Preface

Today, *computer imaging* covers various aspects of *data filtering, pattern recognition, feature extraction, computer aided design, and computer aided inspection and diagnosis*.

Pillars of the field of computer imaging are advanced, stable, and reliable algorithms. In addition, feasibility analysis is required to evaluate practical relevance of the methods. To put these pillars on solid grounds, a significant amount of mathematical tools are required. This handbook makes a humble attempt to provide a survey of such mathematical tools.

We had the vision that this imaging handbook should contain individual chapters which can serve as toolboxes, which, when aligned, form background material for complete applied imaging problems. Therefore it should also give an impression on the broad mathematical knowledge required to solve industrial and applied research applications: The image formation process, very frequently, is assigned to the inverse problems community, which is prominently represented in this handbook. The subsequent step is image analysis. Nowadays, advanced Image Analysis, and Image Processing in general, uses sophisticated methods from Geometry, Differential Geometry, Convex Analysis, Numerical Analysis, to mention just a few. In fact, by the rapid advance of Imaging, the mathematical areas have been pushed forward heavily, and raised their impact in application sciences.

Second Edition

My special thanks go to all individual authors for their valuable contributions and the referees for their help in improving the contributions and making detailed comments. My sincere thanks go to the Springer's editors and staff, Marc Strauss, Annalea Manalili, Michael Hermann, and Saskia Ellis for their patience and their constant support and encouragement over the last two years. My thanks also goes to Vaishali Damle, who initialized the second edition of this handbook.

Finally, I would like to encourage the readers to submit suggestions regarding this handbook's content. For a project of this size, it is likely that essential topics are missed. In a rapidly evolving area like Imaging it is likely that new areas will

appear in a very short time and should be added to this handbook, as well as recent development enforce modifications of existing contributions. We are committed to issuing periodic updates and we look forward to the feedback from the community.

About the Editor

Otmar Scherzer was born on June 10, 1964, in Vöcklabruck, Austria. He studied technical mathematics at the University of Linz, Austria, and received his Diploma in Mathematics in 1987. He received his Ph.D. in 1990 and his habilitation in 1995 from the same university. During 1995 and 1996, he visited Texas A&M University and the University of Delaware in USA. From 1999 to 2001, he held professorships at the Ludwig Maximilian University, Munich, and the University of Bayreuth, Germany. Otmar then joined the University of Innsbruck, Austria, where he served as full professor of Applied and Computer Oriented Mathematics, from 2001 to 2009. In 2009, he accepted a position at the University of Vienna, where he currently heads the Computational Science Center which was created upon his appointment. More information about the center can be found at: <http://www.csc.univie.ac.at/>. He is also group leader of the Inverse Problems and Imaging groups at the Radon Institute of Computational and Applied Mathematics in Linz, Austria. More information on the institute can be found at: <http://www.ricam.oeaw.ac.at/>.

Otmar's research interests include inverse problems, in particular photoacoustic imaging, regularization, image processing, and PDEs. He is a prolific researcher, with more than a 170 research articles published in several well-respected journals. He is the coauthor of two monographs and had coedited 7 volumes, including this handbook, and has served on the editorial board of many prominent journals.

Abstract

This introductory treatment of linear inverse problems is aimed at students and neophytes. A historical survey of inverse problems and some examples of model inverse problems related to imaging are discussed to furnish context and texture to the mathematical theory that follows. The development takes place within the sphere of the theory of compact linear operators on Hilbert space, and the singular value decomposition plays an essential role. The primary concern is regularization theory: the construction of convergent well-posed approximations

C. Groetsch (✉)

Traubert Chair in Science and Mathematics, The Citadel, Charleston, SC, USA

e-mail: charles.groetsch@citadel.edu

to ill-posed problems. For the most part, the discussion is limited to the familiar regularization method devised by Tikhonov and Phillips.

1 Introduction

► ... although nature begins with the cause and ends with the experience we must follow the opposite course, namely ... begin with the experience and by means of it end with the cause.

Leonardo da Vinci

An inverse problem is the flip side of some direct problem. Direct problems treat the transformation of known causes into effects that are determined by some specified model of a natural process. They tend to be future directed and outward looking and are often concerned with forecasting or with determining external effects of internal causes. Direct problems have solutions (causes have effects), and the process of transforming causes into effects is a mathematical *function*: a given cause determines, via the model, a unique effect. In direct problems the operator that maps causes into effects is typically continuous in natural metrics: close causes have close effects. These features of direct problems make them *well posed*.

The idea of a well-posed problem has its origins in Jacques Hadamard's short paper [37] published in 1902. Hadamard held the opinion that an important physical problem must have three attributes:

1. (Existence) It has a solution.
2. (Uniqueness) It has only one solution.
3. (Stability) The solution depends continuously on the data of the problem.

A problem satisfying these three conditions is called *well posed*. In his 1902 paper, Hadamard called a problem *bien posé* if it has properties (1) and (2). Again in his 1923 lectures [38], he called a problem "correctly set" if it satisfies (1) and (2). Condition (3) was not named as a specific requirement of a well-posed problem, but his explicit notice of the lack of continuous dependence on boundary data of the solution of Cauchy's problem for Laplace's equation led to (3) becoming part of the accepted definition of a well-posed problem.

A problem is *ill posed* if it lacks these qualities. Hadamard's suggestion that ill-posed problems are devoid of physical significance (*dépourvu de signification physique*) was unfortunate, as almost all inverse problems in the physical and biological sciences are ill posed. To be fair, it should be noted that Hadamard was speaking about a specific problem, the Cauchy problem for Laplace's equation in a strip. On the other hand, Courant [15] insisted more generally that "a mathematical problem cannot be considered as realistically corresponding to physical phenomena

unless . . . ” it satisfies condition (3). The problems of existence and uniqueness in inverse problems can often be ameliorated by generalizing the notion of solution and constraining the generalized solution, but the key attribute of stability often is a feature that is inherently absent in inverse problems. This essential lack of stability usually has dire consequences when numerical methods, using measured or uncertain data, are applied to inverse problems.

Inverse problems are as old as science itself. In fact, a reasonable working definition of science is the explanation of natural phenomena by the construction of conceptual models for interpreting imperfect observational representations of “true” natural objects or processes. This definition encompasses the three essential ingredients of mathematical inverse problems: a “true” solution, a model, or operator that transforms this true solution into an imperfect representation that is amenable to observations or measurements. One could say that inverse theory embraces an operating principle that is essentially Platonic: true natural objects exist, but it is only through models and imperfectly perceived images that we experience them. The challenge is to “invert” the model to recover a useful estimate of the true object from the observed image. In this sense, all of inverse theory deals with “imaging.”

A mathematical framework for the study of inverse problems must provide sufficient scope for each of the three elements: true solutions, model, and observations. In this chapter the solution space and the space of observations are both taken to be Hilbert spaces, but not necessarily the same Hilbert space, as one naturally desires more of the solution than one demands from the observations. The model is a transformation or operator that carries a possible solution to an observed effect. We consider only linear inverse problems, so our models are linear operators.

Any practical model suppresses some information. If a model represents every bit of information in the objects themselves (i.e., the model operator is the identity operator), then nothing is gained in conceptual economy. In this case one is in the absurd position of Mein Herr in Lewis Carroll’s *Sylvie and Bruno Concluded*:

“We actually made a map of the country, on a scale of a *mile to the mile!*” . . . “It has never been spread out yet,” said Mein Herr: “the farmers objected; they said it would cover the whole country, and shut out the sunlight! So now we use the country itself, as its own map, and I assure you it does nearly as well.”

Finite linear models lead to linear algebra problems. Idealized limiting versions of finite models typically lead to compact linear operators, that is, limits of finite rank operators. A compact operator may have a nontrivial null-space, a non-closed range, or an unbounded (generalized) inverse. Therefore, these operators, which occur widely in models of linear inverse problems, lack all the virtues of well posedness. In this chapter, we provide a somewhat slanted survey of linear inverse problems, mainly involving compact operators, with special attention to concepts underlying methods for constructing stable approximate solutions.

Before draping these ideas on a mathematical framework, we discuss a half dozen examples of model inverse problems that have played significant roles in the development of the physical sciences.

2 Background

► Our science is from the watching of shadows;
Ezra Pound

This brief and incomplete historical survey of physical inverse problems is meant to give some perspective on certain inverse problems closely related to imaging in the broad sense. Our viewpoint involves both the very large scale, treating inverse problems loosely associated with assessing the cosmos, and the human scale, dealing with evaluation of the inaccessible interior of bodies (human or otherwise).

Inverse theory, as a distinct field of inquiry, is a relatively recent development; however, inverse problems are as old as science itself. A desire to know causes of perceived effects is ingrained in the human intellectual makeup. The earliest attempts at explanations, as, for example, in the creation myths of various cultures, were supernatural – grounded in mysticism and mythology. When humankind embarked on a program of rationalization of natural phenomena, inverse problems emerged naturally and inevitably. An early example is Plato's allegory of the cave (ca. 375 B.C.). In the seventh book of his *Republic*, Plato describes the situation. A group of people have been imprisoned since their birth in a cave where they are chained in such a manner that allows them to view only a wall at the back of the cave. Outside the cave life goes on, illuminated by a fire blazing in the distance. The captives in the cave must reconstruct this external reality on the basis of shadows cast on the rear wall of the cave. This is the classic inverse imaging problem: real objects are perceived only as two-dimensional images in the form of shadows on the cave wall. This annihilation of a dimension immediately implies that the reconstruction problem has multiple solutions and that solutions are unstable in that highly disparate objects may have virtually identical images.

Aristotle adapted his teacher Plato's story of the cave to address a scientific inverse problem: the shape of the earth. This shape could not be *directly* assessed in Aristotle's time, so he suggested an *indirect* approach (see Book II of *On the Heavens*.):

As it is, the shapes which the moon itself each month shows are of every kind – straight, gibbous, and concave – but in eclipses the outline is always curved; and since it is the interposition of the earth that makes the eclipse, the form of the line will be caused by the form of the earth's surface, which is therefore spherical.

Aristotle's reasoning provided an *indirect* argument for the sphericity of the earth based on the shapes of shadows cast on the moon.

Inverse imaging has been a technical challenge for centuries. The difficulties that early investigators encountered were vividly captured by Albrecht Dürer's woodcut *Man Drawing a Lute* (1525). We can see the doubts and angst brought on by the inverse imaging problem etched on the face of the crouching technician (Fig. 1).

The character on the left, standing bolt upright in a confident attitude, has the comparatively easy direct problem. He has complete knowledge of the object, and he knows exactly how the projection model will produce the image. On the other hand, the crouching man on the right, with the furrowed brow, faces the more difficult

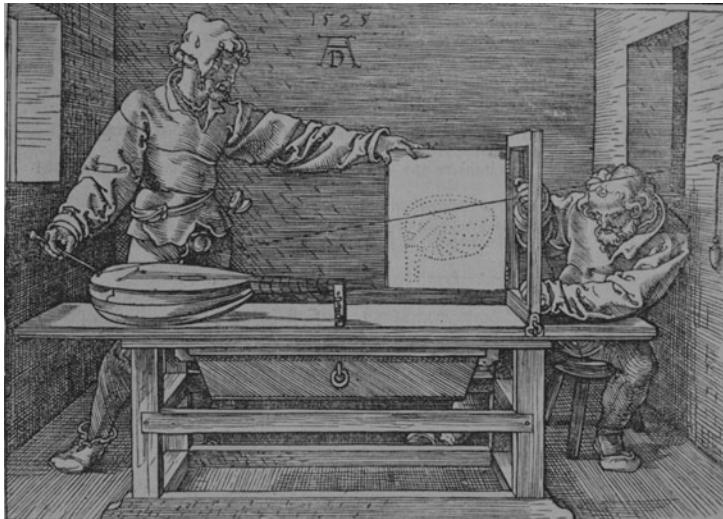

Fig. 1 A renaissance inverse problem

inverse problem of assessing whether the image captures the essential features of the object. Dürer's woodcut is a striking representation of the comparative difficulties of direct and inverse assessment.

Modern imaging science has its roots in Galileo Galilei's lunar observations carried out during the winter of 1609. Prior to Galileo's study, the moon was thought to belong to the realm of the Pythagorean fifth essence, consisting of perfectly uniform material in perfect spherical form. Galileo's eyes, empowered by his improved telescope, the earliest scientific imaging device, showed him otherwise [21]:

... we certainly see the surface of the Moon to be not smooth, even, and perfectly spherical, as the great crowd of philosophers has believed about this and other heavenly bodies, but, on the contrary, to be uneven, rough, and crowded with depressions and bulges. And it is like the Earth itself, which is marked here and there with chains of mountains and depth of valleys.

But Galileo was not satisfied with qualitative evidence. He famously stated that the book of nature is written in the language of mathematics, and he used mathematics, in the form of the Pythagorean theorem, along with some shrewd estimates, to assess indirectly the heights of lunar mountains. The process of indirect assessment is a hallmark of inverse problems in the natural sciences. (See [2] for an account of inverse problems of indirect assessment.)

Nonuniqueness is a feature of many inverse problems that was slow to gain acceptance. An early instance of this phenomenon in a physical inverse problem occurred in the kinematic studies of ballistics carried out by Niccolò Tartaglia in the sixteenth century. Tartaglia claimed to be the inventor of the gunner's square, a device for measuring the angle of inclination of a cannon. Using his square Tartaglia

carried out ranging trials and published some of the earliest firing tables. He studied not only the direct problem of finding ranges for a given firing angle but also the inverse problem of determining the firing angle that results in a given range. Although Tartaglia's treatment was conceptually flawed and lacked rigor, his work contains glimmers of a number of basic principles of mathematical analysis that took several centuries to mature [32]. Tartaglia was particularly struck by nonuniqueness of solutions of the inverse problem. As he put it proudly in the dedication of his book *Nova Scientia* (Venice, 1537):

I knew that a cannon could strike in the same place with two different elevations or aimings,
I found a way of bringing about this event, a thing not heard of and not thought by any other,
ancient or modern.

With this boast Tartaglia was one of the first to call attention to this common feature of nonuniqueness in inverse problems.

Tartaglia found that for a given fixed charge, each range (other than the maximum range) is achieved by two distinct aimings placed symmetrically above and below the 45° inclination. A century and a half later, Edmond Halley [39] took up the more general problem of allowing both the charge and the firing angle to vary while firing on a fixed target situated on an inclined plane. In this case the inverse problem of determining charge-angle pairs that result in a strike on the target has infinitely many solutions. (Of course, Halley did not address air resistance; his results are extended to the case of first-order resistance in [33].) Halley restored uniqueness to the inverse aiming problem by restricting consideration to the solution which minimizes what we would now call the kinetic energy of the emergent cannon ball. The idea of producing uniqueness by seeking the solution that minimizes a quadratic functional would in due course become a key feature of inverse theory.

The model for a modern scientific society was laid out in Francis Bacon's utopian novel *The New Atlantis* (1626). Bacon describes a voyage to the mythical land of Bensalem, which was inhabited by wise men inclined to inverse thinking. Solomon's House, a research institute in Bensalem, was dedicated to the "knowledge of *causes*, and secret motions of things; and the enlarging of the bounds of human empire, to the *effecting* of all things possible" (my italics). The Royal Society of London, founded in 1660 and modeled on Baconian principles, was similarly dedicated. The first great triumph (due largely to Halley's efforts) of the Royal Society was the publication of Newton's magisterial *Principia Mathematica* (1687). In the *Principia*, Newton's laws relating force, mass, and acceleration, combined with his inverse square law of gravity, were marshaled to solve the direct problem of two-body dynamics, confirming the curious form of Kepler's planetary orbits: an inverse square centrally directed force leads to an orbit, which is a conic section. But Newton was not satisfied with this. He also treated the inverse problem of determining what gravitational law (*cause*) can give rise to a given geometrical orbit (*effect*).

In the history of science literature, the problem of determining the orbit, given the law of attraction, is sometimes called the inverse problem; this practice inverts the terminology currently common in the scientific community. The reverse terminology in the history community is evidently a consequence of the fact that

Newton took up the determination of force law first and then treated the orbit determination problem. Indeed, Newton treated the inverse problem of orbits before he took up the direct problem. After all, his primary goal was to discover the laws of nature, the causes, rather than the effects. As Newton put it in the preface to the first edition of his *Principia*: “...the whole burden of philosophy seems to consist of this – from the phenomena of motions to investigate the forces of nature, and then from these forces to demonstrate the other phenomena.”

In 1846, mathematical inverse theory produced a spectacular scientific triumph – the discovery of another world. The seeds of the discovery lay in the observed irregularities in the orbit of Uranus, the most distant of the planets known at the time. The orbit of Uranus did not fit with predictions based on Newton’s theories of gravity and motion. In particular an orbit calculated to fit contemporary observations did not fit observations made in the previous century, and an orbit that fit to the older sightings did not match the contemporary data. This suggested two possibilities: either Newton’s theory had to be modified at great distances or perhaps the anomalies in the orbit of Uranus were the effect of an as yet undiscovered planet (the cause) operating on Uranus via Newton’s laws.

During the summer vacation of 1841, John Couch Adams, an undergraduate of St. John’s College, Cambridge, was intrigued by the second possibility. He recorded this diary entry:

1841, July 3. Formed a design in the beginning of the week, of investigating, as soon as possible after taking my degree, the irregularities in the motion of Uranus, which are yet unaccounted for; in order to find whether they may be attributed to the action of an undiscovered planet beyond it; and if possible thence to determine the elements of its orbit, etc. approximately, which would probably lead to its discovery.

Adams solved the inverse problem of determining the characteristics of the orbit of the undiscovered planet, now known as Neptune, that perturbs Uranus. However, a sequence of lamentable missteps, involving his own timidity, bureaucratic inertia, and other human factors, resulted in the honor of “discovering” the new planet on the basis of mathematics going to Urbain Le Verrier of France, who solved the inverse problem independently of Adams. This of course led to disappointment in England over the botched opportunity to claim the discovery and to a good deal of hauteur in France over the perceived attempt by the English to grab credit deserved by a Frenchman. The fascinating story of the unseemly squabble is well told in [36]. See also [63] for a recent update in which old wounds are reopened.

Newton’s discussion of inverse orbit problems in his *Principia*, and vague doubts about the form of the gravitational force law raised prior to the discovery of Neptune, may have inspired other inverse problems. An early interesting “toy” inverse problem in this vein was published by Ferdinand Joachimstahl in 1861 [47]. The problem Joachimstahl posed, and solved by an Abel transform, was to determine the law of gravitational attraction if the total force at any distance from a line of known mass density is given.

Johann Radon laid the foundation of mathematical imaging science, without knowing it, in his 1917 memoir [61]. (An English translation of Radon’s paper may be found in [17].) Radon was concerned with the purely mathematical problem of

determining a real-valued function of two variables from knowledge of the values of its line integrals over all lines intersecting its domain. Although Radon evidently had no application in mind, his treatment was to become, after its rediscovery a half century later, the basis for the mathematics of computed tomography. (See [14] for more on the history of computed tomography.) Essentially the same result was obtained independently by Viktor Ambartsumian [1] who was interested in a specific inverse problem in astronomy. Proper motions of stars are difficult to determine, but radial velocities (relative to the earth) are obtainable from chromatic Doppler shift measurements. Ambartsumian used a mathematical model essentially equivalent to that of Radon to deduce the true three-dimensional distribution of stellar velocities from the distribution of the radial velocities.

In the mid-1950s of the last century, Allan Cormack, a young physics lecturer at the University of Cape Town, who was moonlighting in the radiology department of Groote Schuur Hospital, had a bright idea. In Cormack's words:

It occurred to me that in order to improve treatment planning one had to know the distribution of the attenuation coefficient of tissues in the body, and that this distribution had to be found by measurements made external to the body. It soon occurred to me that this information would be useful for diagnostic purposes and would constitute a tomogram or series of tomograms, though I did not learn the word "tomogram" for many years.

This was the birth of the mathematical theory of medical imaging. Cormack would not learn of Radon's work for another two decades, but he developed the basic results for radially symmetric attenuation coefficient distributions and tested the theory with good results on a simple manufactured specimen in the form of a cylinder of aluminum encased in an annular prism of wood. The reconstructed piecewise constant attenuation function matched that of the known specimen well enough to show the promise of this revolutionary new imaging technology.

In the 1990s, inverse thinking and indirect assessment led to another spectacular advance in astronomy: the discovery of extrasolar planets. Philosophers had speculated on the reality of planets linked to the stars at least since classical Greek times, and few in modern times doubted the existence of extrasolar planets. But convincing evidence of their existence had to await the development of sufficiently sensitive telescope-mounted spectrometers and the application of simple inverse theory. The indirect evidence of extrasolar planets consisted of spectral shift data extracted from optical observations of a star.

In a single star–planet system, determining the variable radial velocity (relative to the earth) of a star wobbling under the gravitational influence of an orbiting planet of known mass and orbital radius is a simple direct problem – just equate the gravitational acceleration of the planet to its centripetal acceleration. (Consider only the simple case in which the planet, star, and earth are coplanar and the orbit is circular; an orbit oblique to the line of sight from earth introduces an additional unknown quantity. As a consequence of this obliquity, the relative mass estimated from the inverse problem is actually a *lower* bound for this quantity.) Using Doppler shift data, a simple inverse problem model may be developed for determining approximations to the relative planetary mass and orbital radius. The solution of the inverse problem enabled astronomers to announce in 1995 the existence of the first

confirmed extrasolar planet orbiting the star 51Pegasi. The millennia-old question of the existence of extrasolar worlds finally had a convincing positive answer.

We bring this historical survey of inverse problems up to the present day with the greatest challenge in contemporary cosmology: the search for dark matter. Such matter, being “dark,” is by definition inaccessible to direct measurement. But recently an imaging model on the largest scale in the history of science has come to be used in attempts to assay this dark matter. The process of gravitational lensing, which is based on Einstein’s theory of curved space-time, presents the possibility of inverting the imaging model to estimate a dark mass (the gravitational lens) that intervenes between the observer on earth and an immensely distant light source. The dark mass warps space in its vicinity resulting, under appropriate conditions, in focusing onto the earth light rays that in flat space would not intersect the earth. In an extreme case in which the light source (e.g., a galaxy), the intervening gravitational lens (dark matter), and the collected image are collinear, this results in a phenomenon called an Einstein ring (first observed in 1979; see [22]). If the distances from earth to the lens and from the lens to source can be estimated, then the solution of an inverse problem gives an estimate of the dark mass (see [56]).

3 Mathematical Modeling and Analysis

► ... we have to remember that what we observe is not nature in itself
but nature exposed to our method of questioning.

Werner Heisenberg

A Platonic Inverse Problem

Plato’s discussion of captives struggling to discern the real cause of shadows cast on the back wall of a cave is a primeval exemplar of inverse imaging problems. Here we present a toy imaging problem inspired by Plato’s allegory. While the problem is very elementary, it usefully illustrates some important aspects of imaging problems and inverse problems in general.

Imagine a two-dimensional convex object in the xy -plane, which is bounded by the positive coordinate axes, and the graph of a function $y = f(x)$, $0 \leq x \leq 1$ that is positive on $[0, 1]$, strictly decreasing and concave-down, and satisfies $f(1) = 0 = f'(0)$. The object is illuminated by parallel light rays from the left that form angles θ with the negative ray of the horizontal axis, as illustrated in Fig. 2.

The goal is to reconstruct the shape of the object from observations of the extent $s(\theta)$ of the shadow cast by the object. This is accomplished by fashioning a parameterization $(x(\theta), f(x(\theta)))$ of the boundary curve of the object. As a further simplification we assume that $f'(1) = -1$. These assumptions guarantee that for each $s > 1$ there is a unique point $(t, f(t))$ on the graph of f at which the tangent line intersects the x -axis at s . What is required to see this is the existence of a unique

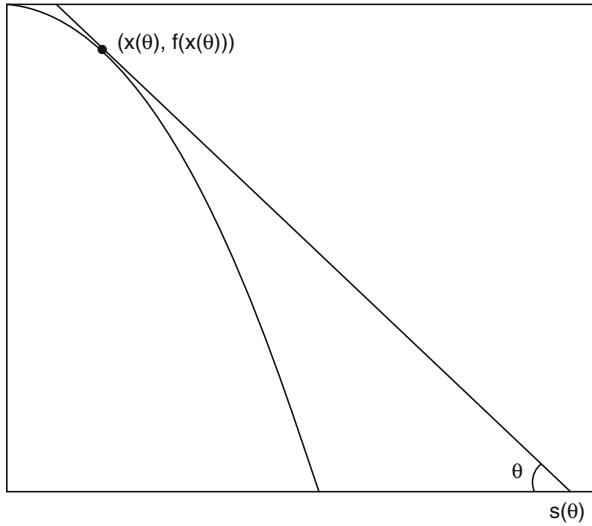

Fig. 2 A model shadow problem

$t \in (0, 1)$ such that the tangent line to the graph at the point $(t, f(t))$ intersects the x -axis at s . That is,

$$(s - t)f'(t) + f(t) = 0.$$

For each fixed $s > 1$, the expression on the left is strictly decreasing for $t \in (0, 1)$, positive at $t = 0$ and negative at $t = 1$, so the existence of a unique such $t = x(\theta)$ is assured. At the point of tangency,

$$-\tan \theta = f'(x(\theta)).$$

Also,

$$f(x(\theta)) = (\tan \theta)(s(\theta) - x(\theta)),$$

and hence determining $x(\theta)$ also gives $(x(\theta), f(x(\theta)))$, which solves the inverse imaging problem. Combining these results we have

$$-(\tan \theta)x'(\theta) = f'(x(\theta))x'(\theta) = (s(\theta) - x(\theta))\sec^2 \theta + (s'(\theta) - x'(\theta))\tan \theta.$$

A bit of simplification yields

$$x(\theta) = s(\theta) + \frac{1}{2} \sin(2\theta)s'(\theta), \quad (1)$$

which explicitly solves the inverse problem of determining the shape $(x(\theta), f(x(\theta)))$ from knowledge of the extent of the shadows $s(\theta)$.

The explicit formula (1) would seem to completely solve the inverse problem. In a theoretical sense this is certainly true. However, the formulation (1) shelters a subversive factor (the derivative) that should alert us to potential challenges involved in the practical solution of the inverse problem. Observations are always subject to measurement errors. The differentiation process, even if performed exactly, may amplify these errors as differentiation is a notoriously unstable process. For example, if a shadow function $s(\theta)$ is perturbed by low-amplitude high-frequency noise of the form $\eta_n(\theta) = \frac{1}{n} \sin n^2\theta$ giving observed data

$$s_n(\theta) = s(\theta) + \eta_n(\theta),$$

then the corresponding shape abscissas provided by (1) satisfy

$$x_n(\theta) = x(\theta) + \eta_n(\theta) + \frac{\sin 2\theta}{2} \eta'_n(\theta).$$

But η_n converges uniformly to 0 as $n \rightarrow \infty$, while $\max |\eta'_n| \rightarrow \infty$, giving a convincing illustration of the instability of the solution of the inverse problem provided by (1). For more examples of model inverse problems with explicit solutions that involve differentiation, see [71].

It is instructive to view the inverse problem from another perspective. Note that by (1), $s(\theta)$ is the solution of the linear differential equation

$$\frac{ds}{d\theta} + \frac{2}{\sin(2\theta)} s = \frac{2}{\sin(2\theta)} x(\theta)$$

satisfying $s(\pi/4) = 1$. This differential equation may be solved by elementary means yielding

$$s(\theta) = \frac{1 + \cos 2\theta}{\sin 2\theta} + \int_{\pi/4}^{\theta} \frac{2(1 + \cos 2\varphi)}{(1 + \cos 2\varphi) \sin 2\theta} x(\varphi) d\varphi. \quad (2)$$

In this formulation, the “hidden” solution $x(\varphi)$ of the inverse problem is seen to be transformed by a linear integral operator into observations of the shadows $s(\theta)$. The goal now is to uncover $x(\varphi)$ from (2) using knowledge of $s(\theta)$, that is, one must solve an integral equation.

The solution of the integral formulation (2) suffers from the same instability as the explicit solution (1). Indeed, one may write (2) as

$$s = \psi + \psi T x$$

where $\psi(\theta) = (1 + \cos 2\theta)/\sin 2\theta$ and

$$(Tx)(\theta) = \int_{\pi/4}^{\theta} \frac{2}{1 + \cos 2\varphi} x(\varphi) d\varphi.$$

If we let $v_n(\varphi) = \frac{n}{2}(1 + \cos 2\varphi)\sin n^2\varphi$ and set

$$s_n = \psi + \psi T(x + v_n)$$

then one finds that $s_n \rightarrow s$ uniformly, while $\max |v_n| \rightarrow \infty$. That is, arbitrarily small perturbations in the data s may correspond to arbitrarily large deviations in the solution x . This story has a moral: instability is intrinsic to the inverse problem itself and not a manifestation of a particular representation of the solution.

Cormack's Inverse Problem

As noted in the previous section, the earliest tomographic test problem explicitly motivated by medical imaging was Cormack's experiment [12] with a fabricated sample having a simple radially symmetric absorption coefficient. The absorption coefficient is a scalar field whose support may be assumed to be contained within the body to be imaged. This coefficient f supplies a measure of the attenuation rate of radiation as it passes through a given body point and is characterized by Bouguer's law

$$\frac{dI}{ds} = -fI,$$

where I is the intensity of the radiation and s is arclength. The integral of f along a line L intersecting the body then satisfies

$$g = \int_L f ds.$$

Here $g = \ln(I_0/I_e)$, where I_0 is the incident intensity, and I_e the emergent intensity, of the beam. The observable quantity g is then a measure of the total attenuation effect that the body has on the beam traversing the line L .

To be more specific, for a given $t \in \mathbf{R}$ and a given unit vector $\vec{\varphi} = (\cos \varphi, \sin \varphi)$, let $L_{t,\varphi}$ represent the line

$$L_{t,\varphi} = \{\vec{x} \in \mathbf{R}^2 : \langle \vec{x}, \vec{\varphi} \rangle = t\}$$

where $\langle \cdot, \cdot \rangle$ is the Euclidean inner product. We will denote the integral of f over $L_{t,\varphi}$ by

$$\mathcal{R}(f)(t, \varphi) = \int_{L_{t,\varphi}} f \, ds = \int_{-\infty}^{\infty} f(t \cos \varphi - s \sin \varphi, t \sin \varphi + s \cos \varphi) \, ds.$$

If f is *radial*, that is, independent of φ , then

$$\mathcal{R}(f)(t, \varphi) = \mathcal{R}(f)(t, 0) = \int_{-\infty}^{\infty} f(t, s) \, ds. \quad (3)$$

Furthermore, if f vanishes exterior to the disk of radius R , then on setting $r = \sqrt{t^2 + s^2}$ and $f(r) = f(t, s)$, one finds

$$g(t) = \int_t^R \frac{2rf(r)}{\sqrt{r^2 - t^2}} \, dr, \quad (4)$$

where $g(t) = \mathcal{R}(f)(t, 0)$. The mapping defined by (4), which for a given line $L_{t,\varphi}$ transforms the radial attenuation coefficient into the function g , is an *Abel transform* of f . It represents, as a direct problem, Cormack's early experiment with a radially symmetric test body. Determining the distribution of the attenuation coefficient requires solving the inverse problem. The Abel transform may be formally inverted by elementary means to furnish a solution of the inverse problem of determining the attenuation coefficient f from knowledge of the loss data g . Indeed, by (4) and a reversal of order of integration,

$$\int_r^R \frac{tg(t)}{\sqrt{t^2 - r^2}} \, dt = \int_r^R f(s)s \int_r^s \frac{2t}{\sqrt{s^2 - t^2}\sqrt{t^2 - r^2}} \, dt \, ds = \pi \int_r^R f(s)s \, ds,$$

since

$$\int_r^s \frac{2t}{\sqrt{s^2 - t^2}\sqrt{t^2 - r^2}} \, dt = \pi$$

(change the variable of integration to $w = \sqrt{s^2 - t^2}/\sqrt{s^2 - r^2}$). However,

$$\int_r^R \frac{tg(t)}{\sqrt{t^2 - r^2}} \, dt = - \int_r^R (t^2 - r^2)^{1/2} g'(t) \, dt$$

and hence on differentiating, we have

$$\int_r^R \frac{rg'(t)}{\sqrt{t^2 - r^2}} \, dt = -\pi rf(r).$$

Therefore,

$$f(r) = -\frac{1}{\pi} \int_r^R \frac{g'(t)}{\sqrt{t^2 - r^2}} \, dt.$$

The derivative lurking within this inversion formula is again a harbinger of instability in the solution of the inverse problem.

