. 28 From *top* to *bottom* and *left* to *right*: original iso-surface of the 3D image, same iso-surface filtered by iterative median filter, by linear sigma filter, and by linear NL-means. The iso-surface extracted from the original image presents many irregularities due to noise. The median filter makes them disappear, but makes important parts disappear and some vessels disconnect or fuse. Linear NL-means keeps most vessels and maintains the topology

The histogram concentration phenomenon is actually visible in the comparative evolution of some slices under the various considered filters, as shown in Fig. 27. The first row shows these slices picked in the interest area. The topology killing effect of the median filter (mean curvature motion) is as follows: small arteries tend to vanish and larger ones shrink and become circular as shown in the third slice showing an artery section. The third row is dedicated to the linear sigma filter, which corresponds to Grady's method applied directly to the image instead of using seeds. It is quite apparent that well-contrasted objects are well maintained and the contrast augmented, in agreement with the consistency of this recursive filter with the Perona-Malik equation. However, the less contrasted objects tend to vanish because, on them, the evolution becomes similar to an isotropic heat equation. The fourth row is the result of applying the 3D nonlocal linear heat equation, where the Laplacian coefficients are computed from the original image. The whole sequence has been treated as a 3D image with a weight support of $(7 \times 7 \times 3)$ and

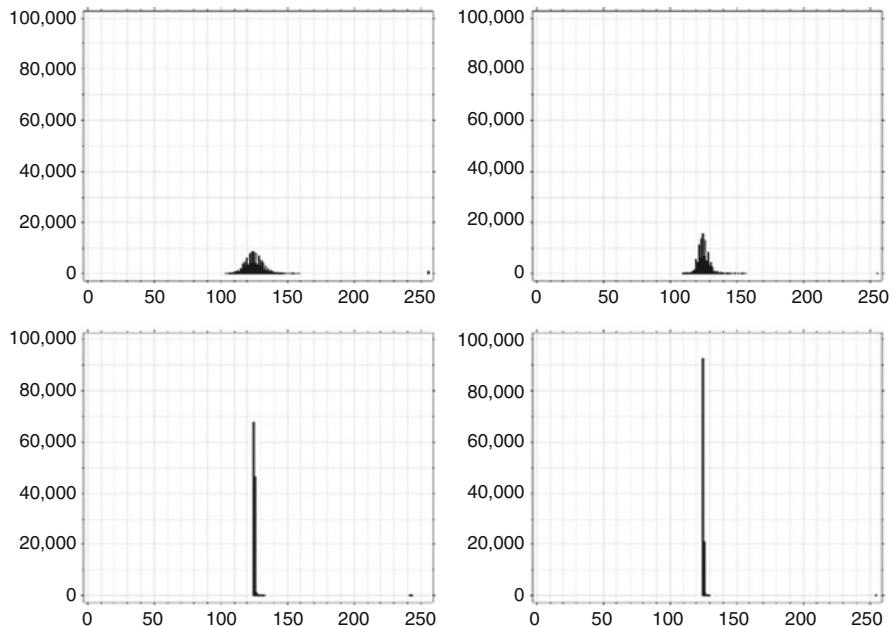

Fig. 29 Gray level histogram of 3D areas of interest. *Top left*: original 3D image before. *Top right*: after median filtering. *Bottom left*: after proposed method with sigma filter weights. *Bottom right*: proposed method with NL-means weights. The background is now represented by a few gray level values when the volume is filtered by the proposed method. A threshold can therefore be more easily and automatically applied

a comparison window of $3 \times 3 \times 3$. Clearly the background is flattened and blood vessels are enhanced on this background. A threshold just above the homogeneously made background level should give back arteries, and this indeed occurs. Thus, in that case, the 3D visualization of objects with complex topology like the cerebral arteries can be achieved by an automatic threshold as illustrated in Fig. 28. The exact segmentation of the artery is a more difficult problem. Even if the histogram is concentrated, a different choice of the visualization threshold can produce slightly different surfaces.

5 Conclusion

This chapter has introduced neighborhood filters and reviewed the impact that they have had in many image-processing problems during these last years.

The neighborhood filters have been analyzed under three different frameworks; a denoising filter, a local smoothing filter and in a variational formulation.

As a denoising algorithm, the denoising filter has motivated state of the art algorithms as its generalization the NL-means algorithm. As a local smoothing filter,

its asymptotic analysis leads to the well known Perona-Malik equation. And its variational formulation is effectively used for segmentation and diffusion purposes, for example, in medical image analysis.

Neighborhood filters remain as one of the main contributions in image processing of the last years and still influences current and future research.

Abstract

Following their success in image processing (see Chapter ▶ [Local Smoothing Neighborhood Filters](#)), neighborhood filters have been extended to 3D surface processing. This adaptation is not straightforward. It has led to several variants for surfaces depending on whether the surface is defined as a mesh, or as a raw data point set. The image gray level in the bilateral similarity measure is replaced by a geometric information such as the normal or the curvature. The first section of this chapter reviews the variants of 3D mesh bilateral filters and compares them to the simplest possible isotropic filter, the mean curvature motion.

In a second part, this chapter reviews applications of the bilateral filter to a data composed of a sparse depth map (or of depth cues) and of the image on which they have been computed. Such sparse depth cues can be obtained by stereovision or by psychophysical techniques. The underlying assumption to these applications is that pixels with similar intensity around a region are likely to have similar depths. Therefore, when diffusing depth information with a bilateral filter based on locality and color similarity, the discontinuities in depth are assured to be consistent with the color discontinuities, which is generally a desirable property. In the reviewed applications, this ends up with the reconstruction of a dense perceptual depth map from the joint data of an image and of depth cues.

1 Introduction

The idea of processing a pixel relatively to its similar looking neighbors proved to be very powerful and was adapted to solve a huge variety of problems. Since its primary goal is to denoise data and since the same denoising problem appeared for 3-dimensional surfaces, the idea of a 3D bilateral filter was only natural. Nevertheless, we shall see that this extension is far from straightforward. Multiple adaptations have in fact been introduced; experimental results show that it is far better for denoising a shape while preserving edges than an isotropic filter (as one could expect).

The bilateral filter could be used not only to filter images but also to diffuse information across an image: in numerous applications some information (e.g., depth value) is given only at some point positions. The problem is then to extrapolate the information for all pixels in the image. This can be used to improve the quality of disparity maps obtained by stereoscopy or to diffuse depth cues in images.

In the present chapter the different applications will be reviewed and tested experimentally. Section 2 reviews bilateral filters applied to 3D data point sets, often organized in a triangulation (a mesh). It ends up with comparative simulations

illustrating the advantage of bilateral filters on isotropic filtering. Section 3 considers the various cases where, in an image, depth values or depth cues are available and shows that the bilateral filter used as a diffusion tool performs well in restoring a dense depth map.

A previous review by Paris et al. [33] discusses the bilateral filter and its implementation. It also provides an overview of numerous applications.