Forward and Reverse Diffusion

Imagine a bar, identified with the interval $[0, \pi]$ of the x -axis, the lateral surface of which is thermally insulated while its ends are kept always at temperature zero. The diffusion of heat in the bar is governed by the one-dimensional heat equation

$$\frac{\partial u}{\partial t} = \kappa \frac{\partial^2 u}{\partial x^2}, \quad 0 < x < \pi$$

where $u(x, t)$ is the temperature at position x and time t and κ is the thermal diffusivity. If the initial temperature distribution in the bar is a function $f(x)$, then the boundary and initial conditions associated with this model are

$$u(0, t) = 0, \quad u(\pi, t) = 0, \quad u(x, 0) = f(x).$$

In the forward diffusion problem, the goal is to find, for a given future time $T > 0$, the temperature distribution $g(x) = u(x, T)$. Formal separation of variable techniques leads to a solution of the form

$$u(x, t) = \sum_{n=1}^{\infty} a_n e^{-\kappa n^2 t} \sin nx,$$

where a_n are the Fourier coefficients of the initial temperature distribution

$$a_n = \frac{2}{\pi} \int_0^{\pi} f(s) \sin ns \, ds.$$

The future temperature distribution is then seen to be, after some rearranging,

$$g(x) = \int_0^{\pi} k(x, s) f(s) \, ds,$$

where

$$k(x, s) = \frac{2}{\pi} \sum_{n=1}^{\infty} e^{-\kappa n^2 T} \sin nx \sin ns.$$

A high degree of smoothing is a notable feature of the forward diffusion process. Specifically, the factors $e^{-\kappa n^2 T}$ in the transformation have the effect of severely damping high-frequency components in the initial temperature distribution f .

A corresponding reverse diffusion process is immediately suggested, namely, the retrodiction of the initial temperature distribution f , from knowledge of the later temperature distribution g . In this inverse problem, one finds that

$$f(x) = \frac{2}{\pi} \sum_{n=1}^{\infty} e^{\kappa n^2 T} \int_0^{\pi} g(s) \sin ns \, ds. \quad (5)$$

The contrast with the forward problem is striking: now high-frequency components in g are *amplified* by the huge factors $e^{\kappa n^2 T}$. Also note that the inverse problem is soluble only for a restricted class of functions g – those for which the series (5) converges in $L^2[0, \pi]$. As will be seen in the next section, the reverse diffusion process is a useful metaphor in the discussion of deblurring.

Deblurring as an Inverse Problem

Cameras and other optical imagers capture a scene, or *object*, and convert it into an imperfect *image*. The object may be represented mathematically by a function $f : \mathbf{R}^2 \rightarrow \mathbf{R}$ that codes, for example, gray scale or intensity. The image produced by the device is a function $g : \mathbf{R}^2 \rightarrow \mathbf{R}$, and the process may be phrased abstractly as $g = Kf$, where K is an operator modeling the operation of the imager. In a perfect imager, $K = I$, the identity operator (recall Mein Herr's map!). The perfect model may be expressed in terms of the two-dimensional delta distribution as

$$f(\vec{x}) = \int \int_{\mathbf{R}^2} \delta(\vec{x} - \vec{\xi}) f(\vec{\xi}) d\vec{\xi}.$$

However, any physical imaging device blurs the object f into an image g , which in many cases can be represented by

$$g(\vec{x}) = \int \int_{\mathbf{R}^2} k(\vec{x} - \vec{\xi}) f(\vec{\xi}) d\vec{\xi} \quad (6)$$

where $k(\cdot)$, the *point spread function* of the device, is some approximation of the delta function centered at the origin. Theoretical examples of such approximations include the tin-can function $\chi_R/(\pi R^2)$, where χ_R is the indicator function of the disk of radius R centered at the origin, and the sinc and sombrero functions given in polar coordinates by

$$\text{sinc}(r, \theta) = \frac{\sin \pi r}{\pi r} \quad \text{and} \quad \text{somb}(r, \theta) = 2 \frac{J_1(\pi r)}{\pi r},$$

respectively, where J_1 is the Bessel function of first kind and order 1. A frequently occurring model uses the Gaussian point spread function

$$k(r, \theta) = \frac{1}{2\pi\sigma^2} e^{-r^2/2\sigma^2}.$$

The problem of deblurring consists of solving (6) for the object f , given the blurred image g . For a good introduction to deblurring, see [44].

Reverse diffusion in two dimensions is a close cousin of deblurring. A basic tool in the analysis is the 2D Fourier transform defined for $f : \mathbf{R}^2 \rightarrow \mathbf{R}$ and $\vec{x}, \vec{\omega} \in \mathbf{R}^2$ by

$$\hat{f}(\vec{\omega}) = \mathcal{F}\{f\}(\vec{\omega}) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{-i\langle \vec{x}, \vec{\omega} \rangle} f(\vec{x}) dx_1 dx_2$$

with the inversion formula

$$f(\vec{x}) = \frac{1}{(2\pi)^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{i\langle \vec{x}, \vec{\omega} \rangle} \hat{f}(\vec{\omega}) d\omega_1 d\omega_2.$$

On integrating by parts, one sees that

$$\mathcal{F}\{\Delta f\}(\vec{\omega}) = -\|\vec{\omega}\|^2 \hat{f}(\vec{\omega}),$$

where Δ is the Laplacian operator: $\Delta = \frac{\partial^2}{\partial x_1^2} + \frac{\partial^2}{\partial x_2^2}$. Consider now the initial value problem for the 2D heat equation

$$\frac{\partial u}{\partial t} = \kappa \Delta u \quad \vec{x} \in \mathbf{R}^2, \quad t > 0, \quad u(\vec{x}, 0) = f(\vec{x}).$$

Applying the Fourier transform yields the initial value problem

$$\frac{dU}{dt} = -\kappa \|\vec{\omega}\|^2 U, \quad U(0) = \hat{f}$$

where $U(t) = \hat{u}(\cdot, t)$ and hence $U(t) = \hat{f} e^{-\|\omega\|^2 \kappa t}$. The convolution theorem then gives

$$u(\vec{x}, t) = \mathcal{F}^{-1}\{e^{-\|\omega\|^2 \kappa t} \hat{f}\} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} k(\vec{x} - \vec{\xi}) f(\vec{\xi}) d\xi_1 d\xi_2$$

where (using the integral result of [25], 12.A)

$$\begin{aligned} k(\vec{x}) &= \mathcal{F}^{-1}\left\{e^{-\omega_1^2 \kappa t} e^{-\omega_2^2 \kappa t}\right\} = \frac{1}{4\pi^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{i\langle \vec{x}, \vec{\omega} \rangle} e^{-(\omega_1^2 + \omega_2^2)\kappa t} d\omega_1 d\omega_2 \\ &= \frac{1}{4\pi^2} \int_{-\infty}^{\infty} e^{ix_1 \omega_1 - \omega_1^2 \kappa t} d\omega_1 \int_{-\infty}^{\infty} e^{ix_2 \omega_2 - \omega_2^2 \kappa t} d\omega_2 = \frac{1}{4\pi \kappa t} e^{-(x_1^2 + x_2^2)/(4\kappa t)}. \end{aligned}$$

The inverse problem of determining the initial distribution $f(\vec{x}) = u(\vec{x}, 0)$, given the distribution $g(\vec{x}) = u(\vec{x}, T)$ at a later time $T > 0$, is equivalent to solving the integral equation of the first kind

$$g(\vec{x}) = \frac{1}{4\pi\kappa T} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{-((x_1 - \xi_1)^2 + (x_2 - \xi_2)^2)/(4\kappa T)} f(\xi_1, \xi_2) d\xi_1 d\xi_2,$$

which is in turn equivalent to the deblurring problem with Gaussian point spread function

$$\Gamma_{\sigma}(\vec{x}) = \frac{1}{2\pi\sigma^2} e^{-\|\vec{x}\|^2/2\sigma^2}$$

having variance $\sigma^2 = 2\kappa T$. The idea of deblurring by reverse diffusion is developed in [8].

Extrapolation of Band-Limited Signals

Extrapolation is a basic challenge in signal analysis. The Fourier transform, \mathcal{F} , is the analytical workhorse in this field. It transforms a time signal $f(t)$, $-\infty < t < \infty$, into a complex-frequency distribution $\hat{f}(\omega)$ via the formula

$$\hat{f}(\omega) = \mathcal{F}\{f\}(\omega) = \int_{-\infty}^{\infty} f(t) e^{-i\omega t} dt.$$

In a suitable setting, the time-to-frequency transformation may be inverted by the formula (e.g., [25])

$$f(t) = \mathcal{F}^{-1}\{\hat{f}\}(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{f}(\omega) e^{i\omega t} dt.$$

Any physically realizable detector is capable of picking up frequencies only in a limited range, say $|\omega| \leq \Omega$. A signal f whose Fourier transform vanishes for $|\omega| > \Omega$, for some given $\Omega > 0$, is called a *band-limited* signal. A detector that operates in the frequency band $-\Omega \leq \omega \leq \Omega$ band-limits signals it collects, that is, it treats only $\chi_{[-\Omega, \Omega]} \hat{f}$, where

$$\chi_{[-\Omega, \Omega]}(\omega) = \begin{cases} 1, & \omega \in [-\Omega, \Omega] \\ 0, & \omega \notin [-\Omega, \Omega]. \end{cases}$$

is the indicator function of the interval $[-\Omega, \Omega]$. Multiplication by $\chi_{[-\Omega, \Omega]}$ in the frequency domain is called a low-pass filter as only components with frequency $|\omega| \leq \Omega$ survive the filtering process.

Reconstruction of the full signal f is generally not possible as information in components with frequency greater than Ω is unavailable. What is available is the signal

$$g = \mathcal{F}^{-1}\{\chi_{[-\Omega, \Omega]}\widehat{f}\}.$$

By the convolution theorem for Fourier transforms, one then has

$$g = \mathcal{F}^{-1}\{\chi_{[-\Omega, \Omega]}\} * f.$$

However,

$$\mathcal{F}^{-1}\{\chi_{[-\Omega, \Omega]}\}(t) = \frac{1}{2\pi} \int_{-\Omega}^{\Omega} e^{i\omega t} d\omega = \frac{\sin \Omega t}{\pi t}.$$

The reconstruction (or *extrapolation*) of the full signal f given the detected signal g requires the solution of the convolution equation

$$g(t) = \int_{-\infty}^{\infty} \frac{\sin(\Omega(t - \tau))}{\pi(t - \tau)} f(\tau) d\tau.$$

The problem of extrapolating a band-limited signal is then seen to be mathematically the same as deblurring the effect of an instrument with the one-dimensional point spread function

$$k_{\Omega}(t) = \frac{\sin(\Omega t)}{\pi t}.$$

PET

CT scanning with X-rays is an instance of *transmission tomography*. A decade and a half prior to Cormack's publications on transmission tomography, an *emission* tomography technique, now known as PET (positron transmission tomography), was proposed [72]. In PET, a metabolically active tracer in the form of a positron-emitting isotope is injected into an area for which it has an affinity and taken up (metabolized) by an organ. The isotope emits positrons that immediately combine with free electrons in so-called annihilation events, which result in the ejection of two photons (γ -rays) along oppositely directed collinear rays. When a pair of detectors located on an array surrounding the body pick up the simultaneous arrival of two photons, one at each detector, respectively, an annihilation event is assumed to have taken place on the segment connecting the two detectors. In PET, the data collected from a very large number of such events is used to construct a two-dimensional tomographic slice of the isotope distribution. Because the uptake of the isotope is metabolically driven, PET is an effective tool for studying metabolism

giving it a diagnostic advantage over X-ray CT scanning. A combination of an X-ray CT scan with a PET scan provides the diagnostician anatomical information (distribution of attenuation coefficient) and physiological information (density of metabolized tracer isotope), respectively.

If $f : \mathbf{R}^2 \rightarrow \mathbf{R}$ (we consider only a simplified version of 2D-PET) is the density of the metabolized tracer isotope, then the number of annihilations occurring along the coincidence line L connecting two detectors is proportional to the line integral

$$\int_L f \, ds.$$

That is, the observed counts of annihilation events are measured by the Radon transform of the density f . However, this does not take account of attenuation effects and can under represent features of deep-seated tissue. If the attenuation distribution is $\mu(\cdot, \cdot)$, and the pair of photons resulting from an annihilation event on the coincidence line L traverse oppositely directed rays L_+ and L_- of L , emanating from the annihilation site, then the detected attenuated signal takes the form

$$\begin{aligned} g &= \int_L e^{-\int_{L_+} \mu du} e^{-\int_{L_-} \mu du} f \, ds \\ &= e^{-\int_L \mu du} \int_L f \, ds. \end{aligned}$$

The model operator may now be viewed as a bivariate operator $K(\mu, f) = g$, in which the operator $K(\cdot, f)$ is nonlinear and the operator $K(\mu, \cdot)$ is linear. In soft tissue the attenuation coefficient is essentially zero, and therefore the solution of the inverse problem is accomplished by a Radon inversion of $K(0, \cdot)$. PET scans may be performed in combination with X-ray CT scans; the CT scan provides the attenuation coefficient, which may then be used in the model above to find the isotope density. See [52] for an extensive survey of emission tomography.

Some Mathematics for Inverse Problems

- Philosophy is written in that great book which ever lies before our gaze – I mean the universe . . . The book is written in the mathematical language . . . without which one wanders in vain through a dark labyrinth.
Galileo Galilei

Hilbert space is a familiar environment that is rich enough for a discussion of the chief mathematical issues that are important in the theory of inverse problems. For the most part we restrict our attention to real Hilbert spaces. The inner product and associated norm will be symbolized by $\langle \cdot, \cdot \rangle$ and $\|\cdot\|$, respectively:

$$\|x\| = \sqrt{\langle x, x \rangle}.$$

We assume the reader is familiar with the basic properties of inner product spaces (see, e.g., [18, Chap. I]), including the Cauchy–Schwarz inequality

$$|\langle x, y \rangle| \leq \|x\| \|y\|.$$

A Hilbert space H is *complete*, that is, Cauchy sequences in H converge:

$$\text{if } \lim_{n,m \rightarrow \infty} \|x_n - x_m\| = 0, \quad \text{then } \|x_n - x\| \rightarrow 0,$$

for some $x \in H$. The smallest (in the sense of inclusion) Hilbert space that contains a given inner product space is known as the *completion* of the inner product space. (Every inner product space has a unique completion.)

The space, denoted $L^2[a, b]$, of measurable functions on an interval $[a, b]$ whose squares are Lebesgue integrable, with inner product

$$\langle f, g \rangle = \int_a^b f(t)g(t) dt,$$

is the prototypical example of a Hilbert space. The *Sobolev space* of order m , $H^{(m)}[a, b]$, is the completion with respect to the norm

$$\|f\|_0 = \left(\sum_{k=0}^m \|f^{(k)}\|_0^2 \right)^{1/2},$$

associated with the inner product

$$\langle f, g \rangle_m = \sum_{k=0}^m \langle f^{(k)}, g^{(k)} \rangle_0,$$

of the space of functions having m continuous derivatives on $[a, b]$. Here $\langle \cdot, \cdot \rangle_0$ and $\|\cdot\|_0$ are the $L^2[a, b]$ norm and inner product; of course, $H^{(0)}[a, b] = L^2[a, b]$.

Two vectors x and y in a Hilbert space H are called *orthogonal*, denoted $x \perp y$, if $\langle x, y \rangle = 0$. The Pythagorean Theorem,

$$x \perp y \iff \|x + y\|^2 = \|x\|^2 + \|y\|^2,$$

is a key notion that suggests the transfer of familiar geometrical ideas from Euclidean space to Hilbert space. The *orthogonal complement* of a set S is the closed subspace

$$S^\perp = \{x \in H : x \perp s, \quad \text{for all } s \in S\}.$$

It is not difficult to show that if S is a subspace, then $S^{\perp\perp} = \bar{S}$, where \bar{S} is the *closure* of S , that is, the smallest closed subspace that contains S . A closed subspace S of a Hilbert space H engenders a Cartesian decomposition of H , symbolized by $H = S \oplus S^\perp$, meaning that each $x \in H$ has a unique representation of the form $x = x_1 + x_2$, where $x_1 \in S$ is the projection of x onto S :

$$\|x - x_1\| = \inf \{\|x - y\| : y \in S\},$$

and similarly x_2 is the projection of x onto S^\perp . The projection of a vector x onto a closed subspace S is denoted by $P_S x$.

A set of mutually orthogonal vectors each of which has unit norm is called an *orthonormal* set. An orthonormal set S is *complete* if $S^\perp = \{0\}$. A *complete orthonormal system* for a Hilbert space is a sequence of vectors in H , which is complete and orthonormal. For example, $\{\sin n\pi t : n = 1, 2, 3, \dots\}$ is a complete orthonormal system for the Hilbert space $L^2[0, 1]$. Each vector $x \in H$ has a convergent Fourier expansion in terms of a complete orthonormal system $\{\varphi_n\}_{n=1}^\infty$ for H :

$$x = \sum_{n=1}^{\infty} \langle x, \varphi_n \rangle \varphi_n,$$

of which *Parseval's identity* is an immediate consequence

$$\|x\|^2 = \sum_{n=1}^{\infty} |\langle x, \varphi_n \rangle|^2.$$

Weak Convergence

“Weak” notions are crucial to our development of mathematics for inverse problems. Suppose the class of functions of interest forms a real Hilbert space H with an inner product $\langle \cdot, \cdot \rangle$ and associated norm $\|\cdot\|$. A *functional* is a mapping from H to \mathbf{R} . It is helpful to think of a functional as a measurement on elements of H . Proportionality and additivity are natural features of most measuring processes. A functional $F : H \rightarrow \mathbf{R}$ with these features, that is, satisfying

$$F(\alpha x + \beta y) = \alpha F(x) + \beta F(y)$$

where α and β are scalars and $x, y \in H$, is called a *linear functional*. Another common and highly desirable feature of a measurement process is *continuity*: elements of H which are nearly the same should result in measurements that are nearly the same. In mathematical terms, a functional F is continuous if, as $n \rightarrow \infty$,

$$\|x_n - x\| \rightarrow 0 \quad \text{implies} \quad |F(x_n) - F(x)| \rightarrow 0.$$

For example, if the Hilbert space is $L^2[0, T]$, the space of square integrable functions on $[0, T]$, then the average value functional,

$$F(x) = \frac{1}{T} \int_0^T x(\tau) d\tau,$$

is a continuous linear functional. (This is an immediate consequence of the Cauchy–Schwarz inequality.)

The Riesz Representation Theorem characterizes continuous linear functionals on a Hilbert space:

A continuous linear functional F on H has a unique representation of the form

$$F(x) = \langle x, \varphi \rangle$$

for some $\varphi \in H$.

This result is so fundamental that it is worthwhile to sketch a micro-proof. We may assume that F is not identically zero (otherwise, take $\varphi = 0$), and hence there is a $z \in H$, with $F(z) = 1$, which is orthogonal to the closed subspace

$$N = \{x \in H : F(x) = 0\}.$$

Then $x - F(x)z \in N$ for all $x \in H$, and hence $\varphi = z/\|z\|^2$ fits the bill

$$0 = \langle x - F(x)z, z/\|z\|^2 \rangle = \langle x, \varphi \rangle - F(x).$$

Any two distinct vectors in H are distinguishable by some measurement in the form of a continuous linear functional. Indeed, if $\langle x - y, \varphi \rangle = 0$ for all $\varphi \in H$, then $x = y$ (set $\varphi = x - y$). However, it is possible for a sequence of vectors $\{x_n\}$, which does not converge in H to any vector, nevertheless to be ultimately indistinguishable from some vector x by bounded linear functionals. This is the idea of weak convergence. We say that $\{x_n\}$ converges *weakly* to x , symbolized $x_n \rightharpoonup x$, if $\langle x_n, \varphi \rangle \rightarrow \langle x, \varphi \rangle$ for every $\varphi \in H$. The simple identity

$$\|x - x_n\|^2 = \langle x - x_n, x - x_n \rangle = \|x\|^2 + \|x_n\|^2 - 2\langle x_n, x \rangle$$

shows that if $x_n \rightharpoonup x$ and $\|x_n\| \rightarrow \|x\|$, then x_n converges *strongly* to x , that is, $\|x_n - x\| \rightarrow 0$.

In a Hilbert space, every sequence of vectors whose norms are uniformly bounded has a subsequence that is weakly convergent (e.g., [18], p. 205). We note that any complete orthonormal system $\{\varphi_n\}$ converges weakly to zero, for by Parseval's identity

$$\sum_n |\langle x, \varphi_n \rangle|^2 = \|x\|^2,$$

and hence $\langle x, \varphi_n \rangle \rightarrow 0$ as $n \rightarrow \infty$ for each $x \in H$.

A set is called weakly closed if it contains the weak limit of every weakly convergent sequence of vectors in the set. Hilbert spaces have the following feature (see, e.g., [30]), which is fundamental in the theory of optimization:

Suppose C is a weakly closed convex subset of a Hilbert space H . For each $x \in H$, there is a unique vector $P_C(x) \in C$ such that

$$\|x - P_C(x)\| = \inf\{\|x - u\| : u \in C\}.$$

$P_C(x)$ is called the metric projection of x onto C . It can be shown that a closed convex set is also weakly closed.

Linear Operators

A bounded linear operator from a Hilbert space H_1 into a Hilbert space H_2 is a mapping $K : H_1 \rightarrow H_2$, which is linear, $K(\alpha x + \beta y) = \alpha Kx + \beta Ky$, and for which the number

$$\|K\| = \sup\{\|Kx\|/\|x\| : x \neq 0\}$$

is finite. Note that we have used the same symbol for the norm in each of the spaces; this generally will be our practice in the sequel. If K is a bounded linear operator, then K is (uniformly) continuous since

$$\|Kx - Ky\| = \|K(x - y)\| \leq \|K\|\|x - y\|.$$

For our purposes, the most cogent example of a bounded linear operator is an integral operator $K : L^2[a, b] \rightarrow L^2[c, d]$ of the form

$$Kf(t) = \int_a^b k(t, s) f(s) ds, \quad c \leq t \leq d, \quad (7)$$

where $k(\cdot, \cdot) \in L^2([c, d] \times [a, b])$ is called the *kernel* of the integral operator. The kernel is called *degenerate* if it has the form

$$k(t, s) = \sum_{j=1}^m T_j(t) S_j(s)$$

where the T_j and the S_j are each linearly independent sets of functions of a single variable. In this case the range, $R(K)$, of the operator K is the finite-dimensional subspace

$$R(K) = \text{span}\{T_j : j = 1, \dots, m\}$$

and

$$Kf(t) = \sum_{j=1}^m \langle k(t, \cdot), f \rangle T_j(t),$$

where $\langle \cdot, \cdot \rangle$ is the $L^2[a, b]$ inner product.

The *adjoint* of a bounded linear operator $K : H_1 \rightarrow H_2$ is the bounded linear operator $K^* : H_2 \rightarrow H_1$, which satisfies

$$\langle Kx, y \rangle = \langle x, K^*y \rangle$$

for all $x \in H_1$ and $y \in H_2$. For example, by changing the order of integration, one can see that the adjoint of the integral operator (7) is

$$K^*g(s) = \int_c^d k(u, s)g(u) du.$$

A bounded linear operator $K : H \rightarrow H$ is called *self-adjoint* if $K^* = K$. The *null-space* of a bounded linear operator $K : H_1 \rightarrow H_2$ is the closed subspace

$$N(K) = \{x \in H_1 : Kx = 0\}.$$

Note that $N(K^*K) = N(K)$ for if $x \in N(K^*K)$, then

$$0 = \langle K^*Kx, x \rangle = \langle Kx, Kx \rangle = \|Kx\|^2.$$

There are fundamental relationships between the null-space and the range

$$R(K) = \{Kx : x \in H_1\},$$

of a linear operator and its adjoint. In fact, $y \in R(K)^\perp$ if and only if

$$0 = \langle Kx, y \rangle = \langle x, K^*y \rangle$$

for all $x \in H_1$, and hence $R(K)^\perp = N(K^*)$. It follows that $\overline{R(K)} = R(K)^{\perp\perp} = N(K^*)^\perp$. Replacing K by K^* in these relations (noting that $K^{**} = K$), we obtain the four fundamental relationships:

$$R(K)^\perp = N(K^*), \quad \overline{R(K)} = N(K^*)^\perp$$

$$R(K^*)^\perp = N(K), \quad \overline{R(K^*)} = N(K)^\perp.$$

Examples in a previous section have highlighted the unstable nature of solutions of inverse problems. This instability is conveniently phrased in terms of linear operators that are *unbounded*. Unbounded linear operators are typically defined only on restricted subspaces of the Hilbert space. For example, $L^2[0, \pi]$ contains discontinuous, and hence nondifferentiable, functions. But the differentiation operator may be defined on the proper subspace of $L^2[0, \pi]$ consisting of differentiable functions with derivatives in $L^2[0, \pi]$. This differentiation operator is unbounded since

$$\left\| \frac{1}{n} \sin n^2 t \right\|^2 = \frac{\pi}{2n^2} \rightarrow 0 \quad \text{as } n \rightarrow \infty,$$

while

$$\left\| \frac{d}{dt} \left(\frac{1}{n} \sin n^2 t \right) \right\|^2 = \frac{\pi}{2} n^2 \rightarrow \infty \quad \text{as } n \rightarrow \infty.$$

The reverse diffusion process is also governed by an unbounded operator. As seen in (5), the operator L , which maps the temperature distribution $g(x) = u(x, T)$ to the initial temperature distribution $f(x) = u(x, 0)$, is defined on the subspace

$$\mathcal{D}(L) = \left\{ g \in L^2[0, \pi] : \sum_{n=1}^{\infty} e^{2kn^2T} |b_n|^2 < \infty \right\},$$

where

$$b_n = \frac{2}{\pi} \int_0^{\pi} g(s) \sin ns \, ds.$$

L is unbounded because the functions $\varphi_m(s) = \sin ms$ reside in $\mathcal{D}(L)$ and satisfy $\|\varphi_m\|^2 = \pi/2$, but by the orthogonality relationships,

$$L\varphi_m = e^{km^2T} \varphi_m,$$

and hence $\|L\varphi_m\|^2 = e^{2km^2T} \pi/2 \rightarrow \infty$ as $m \rightarrow \infty$.

Compact Operators and the SVD

A bounded linear operator $K : H_1 \rightarrow H_2$ of the form

$$Kx = \sum_{j=1}^r \langle x, v_j \rangle u_j, \tag{8}$$

where $\{u_j\}_{j=1}^r$ is a linearly independent set of vectors in H_2 and $\{v_j\}_{j=1}^r$ is a set of vectors in H_1 , is called an operator of finite rank (with rank = r). For example, an integral operator on $L^2[a, b]$ with a degenerate kernel is an operator of finite rank. Finite rank operators transform weakly convergent sequences into strongly convergent sequences: if $x_n \rightharpoonup x$, then

$$Kx_n = \sum_{j=1}^r \langle x_n, v_j \rangle u_j \rightarrow \sum_{j=1}^r \langle x, v_j \rangle u_j = Kx.$$

More generally, a linear operator is called *compact* if it enjoys this weak-to-strong continuity, that is, if $x_n \rightharpoonup x$ implies that $Kx_n \rightarrow Kx$. In terms of our metaphor of bounded linear functionals as measurements, one could say that if the linear operator K modeling an inverse problem is compact, and if all measurements on a sequence of functions $\{x_n\}$ are ultimately indistinguishable from the corresponding measurements on x , then the model values Kx_n are ultimately indistinguishable from Kx . That is, causes, which are ultimately indistinguishable by linear measurement processes, result in effects that are ultimately indistinguishable. It is therefore not surprising that compact operators occur frequently in models of linear inverse problems.

Erhard Schmidt's theory of singular functions, now called the singular value decomposition (SVD), is the most versatile and effective tool for the analysis of compact linear operators. (The SVD has been rediscovered several times in various contexts; for the curious history of the SVD, see [65].) The SVD extends the representation (8) in a particularly useful way. A singular system $\{v_j, u_j; \mu_j\}_{j=1}^{\infty}$ for a compact linear operator K bundles a complete orthonormal system $\{v_j\}_{j=1}^{\infty}$ for $N(K)^{\perp}$, consisting of eigenvectors of K^*K ; a complete orthonormal system $\{u_j\}_{j=1}^{\infty}$ for $N(K^*)^{\perp} = \overline{R(K)}$, consisting of eigenvectors of KK^* ; and a sequence of positive numbers μ_j , called singular values of K . The singular values and singular vectors are tied together by the relationships

$$Kv_j = \mu_j u_j, \quad K^*u_j = \mu_j v_j, \quad j = 1, 2, 3, \dots.$$

Every compact linear operator has a singular system, and the action of the operator may be expressed in terms of the SVD as

$$Kx = \sum_{j=1}^{\infty} \mu_j \langle x, v_j \rangle u_j \tag{9}$$

In case K has finite rank r , this sum terminates at $j = r$, and otherwise

$$\mu_j \rightarrow 0, \quad \text{as } j \rightarrow \infty.$$

We shall see that this fact is singularly important in the analysis of inverse problems.

As an example of the SVD of a nonself-adjoint compact operator, consider the integral operator $K : L^2[0, \pi] \rightarrow L^2[0, \pi]$ defined by

$$(Kf)(t) = \int_0^{\pi} h(t, u) f(u) du$$

where

$$h(t, u) = \begin{cases} 1, & 0 \leq u \leq t \\ 0, & t < u \leq \pi. \end{cases}$$

One can verify that a singular system $\{v_j, u_j; \mu_j\}_{j=1}^{\infty}$ for this operator is

$$v_j(t) = \sqrt{\frac{2}{\pi}} \cos\left(\frac{2j+1}{2}t\right), \quad u_j(s) = \sqrt{\frac{2}{\pi}} \sin\left(\frac{2j+1}{2}s\right), \quad \mu_j = \frac{2}{2j+1}.$$

A compact operator has closed range if and only if it has finite rank. This follows from the SVD and the open mapping theorem (e.g., [18], p. 166). Indeed, if K is compact and $R(K)$ is closed, then the restricted operator $K : N(K)^{\perp} \rightarrow R(K)$ is one-to-one and onto, and hence has a bounded inverse. That is, there is a positive number m such that $\|Kx\| \geq m\|x\|$ for all $x \in N(K)^{\perp}$. But then, by (9),

$$\mu_j = \mu_j \|u_j\| = \|Kv_j\| \geq m\|v_j\| = m > 0,$$

and hence K has only finitely many singular values for otherwise $\mu_j \rightarrow 0$. This result is highly significant in inverse theory for it says that finite rank linear models, when pushed too far toward the limiting case of an operator of infinite rank, will inevitably result in instability.

In 1910, Emil Picard [60] established a criterion that characterizes the existence of solutions of an equation of the first kind

$$Kx = y, \tag{10}$$

where K is a compact linear operator. Picard's criterion plays a role in inverse theory analogous to that which the Fredholm alternative plays for integral equations of the second kind.

Since $\{v_j\}$ is a complete orthonormal system for $N(K)^{\perp}$, the series

$$\sum_{j=1}^{\infty} |\langle x, v_j \rangle|^2$$

is convergent (and equals $\|P_{N(K)^{\perp}}x\|^2$). However, if $y = Kx \in R(K)$, then

$$\langle x, v_j \rangle = \mu_j^{-1} \langle x, K^* u_j \rangle = \mu_j^{-1} \langle Kx, u_j \rangle = \mu_j^{-1} \langle y, u_j \rangle,$$

and so

$$\sum_{j=1}^{\infty} \mu_j^{-2} |\langle y, u_j \rangle|^2 < \infty$$

is a necessary condition for $y \in R(K)$.

On the other hand, this condition guarantees that the series

$$x = \sum_{j=1}^{\infty} \mu_j^{-1} \langle y, u_j \rangle v_j \quad (11)$$

is convergent in $R(K)^\perp$ and the singular value relations show that $Kx = P_{N(K^*)^\perp} y$. Taken together these results establish the *Picard Criterion*:

$$y \in R(K) \Leftrightarrow y \in N(K^*)^\perp \quad \text{and} \quad \sum_{j=1}^{\infty} \mu_j^{-2} |\langle y, u_j \rangle|^2 < \infty. \quad (12)$$

If y satisfies Picard's criterion, then $y = Kx$ where x is given by (11).

The Moore–Penrose Inverse

If $y \notin R(K)$, then the equation $Kx = y$ has no solution, but this should not prevent one from doing the best one can to try to solve the problem. Perhaps the best that can be done is to seek a vector u that is as near as possible to serving as a solution. A vector $u \in H_1$ that minimizes the quadratic functional

$$F(x) = \|Kx - y\|^2$$

is called a *least squares* solution of $Kx = y$. It is not hard to see that a least squares solution exists if and only if y belongs to the dense subspace $R(T) + R(T)^\perp$ of H_2 . Also, as the geometry suggests, u is a least squares solution if and only if $y - Ku \in R(K)^\perp = N(K^*)$, and hence least squares solutions are vector v that satisfy the so-called normal equation

$$K^* Kv = K^* y. \quad (13)$$

Furthermore, the solution set of (13) is closed and convex and therefore contains a unique vector nearest to the origin (i.e., of smallest norm), say v^\dagger . This smallest norm least squares solution v^\dagger lies in $N(K)^\perp$, for otherwise $Pv^\dagger \neq 0$, where P is the orthogonal projector onto $N(K)$. The Pythagorean theorem then gives

$$\|v^\dagger\|^2 = \|v^\dagger - Pv^\dagger\|^2 + \|Pv^\dagger\|^2.$$

But, since $K^* KPv^\dagger = 0$, this implies that $v^\dagger - Pv^\dagger$ is a least squares solution with norm smaller than that of v^\dagger . This contradiction ensures that $v^\dagger \in N(K)^\perp$.

The operator $K^\dagger : \mathcal{D}(K^\dagger) \rightarrow N(K)^\perp$, which associates with each y in the dense subspace $\mathcal{D}(K^\dagger) = R(K) + R(K)^\perp$ of H_2 the unique minimum norm least squares solution $K^\dagger y \in N(K)^\perp$ of the equation $Kx = y$, is called the Moore–Penrose generalized inverse of K . (E. H. Moore died when Roger (now Sir Roger) Penrose was an infant; [5] tells the story of how the names of both men came to be associated with the generalized inverse.)

If K is a compact linear operator with SVD $\{v_j, u_j; \mu_j\}$ and $y \in \mathcal{D}(K^\dagger)$, then the vector

$$\sum_{j=1}^{\infty} \frac{1}{\mu_j} \langle y, u_j \rangle v_j$$

is well defined by Picard's criterion, resides in $N(K)^\perp$, and is a least squares solution. Therefore,

$$K^\dagger y = \sum_{j=1}^{\infty} \frac{1}{\mu_j} \langle y, u_j \rangle v_j. \quad (14)$$

The operator K^\dagger so defined is linear, but it is unbounded (unless K has finite rank) since

$$\|u_n\| = 1, \quad \text{but} \quad \|K^\dagger u_n\| = 1/\mu_n \rightarrow \infty \quad \text{as} \quad n \rightarrow \infty. \quad (15)$$

There is an immense literature on generalized inverses; see [54] for a start.

Alternating Projection Theorem

Draw a pair of intersecting lines. Take a point at random in the plane spanned by the lines, and project it onto the first line. Then project that point onto the second line, and continue in this manner projecting alternately onto each line in turn. It soon becomes apparent that the sequence of points so generated zigzags and converges to the point that is common to both lines. In 1933, von Neumann showed the same behavior for two closed subspaces S_1 and S_2 of a Hilbert space H . Namely, for each $x \in H$,

$$(P_{S_2} P_{S_1})^n x \rightarrow P_{S_2 \cap S_1} x \quad \text{as} \quad n \rightarrow \infty,$$

where P_W stands for the orthogonal projector onto the closed subspace W . This result extends easily to the case where S_1 and S_2 are translates of closed subspaces, that is, closed affine sets (see, e.g., [18, 35] for proofs). In fact, a modification of the method, due to Boyle and Dykstra (see [18], p. 213), provides a sequence that converges to the metric projection onto the intersection of a finite collection of closed convex sets.

Stefan Kaczmarz [48] developed an alternating projection algorithm, independently of von Neumann, for approximating solutions of underdetermined systems of linear algebraic equations. (See [57] concerning Kaczmarz's early and tragic demise.) A solution $\vec{x} \in \mathbf{R}^n$ of a system of m linear equations in n unknowns with coefficient matrix A and right-hand side \vec{b} lies in the intersection of the hyperplanes

$$\pi_i = \{\vec{x} \in \mathbf{R}^n : \langle \vec{a}_i, \vec{x} \rangle = b_i\}, \quad i = 1, 2, \dots, m,$$

where \vec{a}_i is the i th row vector of A . Kaczmarz's algorithm, which consists of successively and cyclically projecting onto these hyperplanes, produces a sequence of vectors that converges to that vector in the intersection of the hyperplanes, which is nearest to the initial approximation (see [20] for a complete treatment of the method). Kaczmarz's method has come to be known as ART (the algebraic reconstruction technique) in the tomography community.

the idea of approximation.
Bertrand Russell

Tikhonov Regularization

The unboundedness of the operator K^\dagger , displayed in (15), is a fundamental challenge when solving linear inverse problems of the form $Kx = y$. This unboundedness is manifested as instability when the data vector y contains errors, which is always the case in practical circumstances as the data result from observation and measurement. Small errors in high-order singular components $\langle y, u_n \rangle$ (n large) will be magnified by the factor $1/\mu_n$ in the representation (14), resulting in large deviations in the computed solution. Such instabilities in numerical solutions were noticed from the very beginning of the use of digital computers to solve linear inverse problems (see [31] for examples and references). The development of theoretical strategies to mitigate this instability is known as *regularization theory*.

One way to stabilize the solution process is to restrict the notion of solution. Tikhonov's classic result [66] of 1943 is an instance of this idea. In that paper Tikhonov treated the inverse problem of determining the spatial distribution of a uniform star-shaped mass lying below the horizontal surface from measurements of the gravitational potential on the surface. He showed that the inverse problem becomes well posed if the forward operator is restricted to a certain compact set. Another approach is to modify the forward operator itself without a restriction on its domain. In what has come to be known as Tikhonov regularization, the notion of solution is generalized to the minimum norm least squares solution, which is unstable, but a stable approximation to this generalized solution, depending on a *regularization parameter*, is constructed.

The idea of Tikhonov regularization may be introduced from either an algebraic or a variational viewpoint. Algebraically, the method, in its simplest form, consists in replacing the normal equation (13) with the second kind equation

$$K^*Kv + \alpha v = K^*y, \quad (16)$$

where α is a positive parameter. The key point is that the problem of solving (16) is *well posed*. Indeed,

$$\|x\|^2 \|K^* K + \alpha I\| \geq \langle (K^* K + \alpha I)x, x \rangle = \|Kx\|^2 + \alpha \|x\|^2 \geq \alpha \|x\|^2,$$

and hence $(K^* K + \alpha I)^{-1}$ is a bounded linear operator; in fact, $\|(K^* K + \alpha I)^{-1}\| \leq 1/\alpha$. The significance of this fact is that for fixed $\alpha > 0$, the approximation

$$x_\alpha = (K^* K + \alpha I)^{-1} K^* y \quad (17)$$

depends continuously on y . Specifically, suppose y^δ is an observed version of y satisfying $\|y - y^\delta\| \leq \delta$, and let x_α^δ be the approximation formed using this approximate data, that is,

$$x_\alpha^\delta = (K^* K + \alpha I)^{-1} K^* y^\delta.$$

From the SVD we have

$$x_\alpha - x_\alpha^\delta = \sum_{j=1}^{\infty} \frac{\mu_j}{\mu_j^2 + \alpha} \langle y - y^\delta, u_j \rangle v_j,$$

and hence

$$\begin{aligned} \|x_\alpha - x_\alpha^\delta\|^2 &\stackrel{?}{=} \sum_{j=1}^{\infty} \frac{\mu_j^2}{\mu_j^2 + \alpha} \frac{1}{\mu_j^2 + \alpha} |\langle y - y^\delta, u_j \rangle|^2 \\ &\leq \frac{1}{\alpha} \sum_{j=1}^{\infty} |\langle y - y^\delta, u_j \rangle|^2 \leq \delta^2 / \alpha. \end{aligned} \quad (18)$$

If the minimum norm least squares solution $K^\dagger y$ satisfies the *source condition* $K^\dagger y = K^* K w$, for some $w \in H_1$, then one can show that

$$K^\dagger y - x_\alpha = \alpha(K^* K + \alpha I)^{-1} K^* K w$$

and hence

$$\|K^\dagger y - x_\alpha\|^2 = \alpha^2 \sum_{j=1}^{\infty} \left(\frac{\mu_j^2}{\mu_j^2 + \alpha} \right)^2 |\langle w, v_j \rangle|^2 \leq \alpha^2 \|w\|^2. \quad (19)$$

Combining this with (18), we see that if $K^\dagger y \in R(K^* K)$, then

$$\|x_\alpha^\delta - K^\dagger y\| \leq \delta / \sqrt{\alpha} + O(\alpha).$$

Therefore, an a priori choice of the regularization parameter of the form

$$\alpha = \alpha(\delta) = C\delta^{2/3}, \quad (20)$$

yields a convergence rate of the form

$$\|x_{\alpha(\delta)}^\delta - K^\dagger y\| = O(\delta^{2/3}). \quad (21)$$

This two thirds power rate is an asymptotic ‘‘brick wall’’ for Tikhonov regularization in the sense that it is impossible to uniformly improve it to a $o(\delta^{2/3})$ rate unless the compact operator K has finite rank (see [27]). Roughly speaking, this says that the best one can hope for is $2m$ -digit accuracy in the solution if there is $3m$ -digit accuracy in the data.

The Tikhonov approximation (17) has a variational characterization that is useful in both theoretical analysis and computational implementation. The equation (16) that characterizes the Tikhonov approximation is the Euler equation for the functional

$$F_\alpha(\cdot; y) = \|K \cdot - y\|^2 + \alpha \|\cdot\|^2, \quad (22)$$

and hence the approximation (17) is a global minimizer of (22). This opens the possibility of applying standard optimization techniques for calculating the Tikhonov approximation. Next we illustrate the usefulness of the variational characterization in a convergence analysis for an a posteriori selection technique for the regularization parameter known as Morozov’s discrepancy principle.

The a priori parameter selection criterion (20) is of theoretical interest as it gives information on the order of magnitude of the regularization parameter that can be expected to result in a convergent procedure. However, a posteriori methods of choosing the regularization parameter that depend on the actual progress of the computations would be expected to lead to more satisfactory results. Morozov’s *discrepancy principle* [53] is the earliest parameter choice strategy of this type. Morozov’s idea (which was presaged by Phillips [31, 59]) is to choose the regularization parameter in such a way that the size of the residual $\|Kx_\alpha^\delta - g^\delta\|$ is equal to error level in the data:

$$\|Kx_\alpha^\delta - y^\delta\| = \delta. \quad (23)$$

It should be recognized that this condition contains some ‘‘slack’’ as δ , the bound for the data error, might not be tight. Nevertheless, this choice is not only possible, but it leads to a convergent procedure, as we now show.

If $\|y^\delta\| > \delta$, that is, there is more signal than noise in the data, and if $y \in R(K)$, then there is a unique positive parameter α satisfying (23). To see this, we use the SVD

$$\|Kx_\alpha^\delta - y^\delta\|^2 = \sum_{j=1}^{\infty} \left(\frac{\alpha}{\mu_j^2 + \alpha} \right)^2 |\langle y^\delta, u_j \rangle|^2 + \|Py^\delta\|^2 \quad (24)$$

where P is the orthogonal projector of H_2 onto $R(K)^\perp$. From this we see that the real function

$$\psi(\alpha) = \|Kx_\alpha^\delta - y^\delta\|$$

is a continuous, strictly increasing function of α satisfying (since $Py = 0$)

$$\lim_{\alpha \rightarrow 0^+} \psi(\alpha) = \|Py^\delta\| = \|Pg^\delta - Pg\| \leq \|y^\delta - y\| \leq \delta$$

and

$$\lim_{\alpha \rightarrow \infty} \psi(\alpha) = \|y^\delta\| > \delta.$$

The intermediate value theorem then guarantees a unique $\alpha = \alpha(\delta)$ satisfying (23).

We now show that the choice $\alpha(\delta)$ as given by the discrepancy method (23) leads to a regular scheme for approximating $K^\dagger y$:

$$x_{\alpha(\delta)}^\delta \rightarrow K^\dagger y \text{ as } \delta \rightarrow 0.$$

To this end it is sufficient to show that for any sequence $\delta_n \rightarrow 0$, there is a subsequence, which we will denote by $\{\delta_k\}$, that satisfies $x_{\alpha(\delta_k)}^{\delta_k} \rightarrow K^\dagger y$. The argument relies on the following previously discussed facts: norm-bounded sequences contain a weakly convergent subsequence, and weak convergence along with convergence of the norms implies strong convergence.

We assume that $y \in R(K)$ and that $K : H_1 \rightarrow H_2$ is a compact linear operator, and we let $x = K^\dagger y$. That is, x is the unique vector in $N(K)^\perp$ satisfying $Kx = y$.

The variational characterization of the Tikhonov approximation $x_{\alpha(\delta)}^\delta$ as the global minimizer of the quadratic functional $F_{\alpha(\cdot)}(\cdot; y^\delta)$ (see (22)) implies that

$$F_{\alpha(\delta)}(x_{\alpha(\delta)}^\delta; y^\delta) \leq F_{\alpha(\delta)}(x; y^\delta),$$

that is,

$$\begin{aligned} \delta^2 + \alpha(\delta) \|x_{\alpha(\delta)}^\delta\|^2 &= \|Kx_{\alpha(\delta)}^\delta - y^\delta\|^2 + \alpha(\delta) \|x_{\alpha(\delta)}^\delta\|^2 \\ &\leq F_{\alpha(\delta)}(x) = \|y - y^\delta\|^2 + \alpha(\delta) \|x\|^2 \\ &\leq \delta^2 + \alpha(\delta) \|x\|^2 \end{aligned}$$

and hence $\|x_{\alpha(\delta)}^\delta\| \leq \|x\|$. Therefore, for any sequence $\delta_n \rightarrow 0$, there is a subsequence $\delta_k \rightarrow 0$ with $x_{\alpha(\delta_k)}^{\delta_k} \rightharpoonup w$ for some w . But

$$x_{\alpha(\delta)}^\delta = K^*(KK^* + \alpha(\delta)I)^{-1}y^\delta \in R(K^*) \subseteq N(K)^\perp$$

and $N(K)^\perp$ is weakly closed, and so $w \in N(K)^\perp$. Furthermore,

$$\left\| Kx_{\alpha(\delta_k)}^{\delta_k} - y^{\delta_k} \right\| \rightarrow 0$$

and hence $Kx_{\alpha(\delta_k)}^{\delta_k} \rightarrow y$. But as K is compact, $Kx_{\alpha(\delta_k)}^{\delta_k} \rightarrow Kw$, and it follows that $Kw = y$ and $w \in N(K)^\perp$, that is, $w = x$. Since $\|x_{\alpha(\delta_k)}^{\delta_k}\| \leq \|x\|$, we then have

$$\|x\|^2 = \lim_{k \rightarrow \infty} \langle x_{\alpha(\delta_k)}^{\delta_k}, x \rangle \leq \lim_{k \rightarrow \infty} \|x_{\alpha(\delta_k)}^{\delta_k}\| \cdot \|x\|$$

and therefore

$$\|x\| \leq \lim_{k \rightarrow \infty} \|x_{\alpha(\delta_k)}^{\delta_k}\| \leq \overline{\lim}_{k \rightarrow \infty} \|x_{\alpha(\delta_k)}^{\delta_k}\| \leq \|x\|.$$

So we have shown that $x_{\alpha(\delta_k)}^{\delta_k} \rightharpoonup x$ and $\|x_{\alpha(\delta_k)}^{\delta_k}\| \rightarrow \|x\|$, and hence $x_{\alpha(\delta_k)}^{\delta_k} \rightarrow x$, completing the proof.

It can be shown that, under the source condition $x \in R(K^*)$, Tikhonov's method with parameter choice by the discrepancy principle (23) achieves an asymptotic order of accuracy $O(\sqrt{\delta})$; however, a swifter rate of $o(\sqrt{\delta})$ is generally impossible except in the case when K has finite rank [26]. Engl and Gfrerer (see [19, Chap. 4]) have developed a modification of the discrepancy principle that achieves the optimal order of convergence.

Our sketch of the basic theory of Tikhonov regularization has assumed that the regularization functional, which augments the least square objective functional $\|K \cdot - y\|^2$, is (the square of) a norm. (Note however that while the same symbol is used for the norm in each of the spaces H_1 and H_2 , these norms may be distinct. In his original paper [67], Tikhonov used a Sobolev norm on the solution space and an L^2 norm on the data space.) Phillips [59], in a paper that barely predates that of Tikhonov, used a regularizing semi-norm – the L^2 norm of the second derivative. In all of these cases, the equation characterizing the regularized approximation is linear. However, certain non-quadratic regularizing functionals, leading to nonlinear problems for determining the regularized approximation, are found to be effective in imaging science. Of particular note is the total variation, or TV, functional:

$$\text{TV}(u) = \int_{\Omega} |\nabla u|,$$

where $u : \Omega \subseteq \mathbf{R}^n \rightarrow \mathbf{R}$. Regularization now consists of minimizing the augmented least squares functional

$$F_\alpha(u) = \|Ku - y\|_{L^2(\Omega)}^2 + \alpha \text{TV}(u),$$

where K is the identity operator for denoising problems, while for deblurring problems, K is the blurring operator associated with a known point spread function. A full exposition may be found in [62].

Iterative Regularization

Ordinary Tikhonov regularization consists in minimizing the functional

$$F_\alpha(z) = \|Kz - y\|^2 + \alpha\|z\|^2$$

for a range of positive regularization parameters α . In iterated Tikhonov regularization, $\alpha > 0$ is *fixed*, an initial approximation x_0 is selected (we take $x_0 = 0$ for simplicity; a general initial approximation requires only small modifications to the arguments), and successive approximations are updated by a multistage optimization scheme in which the n th approximation is chosen to minimize the functional

$$F_n(z) = \|Kz - y\|^2 + \alpha\|z - x_{n-1}\|^2, \quad n = 1, 2, 3, \dots \quad (25)$$

This results in the iterative method

$$x_n = (K^* K + \alpha I)^{-1}(\alpha x_{n-1} + K^* y), \quad n = 1, 2, 3, \dots$$

The conventional proof of the convergence of iterated Tikhonov regularization uses spectral theory. (See [41] for the more general case of nonstationary iterated Tikhonov regularization.) However, the convergence of the method is also an immediate consequence of the alternating projection theorem, as we now show.

Let \mathcal{H} be the product Hilbert space $H_1 \times H_2$ with norm $|\cdot|$ given by

$$|(x, y)|^2 = \|y\|^2 + \alpha\|x\|^2,$$

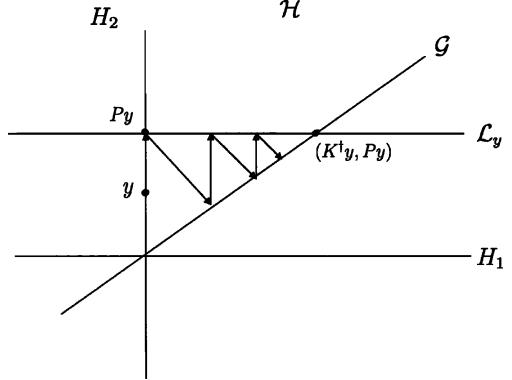

where α is a fixed positive constant. Note that the graph

$$\mathcal{G} = \{(x, Kx) : x \in H_1\}$$

is a closed subspace of \mathcal{H} . For a given $y \in H_2$, let

$$L_y = \{u \in H_1 : Ku = Py\},$$

Fig. 3 The geometry of iterated regularization

where P is the orthogonal projector of H_2 onto $\overline{R(K)}$, be the set of least squares solutions of $Kx = y$. One sees that $y \in \mathcal{D}(K^\dagger)$ if and only if L_y is nonempty. If $L_y = H_1 \times \{Py\}$, then L_y is a closed affine set in the Hilbert space \mathcal{H} , and $y \in \mathcal{D}(K^\dagger) \Leftrightarrow L_y \cap \mathcal{G} \neq \emptyset$. Furthermore,

$$\mathcal{P}_{L_y \cap \mathcal{G}}(0, y) = (K^\dagger y, Py),$$

where \mathcal{P}_W stands for the metric projector of \mathcal{H} onto a closed convex set $W \subseteq \mathcal{H}$.

From the variational characterization (25), one sees that

$$\mathcal{P}_{L_y}(x_0, Kx_0) = \mathcal{P}_{L_y}(0, 0) = (0, Py)$$

and $\mathcal{P}_{\mathcal{G}}(0, Py) = (x_1, Kx_1)$; therefore $(x_1, Kx_1) = \mathcal{P}_{\mathcal{G}}\mathcal{P}_{L_y}(x_0, Kx_0)$, and generally

$$(x_n, Kx_n) = \mathcal{P}_{\mathcal{G}}\mathcal{P}_{L_y}(x_{n-1}, Kx_{n-1}) = \dots = (\mathcal{P}_{\mathcal{G}}\mathcal{P}_{L_y})^n(0, y).$$

This process of projecting in alternate fashion in the space \mathcal{H} is illustrated in Fig. 3.

The alternating projection theorem then gives

$$(x_n, Kx_n) \rightarrow \mathcal{P}_{L_y \cap \mathcal{G}}(0, y) = (K^\dagger y, Py), \quad \text{as } n \rightarrow \infty.$$

If x_n^δ are defined as in (25), with y replaced by y^δ , then it is not difficult to see that

$$\|x_n - x_n^\delta\| \leq \sqrt{n}\|y - y^\delta\|,$$

and hence if $\|y - y^\delta\| \leq \delta$ and $n = n(\delta) \rightarrow \infty$ as $\delta \rightarrow 0$, in such a manner that $\sqrt{n(\delta)}\delta \rightarrow 0$, then $x_{n(\delta)}^\delta \rightarrow K^\dagger x$.

There are many other iterative methods for regularization of ill-posed problems (see [19, 49]). Perhaps the simplest is based on the observation that for any $\lambda > 0$, the subspace $N(K)^\perp$ is invariant under the mapping

$$F(z) = (I - \lambda K^* K)x + \lambda K^* y,$$

and $K^\dagger y$ is the unique fixed point of F in $N(K)^\perp$. Furthermore, if $0 < \lambda < 1/\|K^* K\|$, then F is a contraction and hence the iterative method

$$x_{n+1} = (I - \lambda K^* K)x_n + \lambda K^* y \quad (26)$$

converges to $K^\dagger y$ for any $x_0 \in N(K)^\perp$. This method was studied for Fredholm integral equations of the first kind by Landweber and independently by Fridman. It has since become known as Landweber iteration [51]. For this method one can show easily that if $\|y - y^\delta\| \leq \delta$, and x_n^δ represents the approximation obtained by (26) with y replaced by y^δ , then $x_{n(\delta)}^\delta \rightarrow K^\dagger y$, if $\sqrt{n(\delta)}\delta \rightarrow 0$.

The theory of Landweber iteration has been developed for nonlinear operators, including a stopping criterion based on the discrepancy principle, by Hanke et al. [42] (see also [49]). See [40] for a very useful survey of iterative regularization methods.

Discretization

► ... numerical precision is the very soul of science ...
D'Arcy Wentworth Thompson

The preceding discussion of regularization methods took place in the context of general (infinite-dimensional) Hilbert space. However, practical numerical computations are necessarily finitary. Passing from general elements in an infinite-dimensional space to finitely represented approximations involves a process of *discretization*. Discretization of an ill-posed problem can lead to a well-posed finite-dimensional problem; however, this discretized version generally will be *ill conditioned*. Regularization methods are meant to address this problem. There are two approaches to constructing computable regularizations of linear inverse problems; one could handle the ill posedness by first regularizing the infinite-dimensional problem and then discretizing the result, or one could discretize the original problem and then regularize the resulting ill-conditioned finite-dimensional problem. We give a couple of examples of discretized regularizations of the former type. (For results on discretized versions of general regularization methods, see [34].)

A key point in the theoretical convergence analysis of regularization methods is the interplay between the regularization parameter and the error properties of the data. For example, assuming a source condition of the form $K^\dagger y \in R(K^* K)$, the

balancing of the rate $O(\alpha)$ for the infinite-dimensional Tikhonov approximation x_α using “clean” data with the stability bound $\delta/\sqrt{\alpha}$ for the approximation using noisy data leads to the optimal rate $O(\delta^{2/3})$ found in (21). To obtain an overall convergence rate with respect to the error in data for discretized approximations, it is necessary to juggle three balls: a theoretical convergence rate, a measure of the quality of the discretization, and a stability bound. In both of the cases we consider, the measure of quality of the discretization will be denoted by γ_m . In our first example, γ_m measures how well a given finite-dimensional subspace $V_m \subseteq H_1$ supports the operator K , specifically,

$$\gamma_m = \|K(I - P_m)\|,$$

where P_m is the orthogonal projector of H_1 onto V_m . The smaller γ_m is, the better the subspace V_m supports the operator K . In the second example, the discretization of a regularized version of a Fredholm integral equation of the first kind is accomplished by applying a quadrature method to the iterated kernel that generates the operator K^*K . In this case, γ_m measures the quality of this quadrature. In both examples it is shown that it is theoretically possible to match the optimal rate $O(\delta^{2/3})$ established for the infinite-dimensional approximation in (21).

The variational characterization (22) immediately suggests a Ritz approach to discretization, namely, minimization of the Tikhonov functional over a finite-dimensional subspace. Note that the global minimum x_α of the functional $F_\alpha(\cdot; y)$ on H_1 may be characterized by the condition

$$\langle Kx_\alpha - Kx, Kv \rangle + \alpha \langle x_\alpha, v \rangle = 0, \quad \text{for all } v \in H_1, \quad (27)$$

where $x = K^\dagger y$. The bilinear form defined on H_1 by

$$q(u, v) = \langle Ku, Kv \rangle + \alpha \langle u, v \rangle$$

is an inner product on H_1 , and (27) may be succinctly expressed in terms of this inner product as

$$q(x_\alpha - x, v) = 0 \quad \text{for all } v \in H_1.$$

Suppose that $\{V_m\}_{m=1}^\infty$ is a sequence of finite-dimensional subspaces of H_1 satisfying

$$V_1 \subseteq V_2 \subseteq V_3 \subseteq \dots \subseteq H_1 \quad \text{and} \quad \overline{\cup_{m=1}^\infty V_m} = H_1.$$

The minimizer $x_{\alpha,m}$ of $F_\alpha(\cdot; y)$ over the finite-dimensional subspace V_m satisfies

$$q(x_{\alpha,m} - x, v_m) = 0 \quad \text{for all } v_m \in V_m,$$

and hence

$$q(x_\alpha - x_{\alpha,m}, v_m) = 0 \quad \text{for all } v_m \in V_m.$$

In other words, $x_{\alpha,m} = \mathcal{P}_m x_\alpha$, where \mathcal{P}_m is the projector of H_1 onto V_m , which is orthogonal in the sense of the inner product $q(\cdot, \cdot)$.

If $|\cdot|_q$ denotes the norm on H_1 associated with the inner product $q(\cdot, \cdot)$, that is,

$$|z|_q^2 = \|Kz\|^2 + \alpha\|z\|^2,$$

then, by the characteristic property of projectors,

$$|x_\alpha - x_{\alpha,m}|_q^2 = |x_\alpha - \mathcal{P}_m x_\alpha|_q^2 \leq |x_\alpha - P_m x_\alpha|_q^2,$$

where P_m is the projector of H_1 onto V_m associated with the (original) inner product on H_1 . But then (since projectors are idempotent),

$$\begin{aligned} \alpha\|x_\alpha - x_{\alpha,m}\|^2 &\leq |x_\alpha - x_{\alpha,m}|_q^2 \leq \|Kx_\alpha - KP_m x_\alpha\|^2 + \alpha\|(I - P_m)x_\alpha\|^2 \\ &= \|K(I - P_m)^2 x_\alpha\|^2 + \alpha\|(I - P_m)x_\alpha\|^2 \\ &\leq (\gamma_m + \alpha)\|(I - P_m)x_\alpha\|^2, \end{aligned}$$

where

$$\gamma_m = \|K(I - P_m)\|.$$

Therefore,

$$\|x_\alpha - x_{\alpha,m}\| \leq \sqrt{1 + \gamma_m/\alpha} \quad \|(I - P_m)x_\alpha\|.$$

If $K^\dagger y$ satisfies the source condition $x = K^\dagger y \in R(K^* K)$, say, $x = K^* K w$, then

$$(I - P_m)x_\alpha = (I - P_m)K^*(KK^* + \alpha I)^{-1}KK^*Kw,$$

and hence

$$\|(I - P_m)x_\alpha\| \leq \gamma_m\|Kw\|.$$

If $\gamma_m = O(\alpha_m)$, then we find from (19),

$$\|K^\dagger y - x_{\alpha,m}\| = O(\alpha_m).$$

In the case of approximate data y^δ satisfying $\|y - y^\delta\| \leq \delta$, one can show, using arguments of the same type as above, that a stability bound of the same form as (18) holds for the finite-dimensional approximations:

$$\|x_{\alpha,m} - x_{\alpha,m}^\delta\| \leq \delta/\sqrt{\alpha}.$$

Taking these results together, we see that if $K^\dagger y \in R(K^* K)$ and $\alpha_m = \alpha_m(\delta)$ is chosen in such a way that $\alpha_m = C\delta^{2/3}$ and $\gamma_m = O(\alpha_m)$, then the finite-dimensional approximations achieve the optimal order of convergence:

$$\|K^\dagger y - x_{\alpha(m),m}^\delta\| = O(\delta^{2/3}).$$

Quadrature is another common discretization technique. If a linear inverse problem is expressed as a Fredholm integral equation of the first kind

$$y(s) = \int_a^b k(s,t)x(t)dt, \quad c \leq s \leq d,$$

mapping functions $x \in L^2[a,b]$ to function $y \in L^2[c,d]$, then the Tikhonov approximation x_α is the solution of the well-posed Fredholm integral equation of the second kind

$$\int_c^d k(u,s)y(u)du = \alpha x_\alpha(s) + \int_a^b \tilde{k}(s,t)x_\alpha(t)dt, \quad a \leq s \leq b,$$

where the iterated kernel $\tilde{k}(\cdot, \cdot)$ is given by

$$\tilde{k}(s,t) = \int_c^d k(u,s)k(u,t)du, \quad a \leq s, t \leq b.$$

If a convergent quadrature scheme with positive weights $\{w_j^{(m)}\}_{j=1}^m$, and nodes $\{u_j^{(m)}\}_{j=1}^m$, is applied to the iterated kernel, a degenerate kernel

$$\tilde{k}_m(s,t) = \sum_{j=1}^m w_j^{(m)} k(u_j^{(m)}, s) k(u_j^{(m)}, t)$$

results, converting the infinite-dimensional Tikhonov problem into the finite rank problem

$$\alpha x_{\alpha,m} + \tilde{K}_m x_{\alpha,m} = K^* y \quad (28)$$

where

$$\tilde{K}_m z = \sum_{j=1}^m w_j^{(m)} \langle k_j, z \rangle k_j \quad \text{and} \quad k_j(s) = k(u_j^{(m)}, s).$$

The problem (28) is equivalent to an $m \times m$ linear algebraic system with a unique solution. The convergence of the approximations resulting from this finite system to the infinite-dimensional Tikhonov approximation $x_\alpha \in L^2[a, b]$ depends on the number

$$\gamma_m = \|\tilde{K}_m - K^* K\|.$$

If $\alpha = \alpha(m) \rightarrow 0$ as $m \rightarrow \infty$ and $\gamma_m = O(\alpha(m))$, then it can be shown that $x_{\alpha(m),m} \rightarrow K^\dagger y$. Furthermore, a stability bound of the form $O(\delta/\sqrt{\alpha})$ holds under appropriate conditions, and one can show that the optimal rate $O(\delta^{2/3})$ is achievable if the parameters governing the finite-dimensional approximations are appropriately related [29]. A much more extensive analysis along these lines is carried out in [11]. For more on numerical methods for discrete inverse problems, see [43, 70].

5 Conclusion

► Eventually, we reach the dim boundary . . .
 There, we measure shadows . . .
 Edwin Hubble

The first book devoted exclusively to the mathematical theory of inverse and ill-posed problems was that of Tikhonov and Arsenin [68]. Kirsch [50] is a fine treatment of the general theory of inverse problems, and Engl et al. [19] is the best comprehensive presentation of the theory of regularization for inverse and ill-posed problems. Other useful books on the general topic are [46] and [69]. A number of books and survey articles treat inverse theory in a specific context. Some of the areas treated include astronomy [16], engineering [45], geophysics [58], imaging [6, 7, 9, 10, 20, 44, 55, 62], mathematical physics [24], oceanography [4, 73], parameter estimation [3], indirect measurement [2], and vibration analysis [23].

Abstract

Large-scale inverse problems arise in a variety of significant applications in image processing, and efficient regularization methods are needed to compute meaningful solutions. This chapter surveys three common mathematical models including a linear model, a separable nonlinear model, and a general nonlinear model. Techniques for regularization and large-scale implementations are con-

sidered, with particular focus on algorithms and computations that can exploit structure in the problem. Examples from image deconvolution, multi-frame blind deconvolution, and tomosynthesis illustrate the potential of these algorithms. Much progress has been made in the field of large-scale inverse problems, but many challenges still remain for future research.

1 Introduction

Powerful imaging technologies, including very large telescopes, synthetic aperture radar, medical imaging scanners, and modern microscopes, typically combine a device that collects electromagnetic energy (e.g., photons) with a computer that assembles the collected data into images that can be viewed by practitioners, such as scientists and doctors. The “assembling” process typically involves solving an *inverse problem*; that is, the image is reconstructed from indirect measurements of the corresponding object. Many inverse problems are also *ill-posed*, meaning that small changes in the measured data can lead to large changes in the solution, and special tools or techniques are needed to deal with this instability. In fact, because real data will not be exact (it will contain at least some small amount of noise or other errors from the data collection device), it is not possible to find the exact solution. Instead, a physically realistic approximation is sought. This is done by formulating an appropriate *regularized* (i.e., stabilized) problem, from which a good approximate solution can be computed.

Inverse problems are ubiquitous in imaging applications, including deconvolution (or, more generally, deblurring) [1, 51], superresolution (or image fusion) [18, 27], image registration [70], image reconstruction [74, 75], seismic imaging [31], inverse scattering [15], and radar imaging [17]. These problems are referred to as *large-scale* because they typically require processing a large amount of data (the number of pixels or voxels in the discretized image) and systems with a large (e.g., 10^9 for a 3D image reconstruction problem) number of equations. Mathematicians began to rigorously study inverse problems in the 1960s, and this interest has continued to grow over the past few decades due to applications in fields such as biomedical, seismic, and radar imaging; see, for example, [12, 28, 47, 49, 99] and the references therein.

We remark that the discussion in this chapter does not address some very important issues that can arise in PDE-based inverse problems, such as adjoints and proper meshing. Inverse problems such as these arise in important applications, including PDE parameter identification, seismic imaging, and inverse scattering; we refer those interested in these topics and applications to the associated chapters in this handbook and the references therein.

This chapter discusses computational approaches to compute approximate solutions of large-scale inverse problems. Mathematical models and some applications are presented in Sect. 2. Three basic models are considered: a general nonlinear model, a linear model, and a mixed linear/nonlinear model. Several regularization approaches are described in Sect. 3. Numerical methods that can be used to compute

approximate solutions for the three basic models, along with illustrative examples from specific imaging applications, are described in Sect. 4. Concluding remarks, including a partial list of open questions, are provided in Sect. 5.

2 Background

A mathematical framework for inverse problems is presented in this chapter, including model problems and imaging applications. Although only a limited number of imaging applications are considered, the model problems, which range from linear to nonlinear, are fairly general and can be used to describe many other applications. For more complete treatments of inverse problems and regularization, see [12, 28, 47, 49, 50, 99].

Model Problems

An inverse problem involves the estimation of certain quantities using information obtained from indirect measurements. A general mathematical model to describe this process is given by

$$\mathbf{b}_{\text{exact}} = F(\mathbf{x}_{\text{exact}}), \quad (1)$$

where $\mathbf{x}_{\text{exact}}$ denotes the exact (or ideal) quantities that need to be estimated and $\mathbf{b}_{\text{exact}}$ is used to represent perfectly measured (error-free) data. The function F is defined by the data collection process and is assumed known. Typically, it is assumed that F is defined on Hilbert spaces and that it is continuous and weakly sequentially closed [29].

Unfortunately, in any real application, it is impossible to collect error-free data, so a more realistic model of the data collection process is given by

$$\mathbf{b} = F(\mathbf{x}_{\text{exact}}) + \boldsymbol{\eta}, \quad (2)$$

where $\boldsymbol{\eta}$ represents noise and other errors in the measured data. The precise form of F depends on the application; the following three general problems are considered in this chapter:

- For linear problems, $F(\mathbf{x}) = \mathbf{A}\mathbf{x}$, where \mathbf{A} is a linear operator. In this case, the data collection process is modeled as

$$\mathbf{b} = \mathbf{A}\mathbf{x}_{\text{exact}} + \boldsymbol{\eta},$$

and the inverse problem is: given \mathbf{b} and \mathbf{A} , compute an approximation of $\mathbf{x}_{\text{exact}}$.

- In some cases, \mathbf{x} can be separated into two distinct components, $\mathbf{x}^{(\ell)}$ and $\mathbf{x}^{(n\ell)}$, with $F(\mathbf{x}) = F(\mathbf{x}^{(\ell)}, \mathbf{x}^{(n\ell)}) = \mathbf{A}(\mathbf{x}^{(n\ell)})\mathbf{x}^{(\ell)}$, where \mathbf{A} is a linear operator defined

by $\mathbf{x}^{(n\ell)}$. That is, the data \mathbf{b} depends linearly on $\mathbf{x}^{(\ell)}$ and nonlinearly on $\mathbf{x}^{(n\ell)}$. In this case, the data collection process is modeled as

$$\mathbf{b} = \mathbf{A} \left(\mathbf{x}_{\text{exact}}^{(n\ell)} \right) \mathbf{x}_{\text{exact}}^{(\ell)} + \boldsymbol{\eta},$$

and the inverse problem is: given \mathbf{b} and the parametric form of \mathbf{A} , compute approximations of $\mathbf{x}_{\text{exact}}^{(n\ell)}$ and $\mathbf{x}_{\text{exact}}^{(\ell)}$.

- If the problem is not linear or separable, as described above, then the general nonlinear model,

$$\mathbf{b} = F(\mathbf{x}_{\text{exact}}) + \boldsymbol{\eta},$$

will be considered. In this case, the inverse problem is: given \mathbf{b} and F , compute an approximation of $\mathbf{x}_{\text{exact}}$.

In most of what follows, it is assumed that the problem has been discretized, so \mathbf{x} , \mathbf{b} , and $\boldsymbol{\eta}$ are vectors, and \mathbf{A} is a matrix. Depending on the constraints assumed and the complexity of the model used, problems may range from linear to fully nonlinear. This is true of the applications described in the next subsection.

Imaging Applications

Three applications in image processing that lead to inverse problems are discussed in this subsection. For each application, the underlying mathematical model is described, and some background for the problem is presented. The formulation of each of these problems results in linear, separable, and nonlinear inverse problems, respectively.

Image Deblurring and Deconvolution

In many important applications, such as when ground-based telescopes are used to observe objects in space, the observed image is degraded by blurring and noise. Although the blurring can be partially avoided by using sophisticated and expensive imaging devices, computational post-processing techniques are also often needed to further improve the resolution of the image. This post-processing is known as *image deblurring*. To give a precise mathematical model of image deblurring, suppose $x(t)$, $t \in \mathcal{R}^d$, is a scalar function describing the true d -dimensional (e.g., for a plane image containing pixels, $d = 2$) image. Then the observed, blurred, and noisy image is given by

$$b(s) = \int_{\Omega} k(s, t)x(t)dt + \eta(s), \quad (3)$$

where $s \in \mathcal{R}^d$ and $\eta(s)$ represents additive noise. The kernel $k(s, t)$ is a function that specifies how the points in the image are distorted and is therefore called the point spread function (PSF). The inverse problem of image deblurring is: given k and b , compute an approximation of x . If the kernel has the property that $k(s, t) = k(s-t)$, then the PSF is said to be spatially invariant; otherwise, it is said to be spatially variant. In the spatially invariant case, the blurring operation, $\int k(s-t)x(t)dt$, is convolution, and thus the corresponding inverse problem is called *deconvolution*.

In a realistic problem, images are collected only at discrete points (pixels or voxels) and are only available in a finite bounded region. Therefore, one must usually work directly either with a semi-discrete model

$$b(s_j) = \int_{\Omega} k(s_j, t)x(t)dt + \eta_j \quad j = 1, \dots, N$$

where N is the number of pixels or voxels in the observed image or with the fully discrete model

$$\mathbf{b} = \mathbf{Ax}_{\text{exact}} + \boldsymbol{\eta},$$

where $\mathbf{x}_{\text{exact}}$, \mathbf{b} , and $\boldsymbol{\eta}$ are vectors obtained by discretizing functions x , b , and η and \mathbf{A} is a matrix that arises when approximating the integration operation with, for example, a quadrature rule. Moreover, a precise kernel representation of the PSF may not be known but instead must be constructed experimentally from the imaging system by generating images of “point sources.” What constitutes a point source depends on the application. For example, in atmospheric imaging, the point source can be a single bright star [53]. In microscopy, the point source is typically a fluorescent microsphere having a diameter that is about half the diffraction limit of the lens [24]. For general motion blurs, the PSF is described by the direction (e.g., angle) and speed at which objects are moving [56].

For spatially invariant blurs, one point source image and appropriate boundary conditions are enough to describe the matrix \mathbf{A} . This situation has been well studied; algorithms to compute approximations of \mathbf{x} can be implemented efficiently with fast Fourier transforms (FFT) or other trigonometric transforms [1, 51]. More recently, an approach has been proposed where the data can be transformed to the Radon domain so that computations can be done efficiently with, for example, wavelet filtering techniques [26].

Spatially variant blurs also occur in a variety of important applications. For example, in positron emission tomography (PET), patient motion during the relatively long scan times causes reconstructed images to be corrupted by nonlinear, nonuniform spatially variant motion blur [33, 84]. Spatially variant blurs also occur when the object and image coordinates are tilted relative to each other, as well as in X-ray projection imaging [100], lens distortions [65], and wave aberrations [65]. Moreover, it is unlikely that the blur is truly spatially invariant in any realistic application, especially over large image planes.

Various techniques have been proposed to approximately model spatially variant blurs. For example, in the case of patient motion in PET brain imaging, a motion detection device is used to monitor the position of the patient's head during the scan time. This information can then be used to construct a large sparse matrix \mathbf{A} that models the motion blur. Other, more general techniques include coordinate transformation [68], image partitioning [93], and PSF interpolation [72, 73].

Multi-Frame Blind Deconvolution

The image deblurring problem described in the previous subsection assumes that the blurring operator, or PSF, is known. However, in most cases, only an approximation of the operator, or an approximation of parameters that defines the operator, is known. For example, as previously mentioned, the PSF is often constructed experimentally from the imaging system by generating images of point sources. In many cases, such approximations are fairly good and are used to construct the matrix \mathbf{A} in the linear model. However, there are situations where it is not possible to obtain good approximations of the blurring operator, and it is necessary to include this knowledge in the mathematical model. Specifically, consider the general image formation model

$$\mathbf{b} = \mathbf{A} \left(\mathbf{x}_{\text{exact}}^{(n\ell)} \right) \mathbf{x}_{\text{exact}}^{(\ell)} + \boldsymbol{\eta} \quad (4)$$

where \mathbf{b} is a vector representing the observed, blurred, and noisy image and $\mathbf{x}_{\text{exact}}^{(\ell)}$ is a vector representing the unknown true image to be reconstructed. $\mathbf{A} \left(\mathbf{x}_{\text{exact}}^{(n\ell)} \right)$ is an ill-conditioned matrix defining the blurring operator. For example, in the case of spatially invariant blurs, $\mathbf{x}_{\text{exact}}^{(n\ell)}$ could simply be the pixel (image space) values of the PSF. Or $\mathbf{x}_{\text{exact}}^{(n\ell)}$ could be a small set of parameters that define the PSF, such as with a Zernike polynomial-based representation [67]. In general, the number of parameters defining $\mathbf{x}_{\text{exact}}^{(n\ell)}$ is significantly smaller than the number of pixels in the observed image. As in the previous subsection, $\boldsymbol{\eta}$ is a vector that represents unknown additive noise in the measured data. The term *blind deconvolution* is used for algorithms that attempt to jointly compute approximations of $\mathbf{x}_{\text{exact}}^{(n\ell)}$ and $\mathbf{x}_{\text{exact}}^{(\ell)}$ from the separable inverse problem given by Eq. (4).

Blind deconvolution problems are highly underdetermined, which present many challenges to optimization algorithms that can easily become trapped in local minima. This difficulty has been well-documented; see, for example, [64, 67]. To address challenges of nonuniqueness, it may be necessary to include additional constraints, such as nonnegativity and bounds on the computed approximations $\mathbf{x}^{(n\ell)}$ and $\mathbf{x}^{(\ell)}$.

Multi-frame blind deconvolution (MFBD) [64, 67] reduces some of the nonuniqueness problems by collecting multiple images of the same object, but with different blurring operators. Specifically, suppose a set of (e.g., m) observed images of the same object are modeled as

$$\mathbf{b}_i = \mathbf{A} \left(\mathbf{x}_i^{(n\ell)} \right) \mathbf{x}_{\text{exact}}^{(\ell)} + \boldsymbol{\eta}_i, \quad i = 1, 2, \dots, m. \quad (5)$$

Then, a general separable inverse problem of the form given by Eq.(4) can be obtained by setting

$$\mathbf{b} = \begin{bmatrix} \mathbf{b}_1 \\ \vdots \\ \mathbf{b}_m \end{bmatrix}, \quad \mathbf{x}_{\text{exact}}^{(n\ell)} = \begin{bmatrix} \mathbf{x}_1^{(n\ell)} \\ \vdots \\ \mathbf{x}_m^{(n\ell)} \end{bmatrix}, \quad \boldsymbol{\eta} = \begin{bmatrix} \boldsymbol{\eta}_1 \\ \vdots \\ \boldsymbol{\eta}_m \end{bmatrix}.$$

Although multiple frames reduce, to some extent, the nonuniqueness problem, they do not completely eliminate it. In addition, compared to single-frame blind deconvolution, there is a significant increase in the computational complexity of processing the large, multiple data sets.

There are many approaches to solving the blind and multi-frame blind deconvolution problem; see, for example, [14]. In addition, many other imaging applications require solving separable inverse problems, including super resolution (which is an example of image data fusion) [18, 27, 57, 76], the reconstruction of 3D macromolecular structures from 2D electron microscopy images of cryogenically frozen samples (Cryo-EM) [22, 35, 55, 66, 82, 88], and seismic imaging applications [40].

Tomosynthesis

Modern conventional X-ray systems that use digital technology have many benefits to the classical film X-ray systems, including the ability to obtain high-quality images with lower-dosage X-rays. The term “conventional” is used to refer to a system that produces a 2D projection image of a 3D object, as opposed to computed tomography (CT), which produces 3D images. Because of the inexpensive cost, low X-ray dosage, and ease of use, digital X-ray systems are widely used in medicine, from emergency rooms, to mammography, to dentistry.

Tomosynthesis is a technique that can produce 3D image information of an object using conventional X-ray systems [25]. The basic idea underlying tomosynthesis is that multiple 2D image projections of the object are taken at varying incident angles, and each 2D image provides different information about the 3D object. See Fig. 1 for an illustration of a typical geometry for breast tomosynthesis imaging. The relationship between the multiple 2D image projections and the 3D object can be modeled as a nonlinear inverse problem. Reconstruction algorithms that solve this inverse problem should be able to reconstruct any number of slices of the 3D object. Sophisticated approaches used for 3D CT reconstruction cannot be applied here because projections are only taken from a limited angular range, leaving entire regions of the frequency space unsampled. Thus, alternative approaches need to be considered.

The mathematical model described in this section is specifically designed for breast imaging and assumes a polyenergetic (i.e., multiple energy) X-ray source. It is first necessary to determine what quantity will be reconstructed. Although most X-ray projection models are derived in terms of the values of the attenuation coefficients for the voxels, it is common in breast imaging to interpret the voxels as a composition of adipose tissue, glandular tissue, or a combination of both [42].

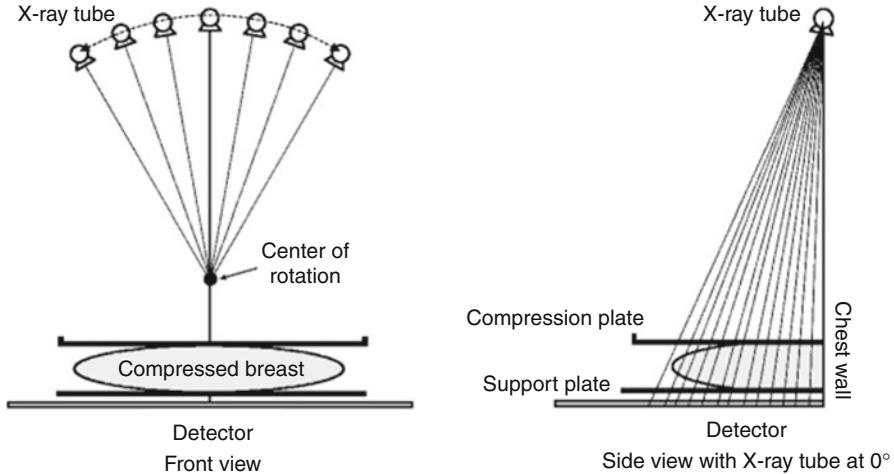

Fig. 1 Breast tomosynthesis example. Typical geometry of the imaging device used in breast imaging

Thus, each voxel of the object can be represented using the percentage glandular fraction, that is, the percentage of glandular tissue present in that voxel. If density or attenuation coefficient values are desired, then these can be obtained from the glandular fraction through a simple algebraic transformation.

Now assume that the 3D object is discretized into a regular grid of voxels and that each of the 2D projection images is discretized into a regular grid of pixels. Specifically, let N represent the number of voxels in the discretized 3D object and let M be the number of pixels in a discretized 2D projection image. In practice, N is on the order of a few billion and M is the order of a few million, depending on the size of the imaging detector. The energy-dependent linear attenuation coefficient for voxel $j = 1, 2, \dots, N$ in the breast can be represented as

$$\mu(e)^{(j)} = s(e)x_{\text{exact}}^{(j)} + z(e),$$

where $x_{\text{exact}}^{(j)}$ represents the percentage glandular fraction in voxel j of the “true” object and $s(e)$ and $z(e)$ are known energy-dependent linear fit coefficients. This type of decomposition to reduce the number of degrees of freedom, which is described in more detail in [20], is similar to an approach used by De Man et al. [23] for CT, in which they express the energy-dependent linear attenuation coefficient in terms of its photoelectric component and Compton scatter component.

The projections are taken from various angles in a predetermined angular range, and the photon energies can be discretized into a fixed number of levels. Let there be n_θ angular projections and assume the incident X-ray has been discretized into n_e photon energy levels. In practice, a typical scan may have $n_\theta = 21$ and $n_e = 43$. For a particular projection angle, compute a monochromatic ray trace for one energy

level and then sum over all energies. Let $a^{(ij)}$ represent the length of the ray that passes through voxel j , contributing to pixel i . Then, the discrete monochromatic ray trace for pixel i can be represented by

$$\sum_{j=1}^N \mu(e)^{(j)} a^{(ij)} = s(e) \sum_{j=1}^N x_{\text{exact}}^{(j)} a^{(ij)} + z(e) \sum_{j=1}^N a^{(ij)}. \quad (6)$$

Using the standard mathematical model for transmission radiography, the i th pixel value for the θ th noise-free projection image, incorporating all photon energies present in the incident X-ray spectrum, can be written as

$$b_\theta^{(i)} = \sum_{e=1}^{n_e} \varrho(e) \exp \left(- \sum_{j=1}^N \mu(e)^{(j)} a^{(ij)} \right), \quad (7)$$

where $\varrho(e)$ is a product of the current energy with the number of incident photons at that energy. To simplify notation, define \mathbf{A}_θ to be an $M \times N$ matrix with entries $a^{(ij)}$. Then Eq. (6) gives the i th entry of the vector

$$s(e)\mathbf{A}_\theta \mathbf{x}_{\text{exact}} + z(e)\mathbf{A}_\theta \mathbf{1},$$

where $\mathbf{x}_{\text{exact}}$ is a vector whose j th entry is $x_{\text{exact}}^{(j)}$ and $\mathbf{1}$ is a vector of all ones. Furthermore, the θ th noise-free projection image in vector form can be written as

$$\mathbf{b}_\theta = \sum_{e=1}^{n_e} \varrho(e) \exp(-[s(e)\mathbf{A}_\theta \mathbf{x}_{\text{exact}} + z(e)\mathbf{A}_\theta \mathbf{1}]), \quad (8)$$

where the exponential function is applied component-wise.

Tomosynthesis reconstruction is a nonlinear inverse problem where the goal is to approximate the volume, $\mathbf{x}_{\text{exact}}$, given the set of projection images from various angles, $\mathbf{b}_\theta, \theta = 1, 2, \dots, n_\theta$. This can be put in the general nonlinear model

$$\mathbf{b} = F(\mathbf{x}_{\text{exact}}) + \boldsymbol{\eta},$$

where

$$\mathbf{b} = \begin{bmatrix} \mathbf{b}_1 \\ \vdots \\ \mathbf{b}_{n_\theta} \end{bmatrix} \quad \text{and} \quad F(\mathbf{x}) = \begin{bmatrix} \sum_{e=1}^{n_e} \varrho(e) \exp(-[s(e)\mathbf{A}_1 \mathbf{x} + z(e)\mathbf{A}_1 \mathbf{1}]) \\ \vdots \\ \sum_{e=1}^{n_e} \varrho(e) \exp(-[s(e)\mathbf{A}_{n_\theta} \mathbf{x} + z(e)\mathbf{A}_{n_\theta} \mathbf{1}]) \end{bmatrix}$$

3 Mathematical Modeling and Analysis

A significant challenge when attempting to compute approximate solutions of inverse problems is that they are typically ill-posed. To be precise, in 1902 Hadamard defined a well-posed problem as one that satisfies the following requirements:

1. The solution is unique;
2. The solution exists for arbitrary data;
3. The solution depends continuously on the data.

Ill-posed problems, and hence most inverse problems, typically fail to satisfy at least one of these criteria. It is worth mentioning that this definition of an ill-posed problem applies to continuous mathematical models and not precisely to the discrete approximations used in computational methods. However, the properties of the continuous ill-posed problem are often carried over to the discrete problem in the form of a particular kind of ill-conditioning, making certain (usually high frequency) components of the solution very sensitive to errors in the measured data; this property is discussed in more detail for linear problems in section “Linear Problems.” Of course, this may depend on the level of discretization; a coarsely discretized problem may not be very ill-conditioned, but it also may not bear much similarity to the underlying continuous problem.

Regularization is a term used to refer to various techniques that modify the inverse problem in an attempt to overcome the instability caused by ill-posedness. Regularization seeks to incorporate a priori knowledge into the solution process. Such knowledge may include information about the amount or type of noise, the smoothness or sparsity of the solution, or restrictions on the values the solution may obtain. Each regularization method also requires choosing one or more regularization parameters. A variety of approaches are discussed in this section.

The theory for regularizing linear problems is much more developed than it is for nonlinear problems. This is due, in large part, to the fact that the numerical treatment of nonlinear inverse problems is often highly dependent on the particular application. However, good intuition can be gained by first studying linear inverse problems.

Linear Problems

Consider the linear inverse problem

$$\mathbf{b} = \mathbf{Ax}_{\text{exact}} + \boldsymbol{\eta},$$

where \mathbf{b} and \mathbf{A} are known, and the aim is to compute an approximation of $\mathbf{x}_{\text{exact}}$. The linear problem is a good place to illustrate the challenges that arise when attempting

to solve large-scale inverse problems. In addition, some of the regularization methods and iterative algorithms discussed here can be used in, or generalized for, nonlinear inverse problems.

SVD Analysis

A useful tool in studying linear inverse problems is the singular value decomposition (SVD). Any $m \times n$ matrix \mathbf{A} can be written as

$$\mathbf{A} = \mathbf{U}\Sigma\mathbf{V}^T \quad (9)$$

where \mathbf{U} is an $m \times m$ orthogonal matrix, \mathbf{V} is an $n \times n$ orthogonal matrix, and Σ is an $m \times n$ diagonal matrix containing the singular values $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_{\min(m,n)} \geq 0$. If \mathbf{A} is nonsingular, then an approximation of $\mathbf{x}_{\text{exact}}$ is given by the inverse solution

$$\mathbf{x}_{\text{inv}} = \mathbf{A}^{-1}\mathbf{b} = \sum_{i=1}^n \frac{\mathbf{u}_i^T \mathbf{b}}{\sigma_i} \mathbf{v}_i = \underbrace{\sum_{i=1}^n \frac{\mathbf{u}_i^T \mathbf{b}_{\text{exact}}}{\sigma_i} \mathbf{v}_i}_{\mathbf{x}_{\text{exact}}} + \underbrace{\sum_{i=1}^n \frac{\mathbf{u}_i^T \boldsymbol{\eta}}{\sigma_i} \mathbf{v}_i}_{\text{error}}$$

where \mathbf{u}_i and \mathbf{v}_i are the singular vectors of \mathbf{A} (i.e., the columns of \mathbf{U} and \mathbf{V} , respectively). As indicated above, the inverse solution is comprised of two components: $\mathbf{x}_{\text{exact}}$ and an error term. Before discussing algorithms to compute approximations of $\mathbf{x}_{\text{exact}}$, it is useful to study the error term.

For matrices arising from ill-posed inverse problems, the following properties hold:

- The matrix \mathbf{A} is severely ill-conditioned, with the singular values σ_i decaying to zero without a significant gap to indicate numerical rank.
- The singular vectors corresponding to the small singular values tend to oscillate more (i.e., have higher frequency) than singular vectors corresponding to large singular values.
- The components $|\mathbf{u}_i^T \mathbf{b}_{\text{exact}}|$ decay on average faster than the singular values σ_i . This is referred to as the *discrete Picard condition* [49].

The first two properties imply that the high-frequency components of the error term are highly magnified by division of small singular values. The computed inverse solution is dominated by these high-frequency components and is in general a very poor approximation of $\mathbf{x}_{\text{exact}}$. However, the third property suggests that there is hope of reconstructing some information about $\mathbf{x}_{\text{exact}}$; that is, an approximate solution can be obtained by reconstructing components corresponding to the large singular values and filtering out components corresponding to small singular values.

Regularization by SVD Filtering

The SVD filtering approach to regularization is motivated by observations made in the previous subsection. That is, by filtering out components of the solution corresponding to the small singular values, a reasonable approximation of $\mathbf{x}_{\text{exact}}$ can be computed. Specifically, an SVD-filtered solution is given by

$$\mathbf{x}_{\text{filt}} = \sum_{i=1}^n \phi_i \frac{\mathbf{u}_i^T \mathbf{b}}{\sigma_i} \mathbf{v}_i, \quad (10)$$

where the *filter factors*, ϕ_i , satisfy $\phi_i \approx 1$ for large σ_i , and $\phi_i \approx 0$ for small σ_i .

That is, the large singular value components of the solution are reconstructed, while the components corresponding to the small singular values are filtered out. Different choices of filter factors lead to different methods. Some examples include:

| Truncated SVD filter | Tikhonov filter | Exponential filter |
|--|---|---|
| $\phi_i = \begin{cases} 1 & \text{if } \sigma_i > \tau \\ 0 & \text{if } \sigma_i \leq \tau \end{cases}$ | $\phi_i = \frac{\sigma_i^2}{\sigma_i^2 + \alpha^2}$ | $\phi_i = 1 - e^{-\sigma_i^2/\alpha^2}$ |

Note that using a Taylor series expansion of the exponential term in the exponential filter, it is not difficult to see that the Tikhonov filter is a truncated approximation of the exponential filter. Moreover, the Tikhonov filter has an equivalent variational form, which is described in section “Variational Regularization and Constraints”.

Observe that each of the filtering methods has a parameter (e.g., in the above examples, τ and α) that needs to be chosen to specify how much filtering is done. Appropriate values depend on properties of the matrix \mathbf{A} (i.e., on its singular values and singular vectors) as well as on the data, \mathbf{b} . Some techniques to help guide the choice of the regularization parameter are discussed in section “Choosing Regularization Parameters.”

Because the SVD can be very expensive to compute for large matrices, this explicit filtering approach is generally not used for large-scale inverse problems. There are some exceptions, though, if \mathbf{A} is highly structured. For example, suppose \mathbf{A} can be decomposed as a Kronecker product,

$$\mathbf{A} = \mathbf{A}_r \otimes \mathbf{A}_c = \begin{bmatrix} a_{11}^{(r)} \mathbf{A}_c & a_{12}^{(r)} \mathbf{A}_c & \cdots & a_{1n}^{(r)} \mathbf{A}_c \\ a_{21}^{(r)} \mathbf{A}_c & a_{22}^{(r)} \mathbf{A}_c & \cdots & a_{2n}^{(r)} \mathbf{A}_c \\ \vdots & \vdots & & \vdots \\ a_{n1}^{(r)} \mathbf{A}_c & a_{n2}^{(r)} \mathbf{A}_c & \cdots & a_{nn}^{(r)} \mathbf{A}_c \end{bmatrix}$$

where \mathbf{A}_c is an $m \times m$ matrix, and \mathbf{A}_r is an $n \times n$ matrix with entries denoted by $a_{ij}^{(r)}$. Then this block structure can be exploited when computing the SVD and when implementing filtering algorithms [51].

It is also sometimes possible to use an alternative factorization. Specifically, suppose that

$$\mathbf{A} = \mathbf{Q}\Lambda\mathbf{Q}^*,$$

where Λ is a diagonal matrix and \mathbf{Q}^* is the complex conjugate transpose of \mathbf{Q} , with $\mathbf{Q}^*\mathbf{Q} = \mathbf{I}$. This is called a spectral factorization, where the columns of \mathbf{Q} are eigenvectors and the diagonal elements of Λ are the eigenvalues of \mathbf{A} . Although every matrix has an SVD, only normal matrices (i.e., matrices that satisfy $\mathbf{A}^*\mathbf{A} = \mathbf{A}\mathbf{A}^*$) have a spectral decomposition. However, if \mathbf{A} has a spectral factorization, then it can be used, in place of the SVD, to implement the filtering methods described in this section. The advantage is that it is sometimes more computationally convenient to compute a spectral decomposition than an SVD; an example of this is given in section “Linear Example: Deconvolution.”

Variational Regularization and Constraints

Variational regularization methods have the form

$$\min_{\mathbf{x}} \left\{ \|\mathbf{b} - \mathbf{Ax}\|_2^2 + \alpha^2 \mathcal{J}(\mathbf{x}) \right\}, \quad (11)$$

where the regularization operator \mathcal{J} and the regularization parameter α must be chosen. The variational form provides a lot of flexibility. For example, one could include additional constraints on the solution, such as nonnegativity, or it may be preferable to replace the least squares criterion with the Poisson log likelihood function [3–5]. As with filtering, there are many choices for the regularization operator, \mathcal{J} , such as Tikhonov, total variation [16, 85, 99], and sparsity constraints [13, 34, 94]:

| Tikhonov | Total variation | Sparsity |
|---|---|---|
| $\mathcal{J}(\mathbf{x}) = \ \mathbf{Lx}\ _2^2$ | $\mathcal{J}(\mathbf{x}) = \left\ \sqrt{(\mathbf{D}_h\mathbf{x})^2 + (\mathbf{D}_v\mathbf{x})^2} \right\ _1$ | $\mathcal{J}(\mathbf{x}) = \ \mathbf{\Phi x}\ _1$ |

Tikhonov regularization, which was first proposed and studied extensively in the early 1960s [69, 83, 89–91], is perhaps the most well-known approach to regularizing ill-posed problems. \mathbf{L} is typically chosen to be the identity matrix, or a discrete approximation to a derivative operator, such as the Laplacian. If $\mathbf{L} = \mathbf{I}$, then it is not difficult to show that the resulting variational form of Tikhonov regularization, namely,

$$\min_{\mathbf{x}} \left\{ \|\mathbf{b} - \mathbf{Ax}\|_2^2 + \alpha^2 \|\mathbf{x}\|_2^2 \right\}, \quad (12)$$

can be written in an equivalent filtering framework by replacing \mathbf{A} with its SVD [49].

For total variation, \mathbf{D}_h and \mathbf{D}_v denote discrete approximations of horizontal and vertical derivatives of the 2D image \mathbf{x} , and the approach extends to 3D images in an obvious way. Efficient and stable implementation of total variation regularization is a nontrivial problem; see [16, 99] and the references therein for further details.

In the case of sparse reconstructions, the matrix Φ represents a basis in which the image, \mathbf{x} , is sparse. For example, for astronomical images that contain a few bright objects surrounded by a significant amount of black background, an appropriate choice for Φ might be the identity matrix. Clearly, the choice of Φ is highly dependent on the structure of the image \mathbf{x} . The usage of sparsity constraints for regularization is currently a very active field of research, with many open problems. We refer interested readers to the chapter in this handbook on *compressive sensing*, and the references therein.

We also mention that when the majority of the elements in the image \mathbf{x} are zero or near zero, as may be the case for astronomical or medical images, it may be wise to enforce nonnegativity constraints on the solution [4, 5, 99]. This requires that each element of the computed solution \mathbf{x} is not negative, which is often written as $\mathbf{x} \geq 0$. Though these constraints add a level of difficulty when solving, they can produce results that are more feasible than when nonnegativity is ignored.

Finally, it should be noted that depending on the structure of matrix \mathbf{A} , the type of regularization, and the additional constraints, a variety of optimization algorithms can be used to solve (11). In some cases, it is possible to use a very efficient filtering approach, but typically it is necessary to use an iterative method.

Iterative Regularization

As mentioned in section “Variational Regularization and Constraints,” iterative methods are often needed to solve the variational form of the regularized problem. An alternate approach to using variational regularization is to simply apply the iterative method to the least squares problem,

$$\min_{\mathbf{x}} \|\mathbf{b} - \mathbf{Ax}\|_2^2.$$

Note that if an iterative method applied to this unregularized problem is allowed to “converge,” it will converge to an inverse solution, \mathbf{x}_{inv} , which is corrupted by noise (recall the discussion in section “SVD Analysis”). However, many iterative methods have the property (provided the problem on which it is applied satisfies the discrete Picard condition) that the early iterations reconstruct components of the solution corresponding to large singular values, while components corresponding to small singular values are reconstructed at later iterations. Thus, there is an observed “semi-convergence” behavior in the quality of the reconstruction, whereby the approximate solution improves at early iterations and then degrades at later iterations (a more detailed discussion of this behavior is given in section “Hybrid Iterative-Direct Regularization” in the context of the iterative method LSQR). If

the iteration is terminated at an appropriate point, a regularized approximation of the solution is computed. Thus, the iteration index acts as the regularization parameter, and the associated scheme is referred to as an *iterative regularization method*.

Many algorithms can be used as iterative regularization methods, including Landweber [61], steepest descent, and the conjugate gradient method (e.g., for nonsymmetric problems, the CGLS implementation [8] or the LSQR implementation [80, 81], and for symmetric indefinite problems, the MR-II implementation [43]). Most iterative regularization methods can be put into a general framework associated with solving the minimization problem

$$\min f(\mathbf{x}) = \frac{1}{2} \mathbf{x}^T \mathbf{A}^T \mathbf{A} \mathbf{x} - \mathbf{x}^T \mathbf{A}^T \mathbf{b} \quad (13)$$

with a general iterative method of the form

$$\mathbf{x}_{k+1} = \mathbf{x}_k + \rho_k \mathbf{M}_k (\mathbf{A}^T \mathbf{b} - \mathbf{A}^T \mathbf{A} \mathbf{x}_k) = \mathbf{x}_k + \rho_k \mathbf{M}_k \mathbf{r}_k, \quad (14)$$

where $\mathbf{r}_k = \mathbf{A}^T \mathbf{b} - \mathbf{A}^T \mathbf{A} \mathbf{x}_k$. With specific choices of ρ_k and \mathbf{M}_k , one can obtain a variety of well-known iterative methods:

- The Landweber method is obtained by taking $\rho_k = \rho$ (i.e., ρ remains constant for each iteration) and $\mathbf{M}_k = \mathbf{I}$ (the identity matrix). Due to its very slow convergence, this classic approach is not often used for linear inverse problems. However, it is very easy to analyze the regularization properties of the Landweber iteration, and it can be useful for certain large-scale nonlinear ill-posed inverse problems.
- The steepest descent method is produced if $\mathbf{M}_k = \mathbf{I}$ is again fixed as the identity, but now ρ_k is chosen to minimize the residual at each iteration. That is, ρ_k is chosen as

$$\rho_k = \arg \min_{\rho > 0} f(\mathbf{x}_k + \rho \mathbf{r}_k).$$

- Again, this method typically has very slow convergence, but with proper preconditioning it may be competitive with other methods.
- It is also possible to obtain the conjugate gradient method by setting $\mathbf{M}_0 = \mathbf{I}$ and $\mathbf{M}_{k+1} = \mathbf{I} - \frac{\mathbf{s}_k \mathbf{y}_k^T}{\mathbf{y}_k^T \mathbf{s}_k}$, where $\mathbf{s}_k = \mathbf{x}_{k+1} - \mathbf{x}_k$ and $\mathbf{y}_k = \mathbf{A}^T \mathbf{A} (\mathbf{x}_{k+1} - \mathbf{x}_k)$. As with the steepest descent method, ρ_k is chosen to minimize the residual at each iteration. Generally, the conjugate gradient method converges much more quickly than Landweber or steepest descent.

Other iterative algorithms that can be put into this general frame work include the Brakhage v methods [10] and Barzilai and Borwein's lagged steepest descent scheme [6].

Hybrid Iterative-Direct Regularization

One of the main disadvantages of iterative regularization methods is that it can be very difficult to determine appropriate stopping criteria. To address this problem, work has been done to develop hybrid methods that combine variational approaches with iterative methods. That is, an iterative method, such as the LSQR implementation of the conjugate gradient method, is applied to the least squares problem $\min_{\mathbf{x}} \|\mathbf{Ax} - \mathbf{b}\|_2^2$, and variational regularization is incorporated within the iteration process. To understand how this can be done, it is necessary to briefly describe how the LSQR iterates are computed.

LSQR is based on the Golub-Kahan (sometimes referred to as Lanczos) bidiagonalization (GKB) process. Given an $m \times n$ matrix \mathbf{A} and vector \mathbf{b} , the k th GKB iteration computes an $m \times (k + 1)$ matrix \mathbf{W}_k , an $n \times k$ matrix \mathbf{Y}_k , an $n \times 1$ vector \mathbf{y}_{k+1} , and a $(k + 1) \times k$ bidiagonal matrix \mathbf{B}_k such that

$$\mathbf{A}^T \mathbf{W}_k = \mathbf{Y}_k \mathbf{B}_k^T + \gamma_{k+1} \mathbf{y}_{k+1} \mathbf{e}_{k+1}^T \quad (15)$$

$$\mathbf{A} \mathbf{Y}_k = \mathbf{W}_k \mathbf{B}_k, \quad (16)$$

where \mathbf{e}_{k+1} denotes the $(k + 1)$ st standard unit vector and \mathbf{B}_k has the form

$$\mathbf{B}_k = \begin{bmatrix} \gamma_1 & & & \\ \beta_2 & \gamma_2 & & \\ \ddots & \ddots & \ddots & \\ \beta_k & \gamma_k & & \\ & & & \beta_{k+1} \end{bmatrix}. \quad (17)$$

Matrices \mathbf{W}_k and \mathbf{Y}_k have orthonormal columns, and the first column of \mathbf{W}_k is $\mathbf{b}/\|\mathbf{b}\|_2$. Given these relations, an approximate solution \mathbf{x}_k can be computed from the *projected* least squares problem

$$\min_{\mathbf{x} \in R(\mathbf{Y}_k)} \|\mathbf{Ax} - \mathbf{b}\|_2^2 = \min_{\hat{\mathbf{x}}} \|\mathbf{B}_k \hat{\mathbf{x}} - \beta \mathbf{e}_1\|_2^2 \quad (18)$$

where $\beta = \|\mathbf{b}\|_2$ and $\mathbf{x}_k = \mathbf{Y}_k \hat{\mathbf{x}}$. An efficient implementation of LSQR does not require storing the matrices \mathbf{W}_k and \mathbf{Y}_k and uses an efficient updating scheme to compute $\hat{\mathbf{x}}$ at each iteration; see [81] for details.

An important property of GKB is that for small values of k , the singular values of the matrix \mathbf{B}_k approximate very well certain singular values of \mathbf{A} , with the quality of the approximation depending on the relative spread of the singular values; specifically, the larger the relative spread, the better the approximation [8, 37, 87]. For ill-posed inverse problems, the singular values decay to and cluster at zero, such as $\sigma_i = O(i^{-c})$ where $c > 1$ or $\sigma_i = O(c^i)$ where $0 < c < 1$ and $i = 1, 2, \dots, n$ [95, 96]. Thus, the relative gap between large singular values is generally much larger than the relative gap between small singular values. Therefore, if the GKB

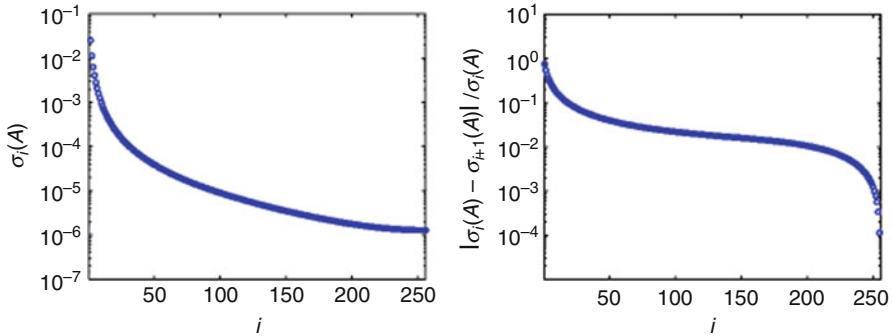

Fig. 2 This figure shows plots of the singular values of \mathbf{A} , denoted as $\sigma_i(\mathbf{A})$ (*left plot*), and the relative spread of \mathbf{A} 's singular values (*right plot*)

iteration is applied to a linear system arising from discretization of an ill-posed inverse problem, then the singular values of \mathbf{B}_k converge very quickly to the largest singular values of \mathbf{A} . The following example illustrates this situation.

Example 1. Consider a linear system obtained by discretization of a one-dimensional first-kind Fredholm integral equation of the form (3), where the kernel $k(s, t)$ is given by the Green's function for the second derivative and which is constructed using *deriv2* in the MATLAB package *Regularization Tools* [48]. Although this is not an imaging example, it is a small-scale canonical ill-posed inverse problem that has properties found in imaging applications. The *deriv2* function constructs an $n \times n$ matrix \mathbf{A} from the kernel

$$k(s, t) = \begin{cases} s(t-1) & \text{if } s < t \\ t(s-1) & \text{if } s \geq t \end{cases}$$

defined on $[0, 1] \times [0, 1]$. We use $n = 256$. There are also several choices for constructing vectors $\mathbf{x}_{\text{exact}}$ and $\mathbf{b}_{\text{exact}}$ (see [48]), but we focus only on the matrix \mathbf{A} in this example.

Figure 2 shows a plot of the singular values of \mathbf{A} and their relative spread; that is,

$$\frac{\sigma_i(\mathbf{A}) - \sigma_{i+1}(\mathbf{A})}{\sigma_i(\mathbf{A})},$$

where the notation $\sigma_i(\mathbf{A})$ is used to denote the i th largest singular value of \mathbf{A} . Figure 2 clearly illustrates the properties of ill-posed inverse problems; the singular values of \mathbf{A} decay to and cluster at 0. Moreover, it can be observed that in general the relative gap of the singular values is larger for the large singular values and smaller for the smaller singular values. Thus, for small values of k , the singular values of \mathbf{B}_k converge quickly to the large singular values of \mathbf{A} . This can be seen in Fig. 3,

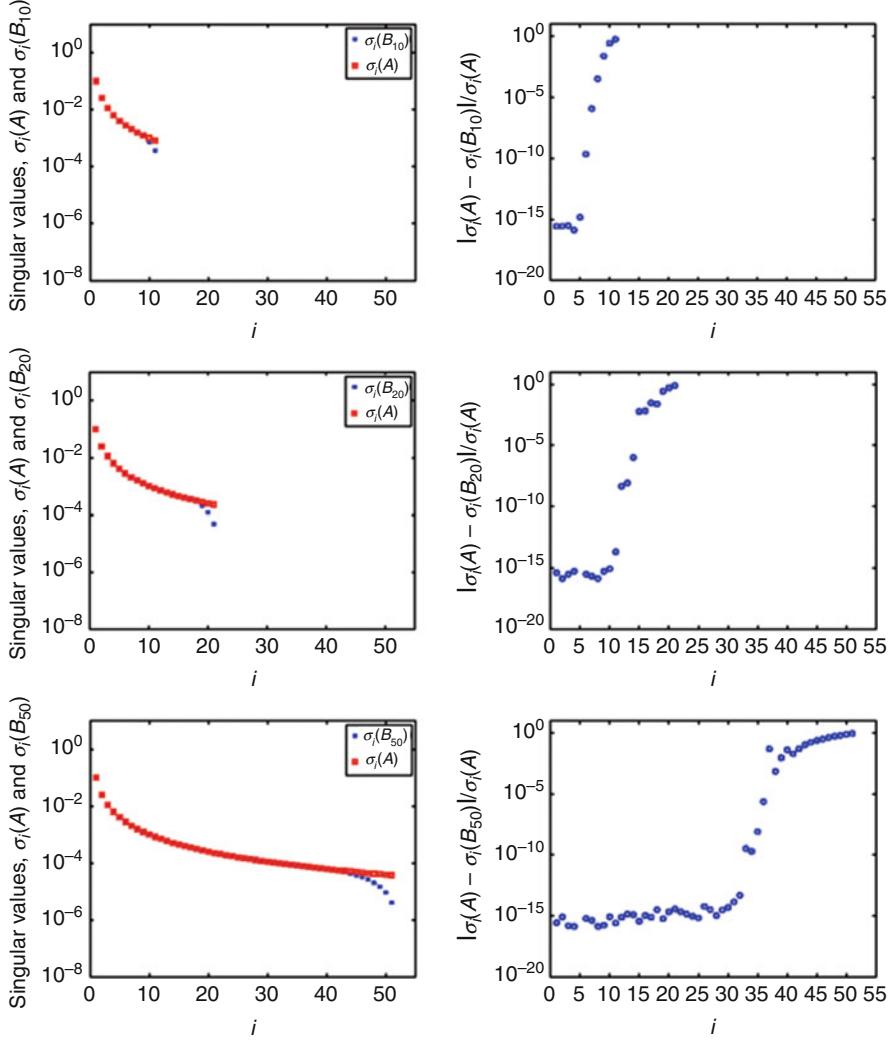

Fig. 3 The plots in the *left column* of this figure show the singular values of \mathbf{A} , denoted as $\sigma_i(\mathbf{A})$, along with the singular values of \mathbf{B}_k , denoted as $\sigma_i(\mathbf{B}_k)$, for $k = 10, 20$, and 50 . The plots in the *right column* show the relative difference, $\frac{|\sigma_i(\mathbf{A}) - \sigma_i(\mathbf{B}_k)|}{\sigma_i(\mathbf{A})}$

which compare the singular values of \mathbf{A} with those of the bidiagonal matrix \mathbf{B}_k for $k = 10, 20$, and 50 .

This example implies that if LSQR is applied to the least squares problem $\min_{\mathbf{x}} \|\mathbf{Ax} - \mathbf{b}\|_2$, then at early iterations the approximate solutions \mathbf{x}_k will be in a subspace that approximates a subspace spanned by the large singular components of \mathbf{A} . Thus, for $k < n$, \mathbf{x}_k is a regularized solution. However, eventually \mathbf{x}_k

should converge to the inverse solution, which is corrupted with noise (recall the discussion in section “Iterative Regularization”). This means that the iteration index k plays the role of a regularization parameter; if k is too small, then the computed approximation \mathbf{x}_k is an over-smoothed solution, while if k is too large, \mathbf{x}_k is corrupted with noise. Again, we emphasize that this semi-convergence behavior requires that the problem satisfies the discrete Picard condition. More extensive theoretical arguments of this semi-convergence behavior of conjugate gradient methods can be found elsewhere; see [43] and the references therein.

Instead of early termination of the iteration, hybrid approaches enforce regularization at each iteration of the GKB method. Hybrid methods were first proposed by O’Leary and Simmons in 1981 [78] and later by Björck in 1988 [7]. The basic idea is to regularize the projected least squares problem (18) involving \mathbf{B}_k , which can be done very cheaply because of the smaller size of \mathbf{B}_k . More specifically, because the singular values of \mathbf{B}_k approximate those of \mathbf{A} , as the GKB iteration proceeds, the matrix \mathbf{B}_k becomes more ill-conditioned. The iteration can be stabilized by including Tikhonov regularization in the projected least square problem (18) to obtain

$$\min_{\hat{\mathbf{x}}} \left\{ \|\mathbf{B}_k \hat{\mathbf{x}} - \beta \mathbf{e}_1\|_2^2 + \alpha^2 \|\hat{\mathbf{x}}\|_2^2 \right\} \quad (19)$$

where again $\beta = \|\mathbf{b}\|_2$ and $\mathbf{x}_k = \mathbf{Y}_k \hat{\mathbf{x}}$. Thus, at each iteration it is necessary to solve a regularized least squares problem involving a bidiagonal matrix \mathbf{B}_k . Notice that since the dimension of \mathbf{B}_k is very small compared to \mathbf{A} , it is much easier to solve for $\hat{\mathbf{x}}$ in Eq. (19) than it is to solve for \mathbf{x} in the full Tikhonov regularized problem (12). More importantly, when solving Eq. (19) one can use sophisticated parameter choice methods to find a suitable α at each iteration.

To summarize, hybrid methods have the following benefits:

- Powerful regularization parameter choice methods can be implemented efficiently on the projected problem.
- Semi-convergence behavior of the relative errors observed in LSQR is avoided, so an imprecise (over) estimate of the stopping iteration does not have a deleterious effect on the computed solution.

Realizing these benefits in practice, though, is nontrivial. Thus, various authors have considered computational and implementation issues, such as robust approaches to choose regularization parameters and stopping iterations; see, for example, [9, 11, 21, 45, 60, 62, 78]. We also remark that our discussion of hybrid methods focused on the case of Tikhonov regularization with $\mathbf{L} = \mathbf{I}$. Implementation of hybrid methods when \mathbf{L} is not the identity matrix, such as a differentiation operator, can be nontrivial; see, for example, [50, 59].

Choosing Regularization Parameters

Each of the regularization methods discussed in this section requires choosing a *regularization parameter*. It is a nontrivial matter to choose “optimal” regularization parameters, but there are methods that can be used as guides. Some require a priori information, such as a bound on the noise or a bound on the solution. Others attempt to estimate an appropriate regularization parameter directly from the given data.

To describe some of the more popular parameter choice methods, let \mathbf{x}_{reg} denote a solution computed by a particular regularization method:

- **Discrepancy Principle.** In this approach, a solution is sought such that

$$\|\mathbf{b} - \mathbf{Ax}_{\text{reg}}\|_2 = \tau \|\boldsymbol{\eta}\|_2$$

Where $\tau > 1$ is a predetermined number [71]. This is perhaps the easiest of the methods to implement, and there are substantial theoretical results establishing its behavior in the presence of noise. However, it is necessary to have a good estimate for $\|\boldsymbol{\eta}\|_2$.

- **Generalized Cross Validation.** The idea behind generalized cross validation (GCV) is that if one data point is removed from the problem, then a good regularized solution should predict that missing data point well. If α is the regularization parameter used to obtain \mathbf{x}_{reg} , then it can be shown [36] that the GCV method chooses α to minimize the function

$$G(\alpha) = \frac{\|\mathbf{b} - \mathbf{Ax}_{\text{reg}}\|^2}{\left(\text{trace}(\mathbf{I} - \mathbf{A}\mathbf{A}_{\text{reg}}^\dagger)\right)^2}.$$

Where $\mathbf{A}_{\text{reg}}^\dagger$ is the matrix such that $\mathbf{x}_{\text{reg}} = \mathbf{A}_{\text{reg}}^\dagger \mathbf{b}$. For example, in the case of Tikhonov regularization (12),

$$\mathbf{A}_{\text{reg}}^\dagger = (\mathbf{A}^T \mathbf{A} + \alpha^2 \mathbf{I})^{-1} \mathbf{A}^T.$$

A weighted version of GCV, W-GCV, finds a regularization parameter to minimize

$$G_\omega(\alpha) = \frac{\|\mathbf{b} - \mathbf{Ax}_{\text{reg}}\|^2}{\left(\text{trace}(\mathbf{I} - \omega \mathbf{A}\mathbf{A}_{\text{reg}}^\dagger)\right)^2}.$$

W-GCV is sometimes more effective at choosing regularization parameters than the standard GCV function for certain classes of problems. Setting the weight $\omega = 1$ gives the standard GCV method, while $\omega < 1$ produces less smooth solutions and $\omega > 1$ produces smoother solutions. Further details about W-GCV can be found in [21].

- **L-Curve.** This approach attempts to balance the size of the discrepancy (i.e., residual) produced by the regularized solution with the size of the solution. In the context of Tikhonov regularization, this can often be found by a log-log scale plot of $\|\mathbf{b} - \mathbf{Ax}_{\text{reg}}\|_2$ versus $\|\mathbf{x}_{\text{reg}}\|_2$ for all possible regularization parameters. This plot often produces an L-shaped curve, and the solution corresponding to the corner of the L indicates a good balance between discrepancy and size of the solution. This observation was first made by Lawson and Hanson [63] and later studied extensively, including efficient numerical schemes to find the corner of the L (i.e., the point of maximum curvature) by Hansen [46, 52]. Although the L-curve tends to work well for many problems, some concerns about its effectiveness have been reported in the literature; see [44, 98].

There exist many other parameter choice methods besides the ones discussed above; for more information, see [28, 49, 99] and the references therein.

A proper choice of the regularization parameter is critical. If the parameter is chosen too small, then too much noise will be introduced in the computed solution. On the other hand, if the parameter is too large, the regularized solution may become over smoothed and may not contain as much information about the true solution as it could. However, it is important to keep in mind that no parameter choice method is “fool proof,” and it may be necessary to solve the problem with a variety of parameters and to use knowledge of the application to help decide which solution is best.

Separable Inverse Problems

Separable nonlinear inverse problems,

$$\mathbf{b} = \mathbf{A} \left(\mathbf{x}_{\text{exact}}^{(n\ell)} \right) \mathbf{x}_{\text{exact}}^{(\ell)} + \boldsymbol{\eta}, \quad (20)$$

arise in many imaging applications, such as blind deconvolution (see section “Multi-frame Blind Deconvolution”), super resolution (which is an example of image data fusion) [18, 27, 57, 76], the reconstruction of 3D macromolecular structures from 2D electron microscopy images of cryogenically frozen samples (Cryo-EM) [22, 35, 55, 66, 82, 88], and seismic imaging applications [40]. One could consider Eq. (20) as a general nonlinear inverse problem and use the approaches discussed in section “Nonlinear Inverse Problems” to compute regularized solutions. However, this section considers approaches that exploit the separability of the problem. In particular, some of the regularization methods described in section “Linear Problems,” such as variational and iterative regularization, can be adapted to Eq. (20). To illustrate, consider the general Tikhonov regularized least squares problem:

$$\min_{\mathbf{x}^{(\ell)}, \mathbf{x}^{(n\ell)}} \left\{ \|\mathbf{A}(\mathbf{x}^{(n\ell)}) \mathbf{x}^{(\ell)} - \mathbf{b}\|_2^2 + \alpha^2 \|\mathbf{x}^{(\ell)}\|_2^2 \right\} = \min_{\mathbf{x}^{(\ell)}, \mathbf{x}^{(n\ell)}} \left\| \begin{bmatrix} \mathbf{A}(\mathbf{x}^{(n\ell)}) \\ \alpha \mathbf{I} \end{bmatrix} \mathbf{x}^{(\ell)} - \begin{bmatrix} \mathbf{b} \\ \mathbf{0} \end{bmatrix} \right\|_2^2. \quad (21)$$

Three approaches to solve this nonlinear least squares problem are outlined in this section.

Fully Coupled Problem

The nonlinear least squares problem given in Eq. (21) can be rewritten as

$$\min_{\mathbf{x}} \phi(\mathbf{x}) = \min_{\mathbf{x}} \frac{1}{2} \|\rho(\mathbf{x})\|_2^2, \quad (22)$$

where

$$\rho(\mathbf{x}) = \rho(\mathbf{x}^{(\ell)}, \mathbf{x}^{(n\ell)}) = \begin{bmatrix} \mathbf{A}(\mathbf{x}^{(n\ell)}) \\ \alpha \mathbf{I} \end{bmatrix} \mathbf{x}^{(\ell)} - \begin{bmatrix} \mathbf{b} \\ \mathbf{0} \end{bmatrix}, \quad \text{and } \mathbf{x} = \begin{bmatrix} \mathbf{x}^{(\ell)} \\ \mathbf{x}^{(n\ell)} \end{bmatrix}$$

Nonlinear least squares problems are solved iteratively, with algorithms having the general form:

Algorithm 1: General Iterative Algorithm

- 1 Choose initial $\mathbf{x}_0 = \begin{bmatrix} \mathbf{x}_0^{(\ell)} \\ \mathbf{x}_0^{(n\ell)} \end{bmatrix}$
- 2 for $k = 0, 1, 2, \dots$
 - Choose a step direction, \mathbf{d}_k
 - Determine step length, τ_k
 - Update the solution: $\mathbf{x}_{k+1} = \mathbf{x}_k + \tau_k \mathbf{d}_k$
 - Stop when a minimum of the objective is obtained

end

Typically, \mathbf{d}_k is chosen to approximate the Newton direction,

$$\mathbf{d}_k = -\left(\hat{\phi}''(\mathbf{x}_k)\right)^{-1} \phi'(\mathbf{x}_k),$$

where $\hat{\phi}''$ is an approximation of ϕ'' , $\phi' = \mathbf{J}_\phi^T \rho$ and \mathbf{J}_ϕ is the Jacobian matrix

$$\mathbf{J}_\phi = \begin{bmatrix} \frac{\partial \rho(\mathbf{x}^{(\ell)}, \mathbf{x}^{(n\ell)})}{\partial \mathbf{x}^{(\ell)}} & \frac{\partial \rho(\mathbf{x}^{(\ell)}, \mathbf{x}^{(n\ell)})}{\partial \mathbf{x}^{(n\ell)}} \end{bmatrix}.$$

In the case of the Gauss-Newton method, which is often recommended for nonlinear least squares problems, $\hat{\phi}'' = \mathbf{J}_\phi^T \mathbf{J}_\phi$.

This general Gauss-Newton approach can work well, but constructing and solving the linear systems required to update \mathbf{d}_k can be very expensive. Note that the dimension of the matrix \mathbf{J}_ϕ corresponds to the number of pixels in the image, $\mathbf{x}^{(\ell)}$, plus the number of parameters in $\mathbf{x}^{(n\ell)}$, and thus \mathbf{J}_ϕ may be on the order of $10^6 \times 10^6$. Thus, instead of using Gauss-Newton, it might be preferable to use a low-storage scheme such as the (nonlinear) conjugate gradient method. But there is a trade off – although the cost per iteration is reduced, the number of iterations needed to attain a minimum can increase significantly.

Relatively little research has been done on understanding and solving the fully coupled problem. For example, methods are needed for choosing regularization parameters. In addition, the rate of convergence of the linear and nonlinear terms may be quite different, and the effect this has on overall convergence rate is not well understood.

Decoupled Problem

Probably the simplest idea to solve the nonlinear least squares problem is to decouple it into two problems, one involving $\mathbf{x}^{(\ell)}$ and the other involving $\mathbf{x}^{(n\ell)}$. Specifically, the approach would have the form:

Algorithm 2: Block Coordinate Descent Iterative Algorithm

- 1 Choose initial $\mathbf{x}_0^{(n\ell)}$
- 2 for $k = 0, 1, 2, \dots$
 - Choose α_k and solve the linear problem:

$$\mathbf{x}_k^{(\ell)} = \arg \min_{\mathbf{x}^{(\ell)}} \left\| \mathbf{A} \left(\mathbf{x}_k^{(n\ell)} \right) \mathbf{x}^{(\ell)} - \mathbf{b} \right\|_2^2 + \alpha_k^2 \left\| \mathbf{x}^{(\ell)} \right\|_2^2$$

- Solve the nonlinear problem:

$$\mathbf{x}_{k+1}^{(n\ell)} = \arg \min_{\mathbf{x}^{(n\ell)}} \left\| \mathbf{A} \left(\mathbf{x}^{(n\ell)} \right) \mathbf{x}_k^{(\ell)} - \mathbf{b} \right\|_2^2 + \alpha_k^2 \left\| \mathbf{x}_k^{(\ell)} \right\|_2^2$$

- Stop when objectives are minimized

end

The advantage of this approach is that any of the approaches discussed in section “Linear Problems,” including methods to determine α , can be used for the linear problem. The nonlinear problem involving $\mathbf{x}^{(n\ell)}$ requires using another iterative method, such as the Gauss-Newton method. However, there are often significantly fewer parameters than in the fully coupled approach discussed in the previous subsection. Thus, a Gauss-Newton method to update $\mathbf{x}_{k+1}^{(n\ell)}$ at each iteration is significantly more computationally tractable. A disadvantage to this approach, which is known in the optimization literature as block coordinate descent, is that it is not clear what are the practical convergence properties of the method. As

mentioned in the previous subsection, the rate of convergence of the linear and nonlinear terms may be quite different. Moreover, if the method does converge, it will typically be very slow (linear), especially for problems with tightly coupled variables [77].

Variable Projection Method

The variable projection method [38, 39, 58, 79, 86] exploits structure in the nonlinear least squares problem (21). The approach exploits the fact that $\phi(\mathbf{x}^{(\ell)}, \mathbf{x}^{(n\ell)})$ is linear in $\mathbf{x}^{(\ell)}$ and that $\mathbf{x}^{(n\ell)}$ contains relatively fewer parameters than $\mathbf{x}^{(\ell)}$. However, rather than explicitly separating variables $\mathbf{x}^{(\ell)}$ and $\mathbf{x}^{(n\ell)}$ as in coordinate descent, variable projection implicitly eliminates the linear parameters $\mathbf{x}^{(\ell)}$, obtaining a reduced cost functional that depends only on $\mathbf{x}^{(n\ell)}$. Then, a Gauss-Newton method is used to solve the optimization problem associated with the reduced cost functional. Specifically, consider

$$\psi(\mathbf{x}^{(n\ell)}) \equiv \phi(\mathbf{x}^{(\ell)}(\mathbf{x}^{(n\ell)}), \mathbf{x}^{(\ell)})$$

where $\mathbf{x}^{(\ell)}(\mathbf{x}^{(n\ell)})$ is a solution of

$$\min_{\mathbf{x}^{(\ell)}} \phi(\mathbf{x}^{(\ell)}, \mathbf{x}^{(n\ell)}) = \min_{\mathbf{x}^{(\ell)}} \left\| \begin{bmatrix} \mathbf{A}(\mathbf{x}^{(n\ell)}) \\ \alpha \mathbf{I} \end{bmatrix} \mathbf{x}^{(\ell)} - \begin{bmatrix} \mathbf{b} \\ \mathbf{0} \end{bmatrix} \right\|_2^2. \quad (23)$$

To use the Gauss-Newton algorithm to minimize the reduced cost functional $\psi(\mathbf{x}^{(n\ell)})$, it is necessary to compute $\psi'(\mathbf{x}^{(n\ell)})$. Note that because $\mathbf{x}^{(\ell)}$ solves (23), it follows that $\frac{\partial \phi}{\partial \mathbf{x}^{(\ell)}} = 0$ and thus

$$\psi'(y) = \frac{d\mathbf{x}}{dy} \frac{\partial \phi}{\partial \mathbf{x}^{(\ell)}} + \frac{\partial \phi}{\partial \mathbf{x}^{(n\ell)}} = \frac{\partial \phi}{\partial \mathbf{x}^{(n\ell)}} = \mathbf{J}_\psi^T \boldsymbol{\rho},$$

where the Jacobian of the reduced cost functional is given by

$$\mathbf{J}_\psi = \frac{\partial (\mathbf{A}(\mathbf{x}^{(n\ell)}) \mathbf{x}^{(\ell)})}{\partial \mathbf{x}^{(n\ell)}}.$$

Thus, a Gauss-Newton method applied to the reduced cost functional has the basic form:

Although computing \mathbf{J}_ψ is nontrivial, it is often much more tractable than constructing \mathbf{J}_ϕ . In addition, the problem of variable convergence rates for the two sets of parameters, $\mathbf{x}^{(\ell)}$ and $\mathbf{x}^{(n\ell)}$, has been eliminated. Another big advantage of the variable projection method for large-scale inverse problems is that standard approaches, such as those discussed in section “Linear Problems,” can be used to solve the linear regularized least squares problem at each iteration, including the schemes for estimating regularization parameters.

Algorithm 3: Variable Projection Gauss-Newton Algorithm

```

1 Choose initial  $\mathbf{x}_0^{(n\ell)}$ 
2 for  $k = 0, 1, 2, \dots$ 
3   Choose  $\alpha_k$ 
4    $\mathbf{x}_k^{(\ell)} = \arg \min_{\mathbf{x}^{(\ell)}} \left\| \begin{bmatrix} \mathbf{A}(\mathbf{x}_k^{(n\ell)}) \\ \alpha_k \mathbf{I} \end{bmatrix} \mathbf{x}^{(\ell)} - \begin{bmatrix} \mathbf{b} \\ \mathbf{0} \end{bmatrix} \right\|_2$ 
5    $\mathbf{r}_k = \mathbf{b} - \mathbf{A}(\mathbf{x}_k^{(n\ell)}) \mathbf{x}_k^{(\ell)}$ 
6    $\mathbf{d}_k = \arg \min_d \|\mathbf{J}_\psi \mathbf{d} - \mathbf{r}_k\|_2$ 
7   Determine step length  $\tau_k$ 
8    $\mathbf{x}_{k+1}^{(n\ell)} = \mathbf{x}_k^{(n\ell)} + \tau_k \mathbf{d}_k$ 
9 end

```

Nonlinear Inverse Problems

Developing regularization approaches for general nonlinear inverse problems can be significantly more challenging than the linear and separable nonlinear case. Theoretical tools such as the SVD that are used to analyze ill-posedness in the linear case are not available here, and previous efforts to extend these tools to the nonlinear case do not always apply. For example, a spectral analysis of the linearization of a nonlinear problem does not necessarily determine the degree of ill-posedness for the nonlinear problem [30]. Furthermore, convergence properties for nonlinear optimization require very strict assumptions that are often not realizable in real applications [28,29]. Nevertheless, nonlinear inverse problems arise in many important applications, motivating research on regularization schemes and general computational approaches. This section discusses some of this work.

One approach for nonlinear problems of the form

$$F(\mathbf{x}) = \mathbf{b} \quad (24)$$

is to reformulate the problem to find a zero of $F(\mathbf{x}) - \mathbf{b} = 0$. Then a Newton-like method, where the nonlinear function is repeatedly linearized around the current estimate, can be written as

$$\mathbf{x}_{k+1} = \mathbf{x}_k + \rho_k \mathbf{p}_k \quad (25)$$

where \mathbf{p}_k solves the Jacobian system

$$\mathbf{J}(\mathbf{x}_k) \mathbf{p} = \mathbf{b} - F(\mathbf{x}_k). \quad (26)$$

Though generally not symmetric, matrix and matrix-transpose multiplications with the Jacobian, whose elements are the first derivatives of $F(\mathbf{x})$, are typically computable. However, the main disadvantages of using this approach are that the

existence and uniqueness of a solution are not guaranteed and the sensitivity of solutions depends on the conditioning of the Jacobian. Furthermore, there is no natural merit function that can be monitored to help select the step length, ρ_k .

Another approach to solve (24) is to incorporate prior assumptions regarding the statistical distribution of the model and maximize the corresponding likelihood function. For example, an additive Gaussian noise model assumption under certain conditions corresponds to solving the following nonlinear least squares problem:

$$\min_{\mathbf{x}} \frac{1}{2} \|\mathbf{b} - F(\mathbf{x})\|_2^2. \quad (27)$$

Since this is a standard nonlinear optimization problem, any optimization algorithm such as a gradient descent or Newton approach can be used here. For problem (27), the gradient vector can be written as $\mathbf{g}(\mathbf{x}) = \mathbf{J}(\mathbf{x})^T(F(\mathbf{x}) - \mathbf{b})$, and Hessian matrix can be written as $\mathbf{H}(\mathbf{x}) = \mathbf{J}(\mathbf{x})^T \mathbf{J}(\mathbf{x}) + \mathbf{Z}(\mathbf{x})$, where $\mathbf{Z}(\mathbf{x})$ includes second derivatives of $F(\mathbf{x})$. The main advantage of this approach is that a variety of line search methods can be used. However, the potential disadvantages of this approach are that the derivatives may be too difficult to compute or that negative eigenvalues introduced in $\mathbf{Z}(\mathbf{x})$ may cause problems in optimization algorithms. Some algorithms for solving nonlinear optimization problems are direct extensions of the iterative methods described in section “Iterative Regularization.” The nonlinear Landweber iteration can be written as

$$\mathbf{x}_{k+1} = \mathbf{x}_k + \mathbf{J}(\mathbf{x}_k)^T (\mathbf{b} - F(\mathbf{x}_k)), \quad (28)$$

which reduces to the standard Landweber iteration if $F(\mathbf{x})$ is linear, and it can be easily extended to other gradient descent methods such as the steepest descent approach. Newton and Newton-type methods are also viable options for nonlinear optimization, resulting in iterates (25) where \mathbf{p}_k solves

$$\mathbf{H}(\mathbf{x}_k)\mathbf{p} = -\mathbf{g}(\mathbf{x}_k). \quad (29)$$

Oftentimes, an approximation of the Hessian is used. For example, the Gauss-Newton algorithm, which takes $\mathbf{H} \approx \mathbf{J}(\mathbf{x}_k)^T \mathbf{J}(\mathbf{x}_k)$, is a preferred choice for large-scale problems because it ensures positive semi-definiteness, but it is not advisable for large residual problems or highly nonlinear problems [40]. Additionally, nonlinear conjugate gradient, truncated-Newton, or quasi-Newton methods, such as LBFGS can be good alternatives if storage is a concern. It is important to remark that finding a global minimizer for a nonlinear optimization problem is in general very difficult, especially since convexity of the objective function is typically not guaranteed, as in the linear case. Thus, it is very likely that a descent algorithm may get stuck in one of many local minima solutions.

When dealing with ill-posed problems, the general approach to incorporate regularization is to couple an iterative approach with a stopping criteria such as the discrepancy principle to produce reasonable solutions. In addition, for Newton-type

methods it is common to incorporate additional regularization for the inner system since the Jacobian or Hessian may become ill-conditioned. For example, including linear Tikhonov regularization in (26) would result in

$$(\mathbf{J}(\mathbf{x}_k)^T \mathbf{J}(\mathbf{x}_k) + \alpha^2 \mathbf{I}) \mathbf{p} = \mathbf{J}(\mathbf{x}_k)^T (\mathbf{b} - F(\mathbf{x}_k)),$$

which is equivalent to a Levenberg-Marquardt iterate, where the update, \mathbf{p}_k , is the solution of a particular Tikhonov minimization problem:

$$\min_{\mathbf{p}} \|F(\mathbf{x}_k) + \mathbf{J}(\mathbf{x}_k)\mathbf{p} - \mathbf{b}\|_2^2 + \alpha^2 \|\mathbf{p}\|_2^2,$$

where $F(\mathbf{x})$ has been linearized around \mathbf{x}_k . Other variations for regularizing the update can be found in [28] and the references therein. Regularization for the inner system can also be achieved by solving the inner system inexactly using an iterative method and terminating the iterations early. These are called *inexact Newton* methods, and the early termination of the inner iterations is a good way not only to make this approach practical for large-scale problems but also to enforce regularization on the inner system.

The variational approaches discussed in section “Variational Regularization and Constraints” can be extended for the second class of algorithms where a likelihood function results in a nonlinear optimization problem. For example, after selecting a regularization operator $\mathcal{J}(\mathbf{x})$ and regularization parameter α for (27), the goal would be to solve a nonlinear optimization problem of the form

$$\min_{\mathbf{x}} \left\{ \|\mathbf{b} - F(\mathbf{x})\|_2^2 + \alpha^2 \mathcal{J}(\mathbf{x}) \right\}. \quad (30)$$

The flexibility in the choice of the regularization operator is nice, but selecting a good regularization parameter a priori can be a computationally demanding task, especially for large-scale problems. Some work on estimating the regularization parameter within a constrained optimization framework has been done [40, 41], but the most common approach for regularization of nonlinear ill-posed inverse problems is to use standard iterative methods to solve (27), where regularization is obtained via early termination of the iterations. It cannot be stressed enough that when using any iterative method to solve a nonlinear inverse problem where the regularization is not already incorporated, a good stopping iteration for the outer iteration that serves as a regularization parameter is imperative. See also [2, 28, 29, 32, 54, 92, 97] for additional references on nonlinear inverse problems.

4 Numerical Methods and Case Examples

Given a specific large-scale inverse problem from an imaging application, it can be nontrivial to implement the algorithms and regularization methods discussed in this chapter. Efficient computations require exploiting the structure of the problem.

Moreover, choosing specific regularization schemes and constraints requires knowledge about the physical process underlying the data collection process. A few illustrative examples, using the imaging applications described in section “Imaging Applications,” are given in this section.

Linear Example: Deconvolution

Perhaps the most well-known and well-studied linear inverse problem is deconvolution. As discussed in section “Image Deblurring and Deconvolution,” this spatially invariant image deblurring problem is modeled as

$$\mathbf{b} = \mathbf{Ax}_{\text{exact}} + \boldsymbol{\eta},$$

where \mathbf{A} is a structured matrix that depends on the PSF and imposed boundary conditions. For example, if periodic boundary conditions are imposed on the blurring operation, then \mathbf{A} has a circulant structure, and moreover, \mathbf{A} has the spectral decomposition

$$\mathbf{A} = \mathbf{F}^* \mathbf{\Lambda} \mathbf{F},$$

where \mathbf{F} is a matrix representing a d -dimensional discrete Fourier transform, which satisfies $\mathbf{F}^* \mathbf{F} = \mathbf{I}$. The matrix \mathbf{F} does not need to be constructed explicitly. Instead, fast Fourier transform (FFT) functions can be used to implement matrix-vector multiplications with \mathbf{F} and \mathbf{F}^* . Specifically, for 2D images:

$$\begin{aligned}\mathbf{Fx} &\Leftrightarrow \text{fft2}(\mathbf{x}) && \text{(2D forward FFT)} \\ \mathbf{F}^*\mathbf{x} &\Leftrightarrow \text{ifft2}(\mathbf{x}) && \text{(2D inverse FFT)}\end{aligned}$$

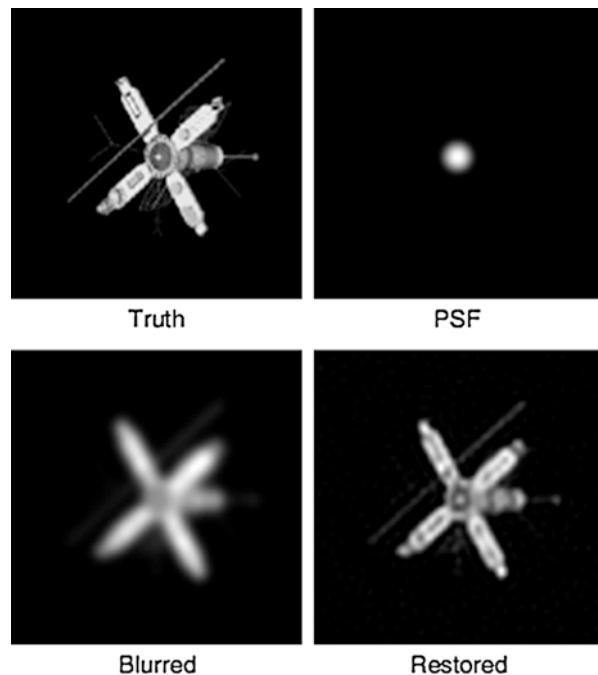

The main advantages are that FFT-based spectral filtering regularization algorithms are very easy to implement and extremely efficient; see [51] for implementation details.

To illustrate, consider the image data shown in Fig. 4, where the simulated observed image was obtained by convolving the PSF with the true image and adding 1 % Gaussian white noise. The PSF was constructed from a Gaussian blurring operator,

$$p_{ij} = \exp\left(\frac{-(i-k)^2 s_2^2 - (j-l)^2 s_1^2 + 2(i-k)(j-l)s_3^2}{2s_1^2 s_2^2 - 2s_3^4}\right) \quad (31)$$

centered at (k, l) (location of point source), with $s_1 = s_2 = 5$ and $s_3 = 0$. An FFT-based Tikhonov spectral filtering solution was computed, with regularization operator $\mathbf{L} = \mathbf{I}$ and regularization parameter $\alpha = 0.00544$, which was chosen using GCV. (All computations for this example were done with MATLAB. The

Fig. 4 Simulated data for an image deconvolution problem. The restored image was computed using an FFT-based spectral filtering method, with Tikhonov regularization and GCV-chosen regularization parameter

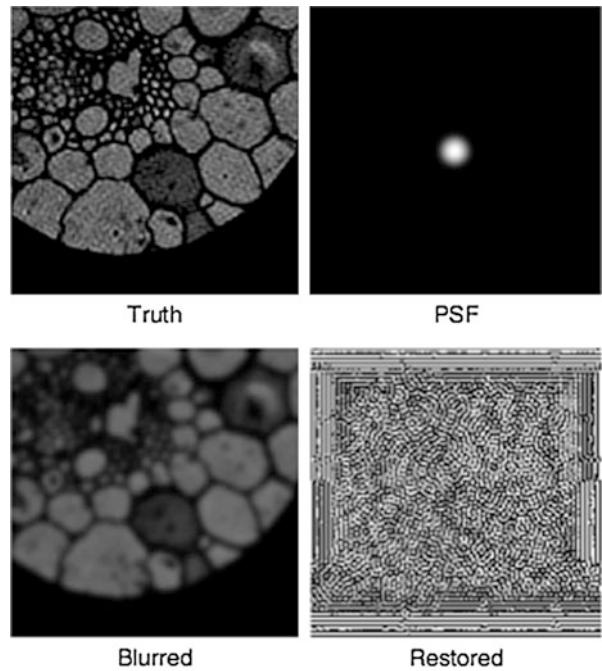

implementation of the FFT-based spectral filter used in this example is described in [51]. The MATLAB code, which is called *tik_fft.m*, can be found at <http://www2.imm.dtu.dk/~pch/HNO/#>) The reconstructed image, which was computed in a fraction of a second on a standard laptop computer, is also shown in Fig. 4.

If there are significant details near the boundary of the image, then the periodic boundary condition assumption might not be an accurate representation of the details outside the viewable region. In this case, severe ringing artifacts can appear in the reconstructed image, and parameter choice methods may perform very poorly in these situations. Consider, for example, the image data shown in Fig. 5. The PSF is the same as in the previous example, but the blurred image contains features at the boundaries of the viewable region. The “restored” image in Fig. 5 was again computed using a Tikhonov spectral filtering solution with regularization operator $\mathbf{L} = \mathbf{I}$, and regularization parameter ($\alpha = 6.30 \times 10^{-5}$) was chosen using GCV. This noise-corrupted reconstructed image indicates that the regularization parameter chosen by GCV is too small.

It is possible that another parameter choice method would perform better, but it is also the case that imposing alternative boundary conditions may improve the situation. For example, reflective boundary conditions assume the image scene outside the viewable region is a mirror image of the details inside the viewable region. With this assumption, and if the PSF is also circularly symmetric, then the

Fig. 5 Simulated data for an image deconvolution problem. The restored image was computed using an FFT-based spectral filtering method, with Tikhonov regularization and GCV-chosen regularization parameter

matrix \mathbf{A} has a symmetric Toeplitz-plus-Hankel structure, and, moreover, \mathbf{A} has the spectral decomposition

$$\mathbf{A} = \mathbf{C}^T \boldsymbol{\Lambda} \mathbf{C},$$

where \mathbf{C} is a matrix representing a d -dimensional discrete cosine transform, which satisfies $\mathbf{C}^T \mathbf{C} = \mathbf{I}$. As with FFTs, the matrix \mathbf{C} does not need to be constructed explicitly, and very efficient functions can be used to implement matrix-vector multiplications with \mathbf{C} and \mathbf{C}^T , such as

$$\begin{aligned} \mathbf{C}\mathbf{x} &\Leftrightarrow \text{dct2}(\mathbf{x}) && \text{(2D forward DCT)} \\ \mathbf{C}^T\mathbf{x} &\Leftrightarrow \text{idct2}(\mathbf{x}) && \text{(2D inverse DCT)} \end{aligned}$$

In addition, DCT-based spectral filtering regularization algorithms are very easy to implement and are extremely efficient; see [51] for implementation details.

Figure 6 illustrates the superior performance that can be obtained if the boundary condition and the corresponding basis (in this case, DCT) is used in the spectral filtering deconvolution algorithms. Specifically, the image on the left in Fig. 6 was computed using a DCT-based Tikhonov spectral filtering method, with regularization operator $\mathbf{L} = \mathbf{I}$ and a GCV-chosen regularization parameter $\alpha = 4.83 \times 10^{-3}$. The image on the right was computed using the FFT-based Tikhonov filter, but instead of using the GCV-chosen regularization parameter (which produced the

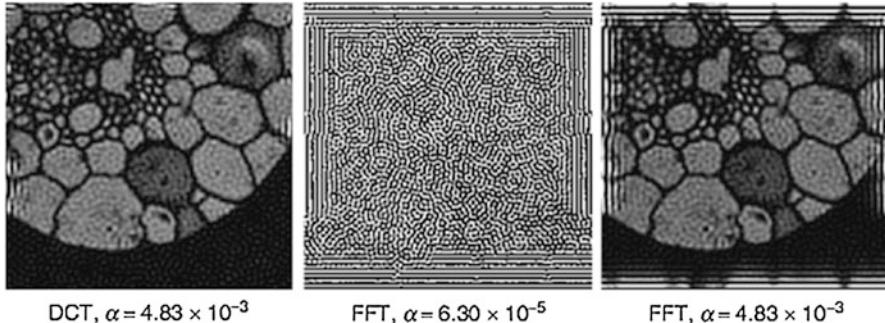

Fig. 6 These restored images were computed using DCT and FFT-based spectral filtering methods, with Tikhonov regularization. For the DCT and the middle FFT reconstructions, the regularization parameter α was chosen by GCV. The FFT reconstruction on the right was obtained using the same regularization parameter as was used for the DCT reconstruction

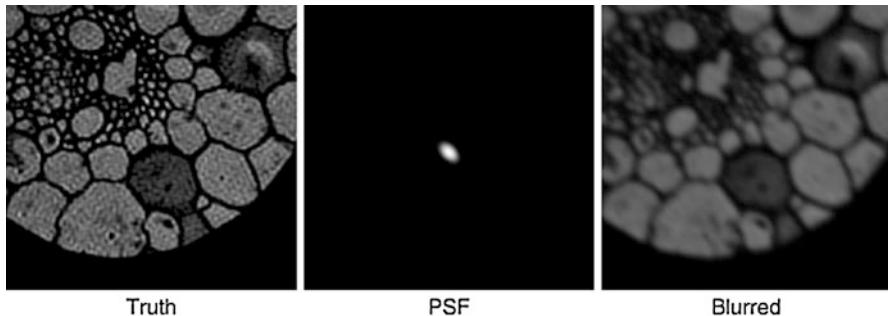

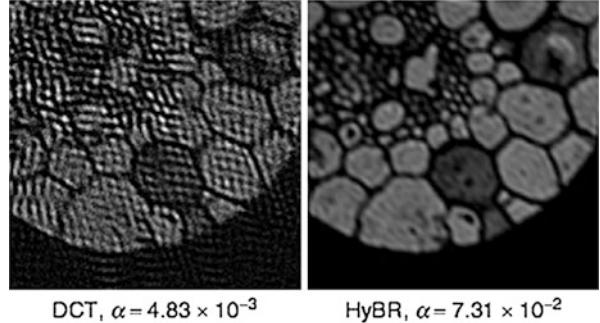

Fig. 7 Simulated deconvolution data with a nonsymmetric Gaussian PSF

poor reconstruction displayed in the middle of this figure), α was set to the same value used by the DCT reconstruction. This example clearly illustrates that the quality of the reconstruction, and the effectiveness of parameter choice methods, can depend greatly on the imposed boundary conditions and corresponding spectral basis. (As with previous examples, all computations described here were done with MATLAB. The implementation of the DCT-based spectral filter is described in [51]. The MATLAB code, which is called *tik_dct.m*, can be found at <http://www2.imm.dtu.dk/~pch/HNO/>.)

Spectral filtering methods work well for many deconvolution problems, but it may not always be possible to find a convenient basis that allows for efficient implementation. Consider, for example, the data shown in Fig. 7. The PSF in this figure was constructed using Eq. (31), with $s_1 = s_2 = 3$ and $s_3 = 2$, and results in a nonsymmetric PSF. As with the previous example, the FFT-based filter does not work well for this deconvolution problem because of its implicit assumption of

Fig. 8 These restored images were computed using a DCT-based spectral filtering method (*left*) and an iterative hybrid method (*right*)

periodic boundary conditions. Reflective boundary conditions are more appropriate, but the lack of circular symmetry in the PSF means that the DCT basis does not diagonalize the matrix \mathbf{A} . The reconstructed image on the left in Fig. 8 illustrates what happens if we attempt to reconstruct the image using a DCT-based Tikhonov filter.

An iterative method may be the best option for a problem such as this; one can impose any appropriate boundary condition (which only needs to be implemented in matrix-vector multiplications with \mathbf{A} and \mathbf{A}^T) without needing to assume any symmetry or further structure in the PSF. The reconstructed image shown on the right in Fig. 8 was obtained using a hybrid approach described in section “Hybrid Iterative-Direct Regularization.” Specifically, Tikhonov regularization is used for the projected subproblem, with regularization parameters chosen by W-GCV. The MATLAB software for this, which is called HyBR, is discussed in [21] and can be obtained from <http://www.math.vt.edu/people/jmchung/hybr.html>. For this particular example, HyBR terminated at iteration 21, with a regularization parameter $\alpha = 7.31 \times 10^{-2}$.

The examples in this subsection illustrate that many approaches can be used for the linear inverse problem deconvolution. It is possible that other methods, such as those that incorporate nonnegativity constraints, may produce better results than those presented here, but this is typical of all inverse problems. It would be impossible to give an exhaustive study and comparison in this chapter.

Separable Example: Multi-Frame Blind Deconvolution

In this section, multi-frame blind deconvolution (MFBD) is used to illustrate a numerical example of a separable (nonlinear) inverse problem,

$$\mathbf{b} = \mathbf{A} \left(\mathbf{x}_{\text{exact}}^{(n\ell)} \right) \mathbf{x}_{\text{exact}}^{(\ell)} + \boldsymbol{\eta}.$$

Recall from section “Multi-frame Blind Deconvolution” that in MFBD, a set of, say, m blurred images of an object are collected, and the aim is to simultaneously

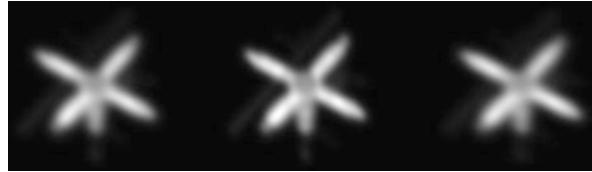

Fig. 9 Simulated MFBD data. The images were obtained by convolving the true satellite image from Fig. 4 with Gaussian PSFs using parameters given in Eq. (32) and then adding 1% white noise

reconstruct an approximation of the true image as well as the PSFs (or the parameters that define the PSFs) associated with each of the observed blurred images. Such an example can be simulated using the Gaussian blurring kernel given in Eq. (31), and the true satellite image given in Fig. 4. Specifically, suppose using Eq. (31), three PSFs are constructed using the following values:

$$\mathbf{x}_{\text{exact}}^{(n\ell)} = \begin{bmatrix} 6.0516 \\ 5.8419 \\ 2.2319 \\ 5.4016 \\ 4.3802 \\ 2.1562 \\ 5.7347 \\ 6.8369 \\ 2.7385 \end{bmatrix} \left\{ \begin{array}{l} \text{Gaussian PSF parameters } s_1, s_2, s_3 \text{ for frame 1} \\ \text{Gaussian PSF parameters } s_1, s_2, s_3 \text{ for frame 2} \\ \text{Gaussian PSF parameters } s_1, s_2, s_3 \text{ for frame 3} \end{array} \right. \quad (32)$$

Simulated observed image data can then be generated by convolving the PSFs constructed from these sets of parameters with the true satellite image and then adding 1% white noise. The resulting simulated observed image frames are shown in Fig. 9.

Image reconstructions can then be computed using the variable projection Gauss-Newton algorithm described in section “Variable Projection Method.” The Jacobian \mathbf{J}_ψ can be constructed analytically for this problem (see, e.g., [19]), but a finite difference approach can also work very well. In the experiments reported here, centered differences were used to approximate the Jacobian.

The hybrid method implementation HyBR, described in the previous subsection, was used to choose α_k and to solve the linear subproblem for $\mathbf{x}_k^{(\ell)}$. The step length τ_k was chosen using an Armijo rule [77]. The initial guess for $\mathbf{x}_0^{(n\ell)}$ was

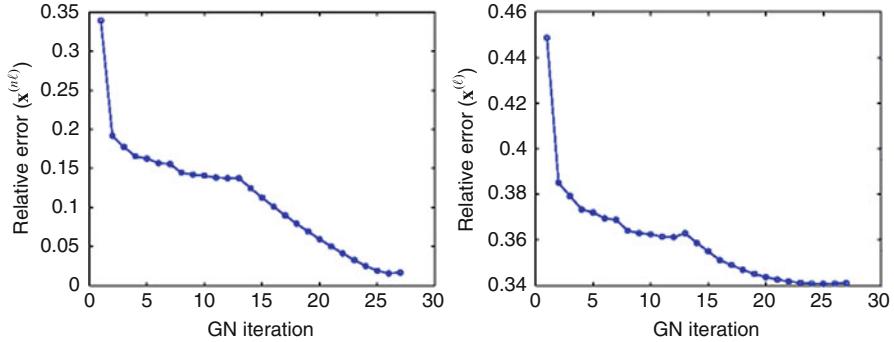

Fig. 10 Convergence results for MFBD. The relative error of the estimated PSF parameters at each iteration is shown in the *left plot*, while the relative error of the reconstructed image at each iteration is shown in the *right plot*

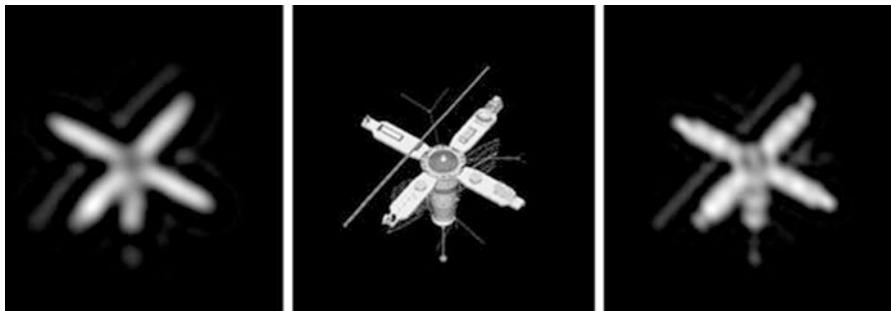

Fig. 11 On the *left* is the initial reconstructed image using $\mathbf{x}_0^{(n\ell)}$ and on the *right* is the final reconstructed image. The true image is displayed in the *middle* for comparison purposes

$$\mathbf{x}_0^{(n\ell)} = \begin{bmatrix} 7.0516 \\ 7.8369 \\ 3.2385 \\ 7.0516 \\ 7.8369 \\ 3.2385 \\ 7.0516 \\ 7.8369 \\ 3.2385 \end{bmatrix} \left\{ \begin{array}{l} \text{initial guess for } s_1, s_2, s_3 \text{ for frame 1} \\ \text{initial guess for } s_1, s_2, s_3 \text{ for frame 2} \\ \text{initial guess for } s_1, s_2, s_3 \text{ for frame 3} \end{array} \right.$$

The results in Fig. 10 show the convergence behavior in terms of relative error at each iteration of the variable projection Gauss-Newton algorithm for this example. The left plot shows the convergence history of $\mathbf{x}_k^{(n\ell)}$, and the right plot shows the convergence history of $\mathbf{x}_k^{(\ell)}$. Note that the convergence behavior of both terms is very similar. Figure 11 shows the reconstructed image after the first variable projection

Gauss-Newton iteration (i.e., the initial reconstruction) and the reconstructed image after the last iteration of the algorithm.

Nonlinear Example: Tomosynthesis

Polyenergetic digital tomosynthesis is an example of a nonlinear inverse problem where the forward problem can be modeled as (8). The typical approach to compute an approximation of $\mathbf{x}_{\text{exact}}$ is to assume that the observed projection image is a realization of a Poisson random variable with mean values

$$\bar{\mathbf{b}}_\theta + \bar{\boldsymbol{\eta}} = \sum_{e=1}^{n_e} \varrho(e) \exp(-[s(e)\mathbf{A}_\theta \mathbf{x} + z(e)\mathbf{A}_\theta \mathbf{1}]) + \bar{\boldsymbol{\eta}}, \quad (33)$$

where $\bar{\boldsymbol{\eta}}$ is the mean of the additive noise. Then the maximum likelihood estimator (MLE) can be found by minimizing the negative log likelihood function:

$$-L_\theta(\mathbf{x}) = \sum_{i=1}^M \left(\bar{b}_\theta^{(i)} + \bar{\eta}^{(i)} \right) - b_\theta^{(i)} \log \left(\bar{b}_\theta^{(i)} + \bar{\eta}^{(i)} \right) + c, \quad (34)$$

where superscripts refer to entries in a vector and c is a constant term. A regularized estimate can be found by solving the following nonlinear optimization problem

$$\mathbf{x}_{\text{MLE}} = \min_{\mathbf{x}} \left\{ \sum_{\theta=1}^{n_\theta} -L_\theta(\mathbf{x}) \right\} \quad (35)$$

using a gradient descent or Newton-type algorithm and terminating the iterations before the noise enters the problem. For this example, the gradient of the objective function with respect to the 3D volume, \mathbf{x} , can be written as

$$\mathbf{g}(\mathbf{x}_k) = \mathbf{A}^T \mathbf{v}_k$$

where the entries of vector \mathbf{v}_k are given by

$$v^{(i)} = \left(\frac{b^{(i)}}{\bar{b}^{(i)} + \bar{\eta}^{(i)}} - 1 \right) \sum_{e=1}^{n_e} \varrho(e) s(e) \exp(-[s(e)\mathbf{a}_i^T \mathbf{x}_k + z(e)\mathbf{a}_i^T \mathbf{1}]).$$

The Hessian matrix can be written as

$$\mathbf{H}_k = \mathbf{A}^T \mathbf{W}_k \mathbf{A}$$

where \mathbf{W}_k is a diagonal matrix with vector \mathbf{w}_k on the diagonal. A mathematical formula for the values of the diagonal can be quite complicated as they depend on

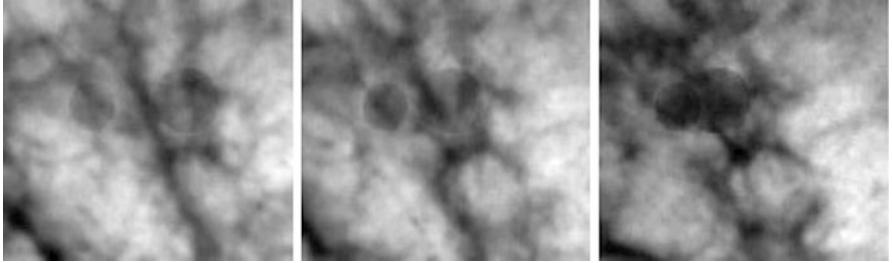

Fig. 12 Extracted regions of sample projection images

the values of the second derivatives. Furthermore, the Newton step at iteration k in Eq. (29) is just the normal equations formulation of the least squares problem

$$\min_{\mathbf{s}_k} \left\| \mathbf{W}_k^{\frac{1}{2}} \mathbf{A} \mathbf{s}_k - \mathbf{W}_k^{-\frac{1}{2}} \mathbf{v}_k \right\|_2 \quad (36)$$

where $\mathbf{W}_k^{\frac{1}{2}} = \text{diag}\left(\mathbf{w}^{\frac{1}{2}}\right)$. For solving the Newton system, CGLS can be used to solve (36) inexactly. Furthermore, regularization for the outer problem is achieved by early termination of the iterative optimization method.

The example illustrated here comes from a true volume of size $128 \times 128 \times 128$ whose values range between 0 and 100, representing the percentage of glandular tissue present in the voxel. Then 21 projection images were taken at equally spaced angles, within an angular range from -30° to 30° at 3° intervals, using the typical geometry for breast tomosynthesis, illustrated in Fig. 1. Each 2D projection image contains 150×200 pixels. Subimages of three of these projections can be found in Fig. 12.

The original object represented a portion of a patient breast with mean compressed breast thickness of size $6.4 \times 6.4 \times 6.4$ cm, and the detector was 7.5×10 cm. The source to detector distance at 0° was set to 66 cm, and the distance from the center of rotation to detector was 0 cm. The incident X-ray spectrum was produced by a rhodium target with a tube voltage of 28 kVp and an added rhodium filter of $25 \mu\text{m}$ thickness, discretized to consist of 47 different energy levels, from 5.0 to 28 keV, in 0.5 keV steps.

For the reconstruction algorithms, the ray trace matrix \mathbf{A}_θ for each projection angle was computed using a cone beam model, and an initial guess of the volume was a uniform image with all voxel values set to 50, meaning half glandular and half adipose tissue. The reconstructed volume consisted of $128 \times 128 \times 40$ voxels with a voxel size of $500 \times 500 \mu\text{m} \times 1.6$ mm. Furthermore, additive Poisson noise was included in the projection images so that there was a relative noise level of approximately 1 %. Some slices of the true volume can be found in Fig. 13.

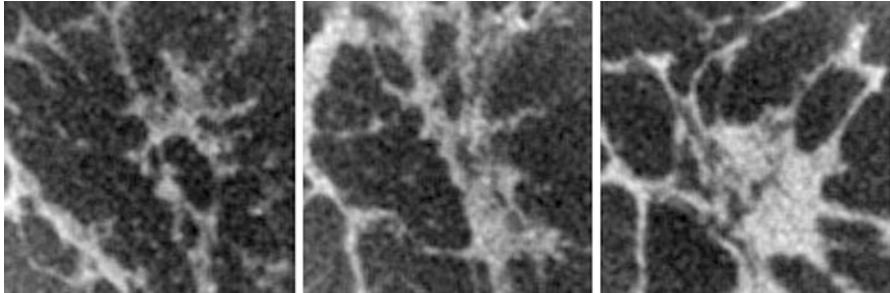

Fig. 13 Sample slices from the original breast volume

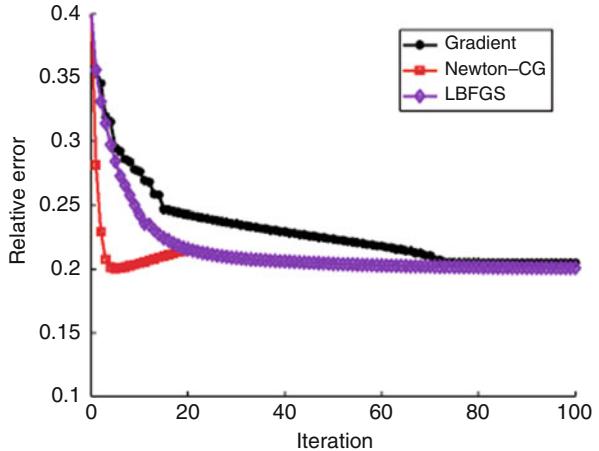

Table 1 Convergence results for polyenergetic tomosynthesis reconstruction

| Gradient descent method | | | | |
|-------------------------|----------------|---------------|------------|-----------------|
| Iteration | Rel. objective | Rel. gradient | Rel. error | |
| 0 | 7.033e – 04 | 1.0000 | 0.4034 | |
| 1 | 6.771e – 04 | 0.8755 | 0.3562 | |
| 5 | 6.586e – 04 | 0.2731 | 0.2948 | |
| 10 | 6.585e – 04 | 0.0641 | 0.2762 | |
| 25 | 6.551e – 04 | 0.0314 | 0.2386 | |
| 50 | 6.548e – 04 | 0.0104 | 0.2237 | |
| Newton-CG | | | | |
| Iteration | Rel. objective | Rel. gradient | Rel. error | CGLS iterations |
| 0 | 7.033e – 04 | 1.0000 | 0.4034 | - |
| 1 | 6.587e – 04 | 0.2525 | 0.2814 | 5 |
| 2 | 6.550e – 04 | 0.0398 | 0.2293 | 9 |
| 3 | 6.547e – 04 | 0.0065 | 0.2075 | 22 |
| 4 | 6.547e – 04 | 0.0013 | 0.2014 | 50 |
| 5 | 6.547e – 04 | 0.0009 | 0.2003 | 50 |

Recall that the goal of digital tomosynthesis is to reconstruct an approximation of the 3D volume, \mathbf{x} , given the set of projection images \mathbf{b}_θ , $\theta = 1, 2, \dots, n_\theta$. Using the above likelihood function, the problem has been reformulated as a nonlinear optimization problem for which standard numerical optimization schemes can be applied. A gradient descent, Newton-CG, and LBFGS algorithm are investigated as methods to solve this problem, and early termination of the iterative method produces a regularized solution.

Results presented in Table 1 include the iteration, the relative objective function value, the relative gradient value, and the relative error for the 3D volume for two iterative algorithms. The relative error can be computed as $\frac{\|\mathbf{x}_k - \mathbf{x}_{\text{exact}}\|_2}{\|\mathbf{x}_{\text{exact}}\|_2}$, where \mathbf{x}_k is the reconstructed volume at the k th iteration. For the inexact Newton-CG algorithm, the stopping criterion used for CGLS on the inner problem (36) was a residual tolerance of 0.17 and a maximum number of 50 iterations. The number of CGLS

Fig. 14 Plot of relative errors

iterations reported for the inner problem at each Newton-CG iteration can be found in the last column of the table. It is worth mentioning here that many parameters such as the number of inner and outer iterations rely heavily on heuristics that may or may not be provided by the application. In any case, appropriate parameters should be used in order to ensure that nonlinearity and ill-posedness of the problem are addressed.

Since each Newton-CG iteration requires the solution of a linear system, it is difficult to present a fair comparison of reconstruction algorithms. In terms of computational effort, the most computationally burdensome aspect of the reconstruction is the matrix-vector and matrix-transpose-vector multiplications with ray trace matrix, \mathbf{A} . Each function and gradient evaluation of the likelihood function requires a total of three “ray trace” multiplications (two for the function evaluation and one more for the gradient), and a multiplication operation with the Hessian (or its transpose) only requires two “ray trace” multiplications. Furthermore, a backtracking line search strategy is used to ensure sufficient descent at each iteration of the optimization scheme. The Cauchy point [77] is used as an initial guess in the line search scheme, thus requiring another multiplication with the Hessian. Thus, the computational cost and timing for, say, one Newton-CG iteration with 50 inner CG iterations with the Hessian is not equivalent to 50 gradient descent iterations.

Another important remark is that although the image errors in Table 1 decrease in the early iterations, these errors eventually increase. This is illustrated in the later Newton-CG iterations in Fig. 14, where plots of the relative errors per iteration for the three algorithms are presented. From Fig. 14, it is evident that the gradient descent method is slow to converge. On the contrary, Newton methods can compute a good approximation very quickly, but corruption from errors occurs quickly as well. Although LBFGS is typically used for problems where the Hessian cannot be computed directly, this approach seems to offer a good balance between fast convergence and slow semi-convergence behavior. An important remark is that

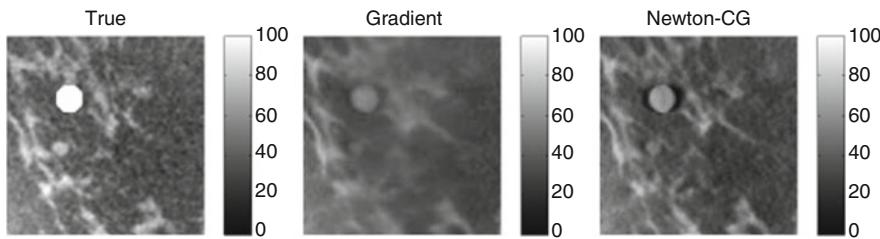

Fig. 15 Comparison of slices from the reconstructed volumes computed after 3 iterations of Newton-CG algorithm and 15 iterations of gradient descent

direct regularization techniques can also be used to regularize the problem, but appropriate regularization operators and good regularization parameter selection methods for this problem are still topics of current research. Thus, regularization via early termination of the iterations is the approach followed here.

For a comparison of images, Fig. 15 contains corresponding slices from the reconstructed volumes after three Newton-CG iterations and 15 gradient descent iterations, each requiring approximately 80 matrix-vector operations. It is evident that the Newton-CG reconstruction has more fine details and more closely resembles the true image slice.

Although nonlinear inverse problems can be difficult to analyze, there are a variety of scientific applications such as polyenergetic digital breast tomosynthesis that require methods for computing approximate solutions. Iterative methods with regularization via early termination can be a good choice, but proper preconditioning techniques may be needed to accelerate the algorithms and good heuristics are required.

5 Conclusion

Large-scale inverse problems arise in many imaging applications. The examples in this chapter illustrate the range of difficulties (from linear to nonlinear) that can be encountered and the issues that must be addressed when designing algorithms. It is important to emphasize that the literature in this field is vast and that this presentation is far from being a complete survey. However, the techniques discussed in this chapter can be used as a foundation on which to learn more about the subject.

The study of inverse problems continues to be an extremely active field of research. Although linear inverse problems have been fairly well studied, some fundamental questions still need to be addressed and many open problems remain. For example, in hybrid algorithms, simple filtering methods (e.g., truncated SVD or standard Tikhonov regularization) and standard regularization parameter choice methods (e.g., discrepancy principle or GCV) are typically used to regularize the projected problem. Some work has been done to generalize this (see, e.g., [59]), but extensions to more sophisticated filtering algorithms and parameter choice methods should be investigated. In addition, the development of novel algorithmic

implementations and software is necessary for running existing algorithms on state-of-the-art computing technologies, as is the development of techniques for uncertainty quantification. Another area of active research for the solution of linear and nonlinear inverse problems is sparse reconstruction schemes, where regularization enforces some structure to be sparse in a certain basis, that is, represented with only a few nonzero coefficients.

As discussed in sections “Separable Inverse Problems” and “Nonlinear Inverse Problems,” there are many open problems related to solving nonlinear inverse problems. For example, in the case of the variable projection Gauss-Newton method, a thorough study of its regularization and convergence properties remains to be done, especially in the context of an iteration-dependent regularization parameter. For more general nonlinear problems, issues that need to be addressed include analyzing the sensitivity of the Jacobian and Hessian matrices, as well as determining appropriate merit functions for selecting step lengths. In nonlinear optimization, difficulties arise because convexity of the objective function cannot be guaranteed, so algorithms can become trapped in local minima. More work also needs to be done in the area of regularization parameter choice methods for nonlinear problems and appropriate stopping criteria for iterative methods. For a further discussion of open problems for nonlinear inverse problems, see [28, 29].

Finally, it should be noted that many open problems are given in the context of the application, such as determining appropriate constraints and regularization operators for the problem. Future directions are often motivated by the application, and many of these questions can be found in application-specific references; see, for example, [17]. With such varied and widespread applications, large-scale inverse problems continue to be a thriving research interest in the mathematics, computer science, and image processing communities.

Acknowledgments We would like to thank Eldad Haber, University of British Columbia, and Per Christian Hansen, Technical University of Denmark, for carefully reading the first draft of this chapter. Their comments and suggestions helped to greatly improve our presentation. The research of J. Chung is supported by the US National Science Foundation (NSF) under grant DMS-0902322. The research of J. Nagy is supported by the US National Science Foundation (NSF) under grant DMS-0811031, and by the US Air Force Office of Scientific Research (AFOSR) under grant FA9550-09-1-0487.

Abstract

In this chapter are outlined some aspects of the mathematical theory for direct regularization methods aimed at the stable approximate solution of nonlinear ill-posed inverse problems. The focus is on Tikhonov type variational regularization applied to nonlinear ill-posed operator equations formulated in Hilbert and Banach spaces. The chapter begins with the consideration of the classical approach in the Hilbert space setting with quadratic misfit and penalty terms, followed by extensions of the theory to Banach spaces and present assertions on convergence and rates concerning the variational regularization with general convex penalty terms. Recent results refer to the interplay between solution smoothness and nonlinearity conditions expressed by variational inequalities.

Six examples of parameter identification problems in integral and differential equations are given in order to show how to apply the theory of this chapter to specific inverse and ill-posed problems.

1 Introduction

This chapter will be devoted to direct regularization methods – theory and examples – for the solution of inverse problems formulated as nonlinear ill-posed operator equations

$$F(x) = y, \quad (1)$$

where the forward operator $F : \mathcal{D}(F) \subseteq X \rightarrow Y$ with domain $\mathcal{D}(F)$ maps between infinite dimensional normed linear spaces X and Y , which are Banach spaces or Hilbert spaces, with norms $\|\cdot\|$. The symbol $\langle \cdot, \cdot \rangle$ designates inner products in Hilbert spaces and dual pairings in Banach spaces. Moreover, the symbols \rightarrow and \rightharpoonup denote the norm convergence and weak convergence, respectively, in such spaces. It is well known that the majority of inverse problems are ill-posed in the sense of Hadamard, i.e., at least one of the following difficulties occurs:

- (i) Equation (1) has no solution in $\mathcal{D}(F)$ if the exact right-hand side y is replaced by a perturbed element y^δ (noisy data) satisfying the inequality

$$\|y^\delta - y\| \leq \delta \quad (2)$$

with noise level $\delta > 0$.

- (ii) The solution to Eq. (1) is not uniquely determined in $\mathcal{D}(F)$.
- (iii) The solution to Eq. (1) is unstable with respect to perturbations, i.e., for $x^\delta \in \mathcal{D}(F)$ with $F(x^\delta) = y^\delta$ and (2) the norm deviation $\|x^\delta - x\|$ may be arbitrarily large. In other words, the possibly multivalued inverse operator F^{-1} fails to be continuous.

Since for nonlinear equations the local behavior of solutions is of main interest, the aspect of local ill-posedness according to [64] is focused on numerous considerations. An operator equation (1) is called locally ill-posed at some solution point $x^\dagger \in \mathcal{D}(F)$ if for any ball $B_\rho(x^\dagger)$ with center x^\dagger and an arbitrarily small radius $\rho > 0$ there exist infinite sequences $\{x_n\} \subset B_\rho(x^\dagger) \cap \mathcal{D}(F)$ such that

$$F(x_n) \rightarrow F(x^\dagger) \quad \text{in } Y, \quad \text{but} \quad x_n \not\rightharpoonup x^\dagger \quad \text{in } X \quad \text{as } n \rightarrow \infty.$$

In case of local ill-posedness, x^\dagger cannot be identified arbitrarily precise by noisy data y^δ even if the noise level δ is arbitrarily small. The aspect of local ill-posedness involves both the non-injectivity of F around x^\dagger corresponding with (ii) and the local instability of (1) corresponding with (iii) in Hadamard's sense. Wide classes of inverse problems that have smoothing, for example, compact, forward operators F lead to locally ill-posed situations.

To overcome the ill-posedness and local ill-posedness of Eq. (1), in particular to compensate the instability of solutions with respect to small changes in the right-hand side expressing a deficit of information in the data with respect to the solution to be determined, regularization methods have to be used for the stable approximate solution of Eq. (1) whenever only noisy data are given. The basic idea of regularization is to replace the ill-posed original problem by a well-posed and stable neighboring problem. A regularization parameter $\alpha > 0$ controls the trade-off between closeness of the neighboring problem expressed by small values α and high stability of the auxiliary problem expressed by large values α . In the former case the approximate solutions are too unstable, whereas in the latter case, approximate solutions are too far from the original one. On the other hand, the loss of information in the data caused by smoothing properties of the forward operator F can be diminished when external a priori information is exploited. This can be done by the choice of appropriate structure in the neighboring problems.

If the forward operator F and hence the operator equation (1) is linear, then in Hilbert spaces a comprehensive and rather complete regularization theory, including a general regularization schema and a well-established collection of methods, assertions on stability, convergence, and convergence rates, is available since more than 20 years; see [10, 35, 77–79, 84]. For recent progress of regularization theory applied to linear ill-posed problems, please refer to the papers [16, 22, 31, 57, 61, 80, 85, 86, 90]. It is well known that inverse problems aimed at the identification of parameter functions in differential equations or boundary conditions from observations of state variables are in general nonlinear even if the differential equations are linear. The nonlinearity of F , however, makes the construction and the use of regularization methods more complicated and diversified; please refer to [9, 26, 27, 33, 38, 45, 49, 56, 66, 71, 81, 87] for more details. Furthermore, there have been recent significant progress in regularization theory for ill-posed problems formulated in Banach spaces (see, e.g., [22, 60, 96, 97, 102, 103, 107, 109]). In this chapter, the focus is on direct regularization methods for the stable approximate solution of nonlinear ill-posed operator equations formulated in Hilbert and Banach spaces, where regularized solutions mostly are solutions of variational problems. The functional to be minimized over a set of admissible solutions contains a regularization parameter $\alpha > 0$ which has to be controlled in an appropriate manner. An alternative way of regularization is the solution of (1) for noisy data y^δ by an iteration process, where the stopping criterion, frequently depending on δ , plays the role of the regularization parameter. For iterative solution methods, please refer to the corresponding chapter of this book and to the monograph [8, 76].

2 Theory of Direct Regularization Methods

In contrast to the classical treatment of linear ill-posed problems, where regularized solutions $x_\alpha^\delta = R_\alpha y^\delta$, i.e., stable approximate solutions to Eq. (1) under the noise model (2), are obtained by applying bounded linear operators $R_\alpha : Y \rightarrow X$ to the data y^δ for regularization parameters $\alpha > 0$, such explicit approach fails if either

in (1) (a) the forward operator F is nonlinear, (b) the domain $\mathcal{D}(F)$ is not a linear subspace of X , or (c) the mapping $y^\delta \mapsto x_\alpha^\delta$ is continuous but nonlinear for all $\alpha > 0$ even if F is linear. All three sources of nonlinearity make it necessary to define the regularized solutions in an implicit manner. The preferred approach of direct regularization methods is variational regularization, where regularized solutions x_α^δ are minimizers of the functional

$$\Phi(x) := \mathcal{S}(F(x), y^\delta) + \alpha \mathcal{R}(x) \quad (3)$$

by assuming that \mathcal{S} is a nonnegative misfit functional measuring the discrepancy between $F(x)$ and the data y^δ , moreover $\alpha > 0$ is the regularization parameter, and \mathcal{R} with domain $\mathcal{D}(\mathcal{R}) := \{x \in X : \mathcal{R}(x) < \infty\}$ is a nonnegative stabilizing functional with small values for elements x being reliable and large values for improbable x . Since the origins of this method go back to the work of A. N. Tikhonov and his collaborators (see [114, 115]), this method is often called Tikhonov type regularization. For example, please refer to the monographs [7, 8, 10, 35, 54, 59, 68, 73, 92, 107, 109, 116, 117] and to the papers [82, 83, 98, 118], which contribute to the theory and practice of this kind of regularization.

Besides the standard version

$$\mathcal{S}(F(x), y^\delta) = \|F(x) - y^\delta\|^p, \quad p \geq 1, \quad (4)$$

which is mostly used in combination with the noise model (2) in Banach spaces, specific noise models like Poisson noise or a stochastic background suggest alternative choices for the misfit term \mathcal{S} like Kullback-Leibler or other divergences. With respect to imaging, e.g., deblurring, image reconstruction, image registration, and partial differential equations occurring there, different chapters of the monographs [2, 15, 39, 41, 91, 94, 106, 107] and the papers [12, 23, 40, 93, 120] motivate and discuss regularized solutions x_α^δ as well as different choices of functionals S and \mathcal{R} . On the other hand, the minimizers of (3) play also an important role in the treatment of statistical inverse problems by Bayesian methods, maximum a posteriori estimation (MAP), and penalized maximum likelihood estimation (see, e.g., [74]), where in some cases the penalty term $\mathcal{R}(x)$ can even be determined by a priori information when the solution x is a realization of a randomized state variable.

A typical property of ill-posed equations is that minimizing $\mathcal{S}(F(x), y^\delta)$ alone is very sensitive to data changes and yields in most cases highly oscillating minimizers. For example, the least-squares approach $\|F(x) - y^\delta\|^2 \rightarrow \min$ as preferred method in Hilbert spaces shows such behavior. Therefore, the regularization parameter $\alpha > 0$ in the variational problem $\Phi(x) \rightarrow \min$ controls the trade-off between optimal data fitting with unstable solutions if α is near zero and a high level of stability and sympathy but larger misfit for the approximate solution if α is more far from zero. The set of admissible solutions in the process of minimizing Φ from (3) is the intersection

$$\mathcal{D} := \mathcal{D}(F) \cap \mathcal{D}(\mathcal{R})$$

of the domains of F and \mathcal{R} . For obtaining a regularized solution x_α^δ to a nonlinear inverse problem, a nonlinear and frequently non-convex optimization problem has to be solved, since either the functional Φ or the set $\mathcal{D}(F)$ can be non-convex. As a consequence, for the numerical treatment of direct regularization methods in combination with discretization approaches, iterative procedures are also required. In this context, the details have been omitted, and the reader is referred to the monographs [25, 35, 107, 116] and to the sample [16, 31, 69, 72, 101] of papers from a comprehensive set of publications on numerical approaches.

The appropriate choice of α is one of the most serious tasks in regularization, where a priori choices $\alpha = \alpha(\delta)$ and a posteriori choices $\alpha = \alpha(\delta, y^\delta)$ have to be distinguished. For a priori choices the decay rate of $\alpha(\delta) \rightarrow 0$ as $\delta \rightarrow 0$ is prescribed with the goal that regularized solutions converge to a solution of (1), i.e., $x_{\alpha(\delta)}^\delta \rightarrow x^\dagger$ as $\delta \rightarrow 0$. Such convergence can be arbitrarily slow depending on smoothness properties of x^\dagger . To obtain convergence rates $\|x_{\alpha(\delta)}^\delta - x^\dagger\| = \mathcal{O}(\varphi(\delta))$ as $\delta \rightarrow 0$, that means a uniform convergence for some nonnegative increasing rate function $\varphi(\delta)$ with $\varphi(0) = 0$, additional conditions on x^\dagger , so-called source conditions, have to be satisfied. In contrast to a priori choices, an a posteriori choice of the regularization parameter α takes into account the present data y^δ and tries to equilibrate the noise level δ and the deviation between $F(x_{\alpha(\delta, y^\delta)}^\delta)$ and y^δ . By the discrepancy principle, as the most prominent approach, α is chosen originally such that $\|F(x_{\alpha(\delta, y^\delta)}^\delta) - x^\dagger\| = C\delta$ with some constant $C \geq 1$ whenever (4) and (2) are supposed. Various discussions, generalizations, and improvements of the discrepancy principle can be found in [3, 5, 69, 92, 113]. If δ is not known sufficiently well, then heuristic methods for choosing $\alpha = \alpha(y^\delta)$ can be exploited as the quasioptimality principle, the L-curve method, and others (see, e.g., [7, 35, 55]). They have theoretical drawbacks, since convergence fails in worst case situations, but the utility of those methods for many classes of applications is beyond controversy.

The choices of \mathcal{S} , \mathcal{R} , and $\alpha = \alpha(\delta, y^\delta)$ should be realized such that the following questions Q1–Q4 can be answered in a positive manner:

- Q1: Do minimizers x_α^δ of the functional Φ from (3) exist for all $\alpha > 0$ and $y^\delta \in Y$?
- Q2: Do the minimizers x_α^δ for fixed $\alpha > 0$ stably depend on the data y^δ ?
- Q3: Is there a convergence $x_{\alpha(\delta, y^\delta)}^\delta \rightarrow x^\dagger$ to a solution x^\dagger of (1) if under (2) $\delta \rightarrow 0$?
- Q4: Are there sufficient conditions imposed on x^\dagger for obtaining convergence rates $\|x_\alpha^\delta - x^\dagger\| = \mathcal{O}(\varphi(\delta))$ as $\delta \rightarrow 0$? In this context, $\varphi : (0, \infty) \rightarrow (0, \infty)$ is an index function, which means that φ is continuous and strictly increasing with $\lim_{\delta \rightarrow +0} \varphi(\delta) = 0$.

Sometimes the requirement of norm convergence is too strong. If, for instance, the penalty functional attains the form $\mathcal{R}(x) = \|x\|^q$, $q > 0$, then \mathcal{R} is stabilizing only in the sense of a topology, which is weaker than the norm topology in X . Precisely, the level sets $\{x \in X : \mathcal{R}(x) \leq c\}$ are weakly sequentially compact in X

if X is a Hilbert space or a reflexive Banach space. In such case, weak convergence $x_{\alpha(\delta,y^\delta)}^\delta \rightharpoonup x^\dagger$ of regularized solutions is a reasonable requirement. This leads to norm convergence of regularized solutions if the Radon-Riesz property is satisfied; see [107, 109]. On the other hand, it may be useful to replace the norm as a measure for the error of regularization by alternative measures $E(x_\alpha^\delta, x^\dagger)$, preferably the Bregman distance if \mathcal{R} is a convex functional and X is a Banach space; see [22, 41, 50, 58, 60].

Tikhonov Regularization in Hilbert Spaces with Quadratic Misfit and Penalty Terms

In Hilbert spaces X and Y , quadratic Tikhonov regularization with the functional

$$\Phi(x) := \|F(x) - y^\delta\|^2 + \alpha \|x - x^*\|^2 \quad (5)$$

to be minimized over $\mathcal{D} = \mathcal{D}(F)$ is the most prominent variant of variational regularization of nonlinear ill-posed operator equations, for which the complete theory with respect to questions Q1–Q4 was elaborated 20 years ago (see [37, 110]). For a comprehensive presentation including the convergence rates results, please refer to [35, Chapter 10].

For some initial guess or reference element, $x^* \in X$ minimizers of (5) tend to approximate x^* -minimum norm solutions x^\dagger to (1) for which

$$\|x^\dagger - x^*\| = \min \{\|x - x^*\| : F(x) = y, x \in \mathcal{D}(F)\}.$$

Note that x^* -minimum norm solutions need not exist. In case of existence they need not be uniquely determined. However, under the following assumption, the existence of a solution $x^\dagger \in \mathcal{D}(F)$ to (1) implies the existence of an x^* -minimum norm solution (see [107, Lemma 3.2]).

- Assumption 1.**
1. The operator $F : \mathcal{D}(F) \subseteq X \rightarrow Y$ maps between Hilbert spaces X and Y with a nonempty domain $\mathcal{D}(F)$.
 2. F is weakly sequentially closed, i.e., weak convergence of the sequences $x_n \rightharpoonup x_0$ and $F(x_n) \rightharpoonup y_0$ with $x_n \in \mathcal{D}(F)$, $x_0 \in X$, $y_0 \in Y$ implies $x_0 \in \mathcal{D}(F)$ and $F(x_0) = y_0$.

For checking item 2 of Assumption 1, it is important to know that in the case of weakly closed and convex domains $\mathcal{D}(F)$, the weak continuity of F , i.e., $x_n \rightharpoonup x_0$ implies $F(x_n) \rightharpoonup F(x_0)$, is a sufficient condition. Moreover, the following proposition (see [35, Section 10.2]) answers the questions Q1–Q3 in a positive manner.

Proposition 1. Under Assumption 1 the functional (5) has a minimizer $x_\alpha^\delta \in \mathcal{D}(F)$ for all $\alpha > 0$ and $y^\delta \in Y$. For fixed $\alpha > 0$ and a sequence $y_n \rightarrow y^\delta$, every infinite sequence $\{x_n\}$ of minimizers to the associated functionals

$$\Phi_n(x) := \|F(x) - y_n\|^2 + \alpha \|x - x^*\|^2 \quad (6)$$

has a convergent subsequence, and all limits of such subsequences are minimizers x_α^δ of (5). Whenever the a priori parameter choice $\alpha = \alpha(\delta) > 0$ for $\delta > 0$ satisfies

$$\alpha(\delta) \rightarrow 0 \quad \text{and} \quad \frac{\delta^2}{\alpha(\delta)} \rightarrow 0, \quad \text{as } \delta \rightarrow 0,$$

and if (1) has a solution in $\mathcal{D}(F)$, $\delta_n \rightarrow 0$ is a sequence of noise levels with corresponding data $y_n = y^{\delta_n}$ such that $\|y_n - y\| \leq \delta_n$, then every associated sequence $\{x_n\}$ of minimizers to (6) has a convergent subsequence, and all limit elements are x^* -minimum norm solutions x^\dagger of (1).

An answer to question Q4 concerning convergence rates is given by the following theorem along the lines of [35, Theorem 10.4].

Theorem 2. In addition to Assumption 1, let $\mathcal{D}(F)$ be convex and x^\dagger be an x^* -minimum norm solution to (1) such that

$$\|F(x) - F(x^\dagger) - A(x - x^\dagger)\| \leq \frac{L}{2} \|x - x^\dagger\|^2 \quad \text{for all } x \in \mathcal{D}(F) \cap B_\rho(x^\dagger) \quad (7)$$

holds for a ball $B_\rho(x^\dagger)$ with sufficiently large radius $\rho > 0$, a constant $L > 0$, and a bounded linear operator $A : X \rightarrow Y$ satisfying a source condition

$$x^\dagger - x^* = A^* w, \quad (8)$$

where $A^* : Y \rightarrow X$ is the adjoint operator to A and $w \in Y$ is some source element fulfilling the smallness condition

$$L \|w\| < 1. \quad (9)$$

Then the error estimate

$$\|x_\alpha^\delta - x^\dagger\| \leq \frac{\delta + \alpha \|w\|}{\sqrt{\alpha} \sqrt{1 - L \|w\|}}$$

and, for the a priori parameter choice $\underline{c}\delta \leq \alpha(\delta) \leq \bar{c}\delta$ with constants $0 < \underline{c} \leq \bar{c} < \infty$, the convergence rate

$$\|x_{\alpha(\delta)}^\delta - x^\dagger\| = \mathcal{O}(\sqrt{\delta}) \quad \text{as } \delta \rightarrow 0 \quad (10)$$

are obtained.

The operator A in (7) must be considered as a linearization of F at the point x^\dagger in the sense of a Gâteaux or Fréchet derivative $F'(x^\dagger)$. The condition (7) characterizes

the structure of nonlinearity of the forward operator F in a neighborhood of x^\dagger . If the Fréchet derivative $F'(x)$ exists and is locally Lipschitz continuous around x^\dagger with Lipschitz constant $L > 0$, then (7) is fulfilled.

For further convergence rate results of Tikhonov regularization in Hilbert spaces with quadratic penalty term, please refer, for example, to [64, 75, 88, 89, 95, 105, 111–113].

Variational Regularization in Banach Spaces with Convex Penalty Term

In Banach spaces X and Y , the wide variety of variational regularization realized by minimizing the functional Φ from (3) allows establishing a priori information about the noise model and the solution x^\dagger to be determined in a more sophisticated manner than Tikhonov regularization in Hilbert spaces with quadratic misfit and penalty terms. Knowledge of the specific situation motivates the selection of the functionals \mathcal{S} and \mathcal{R} , where norm powers (4) are considered here as misfit functional, which, for example, simplifies the numerical treatment of minimization problems if Y is a Lebesgue space $Y = L^p(\Omega)$ or a Sobolev space $Y = W^{l,p}(\Omega)$ with $1 \leq p \leq \infty$, $\Omega \subset \mathbb{R}^k$. Please refer to the papers [6, 32, 44, 51, 53, 63, 99] for a further discussion of alternative misfit functionals \mathcal{S} . In most cases convex penalty functionals \mathcal{R} are preferred. An important class of penalty functionals form the norm powers $\mathcal{R}(x) := \|x\|_{\tilde{X}}^q$, $q > 0$, $x \in \tilde{X}$, where as an alternative to the standard case $X = \tilde{X}$ the space \tilde{X} can also be chosen as a dense subspace of X with stronger norm, e.g., $X = L^q(\Omega)$, $\tilde{X} = W^{l,q}(\Omega)$, $l = 1, 2, \dots$. To reconstruct non-smooth solutions x^\dagger , the exponent q can be chosen smaller than two, for example, close to one or $q = 1$ if the solution is assumed to be sparse. To recover solutions for which the expected smoothness is low, also penalty terms $\mathcal{R}(x) = TV(x)$ are frequently applied, partly in a modified manner, where $TV(x) = \int\limits_{\Omega} |\nabla x|$ expresses the total variation of the function x (see, e.g., [1, 13, 107, 118, 119]). For specific applications in imaging (see [107, Chapter 5]) and to handle sparsity of solutions (see [3, 18, 19, 50, 52, 122] and [107, Section 3.3]), the systematic use of non-convex misfit and penalty functionals can be appropriate, in particular $0 < q < 1$ for the norm power penalties \mathcal{R} . In the sequel, however, the focus in this section in combination with the noise model (2) is upon the functional

$$\Phi(x) := \|F(x) - y^\delta\|^p + \alpha\mathcal{R}(x), \quad 1 \leq p < \infty, \quad (11)$$

with a convex penalty functional \mathcal{R} to be minimized over $\mathcal{D} = \mathcal{D}(F) \cap \mathcal{D}(\mathcal{R})$ yielding minimizers x_α^δ .

Assumption 3. 1. The operator $F : \mathcal{D}(F) \subseteq X \rightarrow Y$ maps between reflexive Banach spaces X and Y with duals X^* and Y^* , respectively.

2. F is weakly sequentially closed, $\mathcal{D}(F)$ is convex and weakly closed, and the intersection $\mathcal{D} = \mathcal{D}(F) \cap \mathcal{D}(\mathcal{R})$ is nonempty.
3. The functional \mathcal{R} is convex and weakly sequentially lower semicontinuous.
4. The functional \mathcal{R} is stabilizing, which means that for every $\alpha > 0$, $c \geq 0$, and for the exact right-hand side y of (1), the level sets

$$\mathcal{M}_\alpha(c) := \{x \in \mathcal{D} : \|F(x) - y\|^p + \alpha\mathcal{R}(x) \leq c\} \quad (12)$$

are weakly sequentially pre-compact in the following sense: every infinite sequence $\{x_n\}$ in $\mathcal{M}_\alpha(c)$ has a subsequence, which is weakly convergent in X to some element from X .

5. The operator F possesses for all $x_0 \in \mathcal{D}$ a one-sided directional derivative with Gâteaux derivative-like properties, i.e., for every $x_0 \in \mathcal{D}$ there is a bounded linear operator $F'(x_0) : X \rightarrow Y$ such that

$$\lim_{t \rightarrow +0} \frac{1}{t} (F(x_0 + t(x - x_0)) - F(x_0)) = F'(x_0)(x - x_0)$$

is valid for all $x \in \mathcal{D}(F)$.

Under Assumption 3 existence and stability of regularized solutions x_α^δ can be shown (see [60, §3]), i.e., the questions Q1–Q2 above get a positive answer. In Banach spaces regularization errors are estimated by upper bounds of $E(x_\alpha^\delta, x^\dagger)$, where E denotes an appropriate nonnegative error measure. Besides the norm deviation

$$E(x_\alpha^\delta, x^\dagger) = \|x_\alpha^\delta - x^\dagger\|, \quad (13)$$

which is the standard error measure in Hilbert spaces, in Banach spaces and for convex functionals \mathcal{R} with subdifferential $\partial\mathcal{R}$, the Bregman distance

$$E(x_\alpha^\delta, x^\dagger) = D_\xi(x_\alpha^\delta, x^\dagger) := \mathcal{R}(x_\alpha^\delta) - \mathcal{R}(x^\dagger) - \langle \xi, x_\alpha^\delta - x^\dagger \rangle \quad (14)$$

at $x^\dagger \in \mathcal{D}_B(\mathcal{R}) \subseteq X$ and $\xi \in \partial\mathcal{R}(x^\dagger) \subseteq X^*$ is frequently used as error measure, where the set $\mathcal{D}_B(\mathcal{R}) := \{x \in \mathcal{D}(\mathcal{R}) : \partial\mathcal{R}(x) \neq \emptyset\}$ represents the Bregman domain. An element $x^\dagger \in \mathcal{D}$ is called an \mathcal{R} -minimizing solution to (1) if

$$\mathcal{R}(x^\dagger) = \min \{\mathcal{R}(x) : F(x) = y, x \in \mathcal{D}\} < \infty.$$

Such \mathcal{R} -minimizing solutions exist under Assumption 3 if (1) has a solution $x \in \mathcal{D}$. For given $\alpha_{\max} > 0$ let x^\dagger denote an \mathcal{R} -minimizing solution of (1). By setting

$$\rho := 2^{p-1}\alpha_{\max} (1 + \mathcal{R}(x^\dagger)), \quad (15)$$

it holds $x^\dagger \in \mathcal{M}_{\alpha_{\max}}(\rho)$ and there exists some $\delta_{\max} > 0$ such that

$$x_{\alpha(\delta)}^\delta \in \mathcal{M}_{\alpha_{\max}}(\rho) \quad \text{for all} \quad 0 \leq \delta \leq \delta_{\max}.$$

Along the lines of [107, Section 3.2], [109, Chapters 3 and 4], and [3, 17, 58, 60, 62, 65], there are presented in the following some results on the regularization theory for that setting.

Under an a priori parameter choice $\alpha = \alpha(\delta) > 0$ satisfying

$$\alpha(\delta) \rightarrow 0 \quad \text{and} \quad \frac{\delta^p}{\alpha(\delta)} \rightarrow 0, \quad \text{as } \delta \rightarrow 0,$$

a positive answer to question Q3 can be given and weak convergence $x_{\alpha(\delta)}^\delta \rightharpoonup x^\dagger$ as $\delta \rightarrow 0$ (for subsequences in analogy to Proposition 1) of regularized solutions to \mathcal{R} -minimizing solutions x^\dagger is shown. For stronger convergence results concerning the norm convergence, please refer, for example, to Proposition 3.32 in [107].

Taking into account the advantages of a posteriori choices of the regularization parameter $\alpha > 0$, it is of interest to select such parameter choice rules $\alpha = \alpha(\delta, y^\delta)$ which obey the conditions

$$\alpha(\delta, y^\delta) \rightarrow 0 \quad \text{and} \quad \frac{\delta^p}{\alpha(\delta, y^\delta)} \rightarrow 0 \quad \text{as} \quad \delta \rightarrow 0. \quad (16)$$

Such study was performed for the sequential discrepancy principle which will be introduced in the following. The basis of this variety of discrepancy principle is, for prescribed $0 < q < 1$ and $\alpha_0 > 0$, a sequence

$$\Delta_q := \{\alpha_j > 0 : \alpha_j = q^j \alpha_0, j \in \mathbb{Z}\} \quad (17)$$

of regularization parameters and the specification of some constant $\tau > 1$.

Definition 1 (sequential discrepancy principle). For fixed $\delta > 0$ and $y^\delta \in Y$, it is said that $\alpha = \alpha(\delta, y^\delta) \in \Delta_q$ is chosen according to the sequential discrepancy principle if

$$\|F(x_\alpha^\delta) - y^\delta\| \leq \tau \delta < \|F(x_{\alpha/q}^\delta) - y^\delta\|. \quad (18)$$

Due to Assumption 3, the set $X_{\min} := \{x \in \mathcal{D} : \mathcal{R}(x) = \mathcal{R}_{\min}\}$ is nonempty for the value $\mathcal{R}_{\min} := \inf_{x \in \mathcal{D}} \mathcal{R}(x) \geq 0$ and so is $Y_{\min} := F(X_{\min})$, where

$$F(S) := \{\hat{y} \in Y : \hat{y} = F(x), x \in S\}$$

is defined for subsets $S \subseteq \mathcal{D}(F)$. Moreover, there is an element $x_{\min} \in X_{\min}$ such that $\text{dist}(y^\delta, Y_{\min}) := \inf_{x \in X_{\min}} \|F(x) - y^\delta\| = \|F(x_{\min}) - y^\delta\|$. Using this notation, the Proposition 2 below still needs the following two definitions concerning the exact penalization veto and requirements on data compatibility, respectively.

Definition 2 (exact penalization veto). It is said that the exact penalization veto is satisfied for $y \in F(\mathcal{D})$ if, for all $\alpha > 0$, any minimizer x^\dagger of the functional

$$\Phi_0(x) := \|F(x) - y\|^p + \alpha \mathcal{R}(x)$$

over \mathcal{D} , which is simultaneously an \mathcal{R} -minimizing solution of (1), belongs to X_{\min} .

Definition 3 (compatible data). For $y \in F(\mathcal{D})$ and prescribed $\tau > 1$, it is said that there is data compatibility if there is some $\delta_{\max} > 0$ such that for all data $y^\delta \in Y$ fulfilling (2), the condition

$$\tau \delta < \text{dist}(y^\delta, Y_{\min}) \quad \text{for all } 0 < \delta \leq \delta_{\max}$$

is satisfied.

In the paper [3], there have been formulated sufficient conditions for fulfilling the exact penalization veto, which is mostly the case if $p > 1$ for the norm exponent in the misfit term of the Tikhonov functionals Φ and Φ_0 . Sufficient conditions for obtaining data compatibility can also be found in that paper. The following proposition is a direct consequence of the corresponding studies in [3] for an α -selection according to the sequential discrepancy principle.

Proposition 2. *Let for the exact right-hand side $y \in F(\mathcal{D})$ of Eq. (1) the exact penalization veto be satisfied and assume for prescribed $\tau > 1$ data compatibility. Then there is some $\delta_{\max} > 0$ such that $\alpha = \alpha(\delta, y^\delta)$ can be chosen according to the sequential discrepancy principle for all $0 < \delta \leq \delta_{\max}$. Moreover, this parameter choice satisfies condition (16), and consequently weak convergence $x_{\alpha(\delta, y^\delta)}^\delta \rightharpoonup x^\dagger$ as $\delta \rightarrow 0$ occurs in the sense of subsequences to \mathcal{R} -minimizing solutions x^\dagger of (1) with the limit condition $\lim_{\delta \rightarrow 0} \mathcal{R}(x_{\alpha(\delta, y^\delta)}^\delta) = \mathcal{R}(x^\dagger)$.*

The weak convergence of regularized solutions $x_{\alpha(\delta, y^\delta)}^\delta \rightharpoonup x^\dagger$ in the sense of subsequences from Proposition 2 is not worth too much. Even if the Radon-Riesz property, which ensures that $x_{\alpha(\delta, y^\delta)}^\delta \rightharpoonup x^\dagger$ and $\mathcal{R}(x_{\alpha(\delta, y^\delta)}^\delta) \rightarrow \mathcal{R}(x^\dagger)$ lead to $x_{\alpha(\delta, y^\delta)}^\delta \rightarrow x^\dagger$ as $\delta \rightarrow 0$, allows amplifying this to norm convergence, this convergence can be arbitrarily slow for awkward solutions x^\dagger . To get more, namely, a uniform error estimate for classes of solutions x^\dagger in the sense of convergence rates with an index function φ determining the rate (see question Q4 above), additional requirements must be imposed on all elements x^\dagger from the class under consideration. In practice, one can restrict the considerations to rate functions φ which are concave. The abovementioned requirements are always smoothness conditions. Precisely, the \mathcal{R} -minimizing solutions x^\dagger to be approximated by regularized solutions

must have a certain level of smoothness with respect to F . For nonlinear forward operators F also the specific structure of nonlinearity influences the rate function φ .

With respect to operator properties, first the concept of a degree of nonlinearity from [58] is exploited:

Definition 4 (degree of nonlinearity in Banach space). Let $c_1 \geq 0$, $c_2 \geq 0$, and $c_1 + c_2 > 0$. Then F is said to be nonlinear of degree (c_1, c_2) for the Bregman distance $D_\xi(\cdot, x^\dagger)$ of \mathcal{R} at a solution $x^\dagger \in \mathcal{D}_B(\mathcal{R}) \subseteq X$ of (1) with $\xi \in \partial\mathcal{R}(x^\dagger) \subseteq X^*$ if there is a constant $K > 0$ such that

$$\|F(x) - F(x^\dagger) - F'(x^\dagger)(x - x^\dagger)\| \leq K \|F(x) - F(x^\dagger)\|^{c_1} D_\xi(x, x^\dagger)^{c_2} \quad (19)$$

for all $x \in \mathcal{M}_{\alpha_{\max}}(\rho)$.

On the other hand, the solution smoothness of x^\dagger in combination with a well-defined degree of nonlinearity can be expressed in an efficient manner by variational inequalities

$$\langle \xi, x^\dagger - x \rangle \leq \beta_1 D_\xi(x, x^\dagger) + \beta_2 \|F(x) - F(x^\dagger)\|^\kappa \quad \text{for all } x \in \mathcal{M}_{\alpha_{\max}}(\rho) \quad (20)$$

with some $\xi \in \partial\mathcal{R}(x^\dagger)$, two multipliers $0 \leq \beta_1 < 1$, $\beta_2 \geq 0$, and an exponent $\kappa > 0$ for obtaining convergence rates. The subsequent theorem (for a proof see [65]) shows the utility of such variational inequalities for ensuring convergence rates in variational regularization (for more details in the case $\kappa = 1$, see also [60] and [107, Section 3.2]).

Theorem 4. *For regularized solutions x_α^δ minimizing Φ from (11) with $p > 1$ under Assumption 3 and provided that there is an \mathcal{R} -minimizing solution $x^\dagger \in \mathcal{D}_B(\mathcal{R})$, the convergence rate*

$$E(x_{\alpha(\delta)}^\delta, x^\dagger) = \mathcal{O}(\delta^\kappa) \quad \text{as } \delta \rightarrow 0 \quad (21)$$

is valid for the Bregman distance (14) as error measure and for an a priori parameter choice $\alpha(\delta) \asymp \delta^{p-\kappa}$ if there exist an element $\xi \in \partial\mathcal{R}(x^\dagger)$ and constants $0 \leq \beta_1 < 1$, $\beta_2 \geq 0$ such that the variational inequality (20) holds for some $0 < \kappa \leq 1$ and with ρ from (15).

This result which is based on Young's inequality can immediately be extended to the situation $0 < \kappa < p \leq 1$. Moreover, the situation $\kappa = p \leq 1$ characterizes the exact penalization case. For noisy data and $\kappa = p \leq 1$, it holds $D_\xi(x_{\alpha_0}^\delta, x^\dagger) = \mathcal{O}(\delta^p)$ as $\delta \rightarrow 0$ for a regularization parameter $\alpha = \alpha_0$ which is fixed but sufficiently small (see [22]). An extension of such results to convergence rates of higher order is outlined in [97].

To verify different situations for the exponent $\kappa > 0$, the setting is restricted as follows:

Assumption 5. *In addition to Assumption 3, assume for an \mathcal{R} -minimizing solution x^\dagger to (1):*

1. *The operator F is Gâteaux differentiable in x^\dagger with the Gâteaux derivative $F'(x^\dagger)$.*
2. *The functional \mathcal{R} is Gâteaux differentiable in x^\dagger with the Gâteaux derivative $\xi = \mathcal{R}'(x^\dagger) \in X^*$; hence, the subdifferential $\partial\mathcal{R}(x^\dagger) = \{\xi\}$ is a singleton.*

The following proposition (see [65, Proposition 4.3]) shows that exponents $\kappa > 1$ in the variational inequality (20) under Assumption 5 in principle cannot occur.

Proposition 3. *Under the Assumption 5 the variational inequality (20) cannot hold with $\xi = \mathcal{R}'(x^\dagger) \neq 0$ and multipliers $\beta_1, \beta_2 \geq 0$ whenever $\kappa > 1$.*

Now the following proposition will highlight the borderline case $\kappa = 1$ and the cross connections between variational inequalities and source conditions for the Banach space setting. Moreover, in the next subsection, the interplay with (8) and generalized source condition can be discussed.

Proposition 4. *Under Assumption 5 the following two assertions hold:*

(a) *The validity of a variational inequality*

$$\langle \xi, x^\dagger - x \rangle \leq \beta_1 D_\xi(x, x^\dagger) + \beta_2 \|F(x) - F(x^\dagger)\| \quad \text{for all } x \in \mathcal{M}_{\alpha_{\max}}(\rho) \quad (22)$$

for $\xi = \mathcal{R}'(x^\dagger)$ and two multipliers $\beta_1, \beta_2 \geq 0$ implies the source condition

$$\xi = F'(x^\dagger)^* w, \quad w \in Y^*. \quad (23)$$

(b) *Let F be nonlinear of degree $(0, 1)$ for the Bregman distance $D_\xi(\cdot, x^\dagger)$ of \mathcal{R} at x^\dagger , i.e.,*

$$\|F(x) - F(x^\dagger) - F'(x^\dagger)(x - x^\dagger)\| \leq K D_\xi(x, x^\dagger) \quad (24)$$

holds for a constant $K > 0$ and all $x \in \mathcal{M}_{\alpha_{\max}}(\rho)$. Then the source condition (23) together with the smallness condition

$$K \|w\|_{Y^*} < 1 \quad (25)$$

implies the validity of a variational inequality (22) with $\xi = \mathcal{R}'(x^\dagger)$ and multipliers $0 \leq \beta_1 = K \|w\|_{Y^} < 1$, $\beta_2 = \|w\|_{Y^*} \geq 0$.*

Sufficient conditions for the validity of a variational inequality (20) with fractional exponents $0 < \kappa < 1$ are formulated in [58] based on the method of approximate source conditions using appropriate distance functions that measure the degree of violation of the source condition (23) for the solution x^\dagger . Assertions on convergence rates for that case can be made when the degree of nonlinearity is such that $c_1 > 0$ as the next proposition shows.

Proposition 5. *Under Assumption 5 let F be nonlinear of degree (c_1, c_2) with $0 < c_1 \leq 1$, $0 \leq c_2 < 1$, $c_1 + c_2 \leq 1$ for the Bregman distance $D_\xi(\cdot, x^\dagger)$ of \mathcal{R} at x^\dagger , i.e.,*

$$\|F(x) - F(x^\dagger) - F'(x^\dagger)(x - x^\dagger)\| \leq K \|F(x) - F(x^\dagger)\|^{c_1} D_\xi(u, x^\dagger)^{c_2} \quad (26)$$

holds for a constant $K > 0$ and all $x \in \mathcal{M}_{\alpha_{\max}}(\rho)$. Then the source condition (23) immediately implies the validity of a variational inequality (20) with

$$\kappa = \frac{c_1}{1 - c_2}, \quad (27)$$

$\xi = \mathcal{R}'(x^\dagger)$, and multipliers $0 \leq \beta_1 < 1$, $\beta_2 \geq 0$.

Some Specific Results for Hilbert Space Situations

The abstract concepts of the last subsection for the Tikhonov regularization with quadratic functionals under Assumption 5, but with Assumption 1 in Hilbert spaces, will be illustrated next. For

$$\mathcal{R}(x) := \|x - x^*\|^2$$

the \mathcal{R} -minimizing solutions and the classical x^* -minimum norm solutions coincide. Moreover, it holds $\mathcal{D} = \mathcal{D}(F)$ and for ξ and $D_\xi(\tilde{x}, x)$ the simple structure

$$\xi = 2(x^\dagger - x^*) \quad \text{and} \quad D_\xi(\tilde{x}, x) = \|\tilde{x} - x\|^2$$

with Bregman domain $\mathcal{D}_B(\mathcal{R}) = X$. Then the source condition (23) attains the form (8) with $A = F'(x^\dagger)/2$.

To focus on the distinguished character of the setting for Hilbert spaces X and Y , the Definition 4 will be specified as follows:

Definition 5 (Degree of nonlinearity in Hilbert space). Let $c_1 \geq 0$, $c_2 \geq 0$, and $c_1 + c_2 > 0$. Define F to be nonlinear of degree (c_1, c_2) at a solution $x^\dagger \in \mathcal{D}(F)$ of (1) if there is a constant $K > 0$ such that

$$\|F(x) - F(x^\dagger) - F'(x^\dagger)(x - x^\dagger)\| \leq K \|F(x) - F(x^\dagger)\|^{c_1} \|x - x^\dagger\|^{2c_2} \quad (28)$$

for all $x \in \mathcal{M}_{\alpha_{\max}}(\rho)$.

Furthermore, in Hilbert spaces Hölder source conditions

$$\xi = \left(F'(x^\dagger)^* F'(x^\dagger) \right)^{\eta/2} v, \quad v \in X, \quad (29)$$

can be formulated that allow expressing a lower level of solution smoothness of x^\dagger for $0 < \eta < 1$ compared to the case $\eta = 1$, where (29) is equivalent to

$$\xi = F'(x^\dagger)^* w, \quad w \in Y$$

(cf. condition (8) in Theorem 2). For that situation of lower smoothness, the following theorem (see [65, Proposition 6.6]) complements the Theorem 2.

Theorem 6. *Under the Assumption 5 let the operator F mapping between the Hilbert spaces X and Y be nonlinear of degree (c_1, c_2) at x^\dagger with $c_1 > 0$ and let with $\mathcal{R}(x) = \|x - x^*\|^2$ the element $\xi = 2(x^\dagger - x^*)$ satisfy the Hölder source condition (29). Then the variational inequality (20) holds with exponent*

$$\kappa = \min \left\{ \frac{2\eta c_1}{1 + \eta(1 - 2c_2)}, \frac{2\eta}{1 + \eta} \right\}, \quad 0 < \eta \leq 1, \quad (30)$$

for all $x \in \mathcal{M}_{\alpha_{\max}}(\rho)$ and multipliers $0 \leq \beta_1 < 1, \beta_2 \geq 0$. Consequently, for regularized solutions $x_{\alpha(\delta)}^\delta$ minimizing the functional Φ from (5), the convergence rate

$$E(x_{\alpha(\delta)}^\delta, x^\dagger) = \mathcal{O}(\delta^{\kappa/2}) \quad \text{as } \delta \rightarrow 0 \quad (31)$$

holds for the norm distance (13) as error measure and for an a priori parameter choice $\alpha(\delta) \asymp \delta^{p-\kappa}$.

For parameter identification problems in partial differential equations (cf., e.g., [9, 68]), which can be written as nonlinear operator equations (1) with implicitly given forward operators F , it is difficult to estimate the Taylor remainder $\|F(x) - F(x^\dagger) - F'(x^\dagger)(x - x^\dagger)\|$ and the variational inequality approach may fail. However, if in addition to the Hilbert space X a densely defined subspace \tilde{X} with stronger norm is considered, then in many applications for all $R > 0$, there hold conditional stability estimates of the form

$$\|x_1 - x_2\| \leq K \|F(x_1) - F(x_2)\|^{\kappa} \quad \text{if } x_i \in \mathcal{D}(F) \cap \tilde{X}, \quad \|x_i\|_{\tilde{X}} \leq R \quad (i = 1, 2) \quad (32)$$

with some $0 < \kappa \leq 1$ and a constant $K = K(R) > 0$, which may depend on the radius R .

Then along the lines of the paper, [31] the following theorem can be formulated.

Theorem 7. *Let X and Y be Hilbert spaces and let $B : \mathcal{D}(B) \subset X \rightarrow X$ be an unbounded injective, positive definite, self-adjoint linear operator with domain $\tilde{X} = \mathcal{D}(B)$ dense in X . Furthermore, let $\tilde{C} > 0$ be a constant such that $\|x\|_{\tilde{X}} := \|Bx\| \geq \tilde{C} \|x\|$ holds for $x \in \tilde{X}$ and \tilde{X} becomes a Hilbert space with norm $\|\cdot\|_{\tilde{X}}$ stronger than the norm in X . For the nonlinear operator $F : \mathcal{D}(F) \subseteq X \rightarrow Y$, consider regularized solutions x_{α}^{δ} as minimizers over $\mathcal{D} := \mathcal{D}(F) \cap \tilde{X}$ of the functional*

$$\Phi(x) := \|F(x) - y^{\delta}\|^2 + \alpha \|x\|_{\tilde{X}}^2. \quad (33)$$

Moreover, for all $R > 0$ let hold a conditional stability estimate of the form (32) with some $0 < \kappa \leq 1$ and a constant $K = K(R) > 0$. Then for a solution $x^{\dagger} \in \mathcal{D}$ of Eq. (1), the convergence rate

$$E(x_{\alpha(\delta)}^{\delta}, x^{\dagger}) = \mathcal{O}(\delta^{\kappa}) \quad \text{as } \delta \rightarrow 0 \quad (34)$$

is obtained with the norm distance (13) as error measure and for an a priori parameter choice $\underline{c}\delta^2 \leq \alpha(\delta) \leq \bar{c}\delta^2$ for constants $0 < \underline{c} \leq \bar{c} < \infty$.

The papers [28, 65] show that the convergence rate result of Theorem 7 can be extended to Banach space situations.

Further Convergence Rates Under Variational Inequalities

Returning to the Banach space setting, in Theorem 4, convergence rates were drawn from the variational inequality (20) benefit. For the error measure E from (14) and taking into account that the penalty functional \mathcal{R} is convex, this inequality can be reformulated as

$$\beta E(x, x^{\dagger}) \leq \mathcal{R}(x) - \mathcal{R}(x^{\dagger}) + C \|F(x) - F(x^{\dagger})\| \quad \text{for all } x \in \mathcal{M},$$

for constants $0 < \beta \leq 1$ and $C > 0$, where \mathcal{M} denotes an appropriate set which contains x^{\dagger} and all regularized solutions x_{α}^{δ} for sufficiently small $\delta > 0$. Such variational inequalities (also called variational range conditions or variational smoothness assumptions) are in the case of general nonnegative error measures E a powerful tool for obtaining convergence rates in Tikhonov type regularization, and please refer to the overview in [42]. In the extended form

$$\beta E(x, x^\dagger) \leq \mathcal{R}(x) - \mathcal{R}(x^\dagger) + C \varphi(\|F(x) - F(x^\dagger)\|) \quad \text{for all } x \in \mathcal{M}, \quad (35)$$

with some concave index function φ , such variational inequalities were intensively studied in [62]. Inequalities of this type combine assertions on the solution smoothness of x^\dagger with assertions on the structure of nonlinearity of F around x^\dagger . In [17] it was shown that inequalities of the form (35) are a consequence of nonlinearity conditions

$$\|F'(x^\dagger)(x - x^\dagger)\| \leq \sigma(\|F(x) - F(x^\dagger)\|) \quad \text{for all } x \in \mathcal{M}, \quad (36)$$

with concave index functions σ , where φ depends on σ , and both functions even coincide if x^\dagger satisfies the source condition

$$\xi = F'(x^\dagger)^* w, \quad w \in Y^*, \quad (37)$$

for some subgradient $\xi \in \partial \mathcal{R}(x^\dagger)$.

Theorem 8. Suppose that for $y \in F(\mathcal{D})$ the \mathcal{R} -minimizing solution $x^\dagger \in \mathcal{D}$ of Eq. (1) obeys for the nonnegative error measure E the variational inequality (35) with some set $\mathcal{M} \subseteq X$, constants $0 < \beta \leq 1$, $C > 0$, and a concave index function φ . Then, for the a priori parameter choice

$$\alpha(\delta) = \alpha_0 \frac{\delta^p}{\varphi(\delta)}$$

and provided that the Tikhonov-regularized solutions satisfy the condition $x_{\alpha(\delta)}^\delta \in \mathcal{M}$ for $0 < \delta \leq \delta_{\max}$, the convergence rate

$$E(x_{\alpha(\delta)}^\delta, x^\dagger) = \mathcal{O}(\varphi(\delta)) \quad \text{as } \delta \rightarrow 0 \quad (38)$$

holds for arbitrarily chosen $\alpha_0 > 0$ whenever the norm exponent p in (11) is taken from the interval $1 < p < \infty$ and for $0 < \alpha_0 < 1$ if $p = 1$.

The same convergence rate result can also be derived from the variational inequality (35) if the regularization parameter α is chosen according to the sequential discrepancy principle. For linear injective operators F and an ℓ^1 -penalty term \mathcal{R} , this was exploited in [21] (see also [4]) for obtaining convergence rates under conjectured sparsity constraints when the sparsity fails, but x^\dagger is in ℓ^1 . Then the decay rate of solution components $x_k^\dagger \rightarrow 0$ as $k \rightarrow \infty$ influences the function φ in (35).

3 Examples

In this section, several examples of parameter identification problems in integral and differential equations will be presented in order to show how to apply the regularization theory outlined above to specific ill-posed and inverse problems. The examples refer either to nonlinear inverse problems, which can be formulated as operator equations (1) with forward operator F mapping from a Hilbert space X to a Hilbert space Y , or to linearizations of such problems, which then appear as linear operator equations. All discussed examples originally represent ill-posed problems in the sense that small data changes may lead to arbitrarily large errors in the solution. If the forward operator F is linear, then this phenomenon can be characterized by the fact that the range of the operator F is a nonclosed subspace in Y . For nonlinear F such simple characterization fails, but a local version of ill-posedness (see [64]) takes place in general. In order to make clear the cross connections to the theory, as in the previous sections, the unknown parameter functions are denoted by x , in particular the exact solution to (1) by x^\dagger , and the exact and noisy data are denoted by y and y^δ , respectively. For conciseness, this section restricts to six examples. More examples can be found in the corresponding references of this book.

Example I ((Identification of coefficients in wave equations)). Let $\Omega \subset \mathbb{R}^n$, $n = 1, 2, 3$, be a bounded domain with C^2 -boundary $\partial\Omega$. Consider

$$\begin{cases} \frac{\partial^2 u}{\partial t^2}(\zeta, t) = \Delta u(\zeta, t) + x(\zeta)u(\zeta, t), & \zeta \in \Omega, 0 < t < T, \\ u(\zeta, 0) = a(\zeta), \quad \frac{\partial u}{\partial t}(\zeta, 0) = b(\zeta), & \zeta \in \Omega, \\ \frac{\partial u}{\partial v}(\zeta, t) = 0, & \zeta \in \partial\Omega, \quad 0 < t < T. \end{cases} \quad (39)$$

Here and henceforth $\frac{\partial}{\partial v}$ denotes the normal derivative. Fix initial values a and b such that

$$a \in H^3(\Omega), \quad b \in H^2(\Omega), \quad \frac{\partial a}{\partial v} |_{\partial\Omega \times (0, T)} = \frac{\partial b}{\partial v} |_{\partial\Omega \times (0, T)} = 0. \quad (40)$$

Then for any function $x \in W^{1,\infty}(\Omega)$, there exists a unique solution

$$u(x) = u(x)(\zeta, t) \in C([0, T]; H^3(\Omega)) \cap C^1([0, T]; H^2(\Omega)) \cap C^2([0, T]; H^1(\Omega))$$

to (39) (see, e.g., [67]).

The inverse problem here consists in the identification of the parameter function $x = x(\zeta)$, $\zeta \in \Omega$, occurring in the hyperbolic partial differential equation based on noisy observations y^δ of time derivatives y of the state variable $[u(x)](\zeta, t)$ on the boundary $(\zeta, t) \in \partial\Omega \times (0, T)$. In addition to (40), assume that

$$T > \min_{\zeta' \in \overline{\Omega}} \max_{\zeta \in \Omega} |\zeta - \zeta'| \quad (41)$$

and

$$|a(\zeta)| > 0, \quad \zeta \in \overline{\Omega}. \quad (42)$$

Moreover, set

$$\mathcal{U}_M = \{x \in W^{1,\infty}(\Omega) : \|x\|_{W^{1,\infty}(\mathbb{R})} \leq M\} \quad (43)$$

for $M > 0$.

In [67], it is proved that there exists a constant $C = C(\Omega, T, a, b, M) > 0$ such that

$$\|x_1 - x_2\|_{L^2(\Omega)} \leq C \left\| \frac{\partial}{\partial t} (u(x_1) - u(x_2)) \right\|_{H^1(\partial\Omega \times (0, T))} \quad (44)$$

for all $x_1, x_2 \in \mathcal{U}_M$.

The forward operator F is defined as a mapping from the space $X = L^2(\Omega)$ to the space $Y = H^1(\partial\Omega \times (0, T))$ according to

$$[F(x)](\zeta, t) := \frac{\partial u(x)}{\partial t} \Big|_{\partial\Omega \times (0, T)}, \quad (\zeta, t) \in \partial\Omega \times (0, T).$$

This is a nonlinear operator mapping between the Hilbert spaces X and Y , and Ill-posedness of the corresponding operator equation can be indicated. However, the estimate (44) shows that this inverse problem possesses good stability properties if the set of admissible solutions is restricted suitably or if the regularization term is chosen in an appropriate manner.

A Tikhonov regularization approach as outlined in the previous sections is useful. If the functional Φ is chosen as

$$\Phi(x) = \|F(x) - y^\delta\|_Y^2 + \alpha \|x - x^*\|_X^2,$$

the theory applies. Alternatively, the penalty term can also be chosen by using a stronger norm. In this case, the functional Φ is chosen as

$$\Phi(x) = \|F(x) - y^\delta\|_Y^2 + \alpha \|x\|_{\tilde{X}}^2.$$

where $\tilde{X} = W^{1,\infty}(\Omega)$.

Then by the conditional stability estimation (44), the convergence rate

$$\|x_\alpha^\delta - x^\dagger\|_{L^2(\Omega)} = \mathcal{O}(\delta) \quad \text{as } \delta \rightarrow 0$$

is obtained with the choice $\alpha = \delta^2$.

Example II (Determination of shapes of boundaries). Using polar coordinates (r, θ) , the shape of a boundary in \mathbb{R}^2 is identified. For $M > 0$ and $0 < m_0 <$

$m_1 < 1$, set

$$\mathcal{U}_{m_1, M} = \left\{ x = x(\theta) \in C^2[0, 2\pi] : \frac{d^k x}{d\theta^k}(0) = \frac{d^k x}{d\theta^k}(2\pi), k = 0, 1, 2, \right. \\ \left. \|x\|_{C^2[0, 2\pi]} \leq M, \|x\|_{C[0, 2\pi]} \leq m_1 \right\}$$

and

$$\mathcal{Q}_{m_0} = \{x \in C^2[0, 2\pi] : x(\theta) \geq m_0, 0 \leq \theta \leq 2\pi\}.$$

Now with a function $x \in \mathcal{U}_{m_1, M}$, let $\Omega(x) \subset \mathbb{R}^2$ denote a domain being a subset of the unit circle, which is bounded by the curve $\gamma(x) = \{\xi = (r, \theta) : r = x(\theta), 0 \leq \theta \leq 2\pi\}$. Consider the Laplacian field in $\Omega(x)$:

$$\begin{cases} \Delta u = 0 & \text{in } \Omega(x), \\ u|_{\gamma(x)} = 0, & u|_{\Gamma} = \psi, \end{cases} \quad (45)$$

where $\psi \in C^3(\Gamma)$ is fixed and $\psi \geq 0$ does not vanish identically on Γ . Then there exists a unique classical solution $u(x) = u(x)(\xi)$ to (45).

The inverse problem in this example is aimed at the identification of the interior subboundary $\gamma(x)$ from noisy data y^δ of $y := \frac{\partial u(x)}{\partial v}|_{\Gamma'}$ where Γ' is an arbitrary relatively open subset of Γ .

In the paper [20], a uniqueness assertion was proved, namely, that it can be concluded, for $x_1, x_2 \in \mathcal{U}_{m_1, M} \cap \mathcal{Q}_{m_0}$, from the equality of two potential flux functions

$$\frac{\partial u(x_1)}{\partial v} = \frac{\partial u(x_2)}{\partial v} \quad \text{on } \Gamma'$$

that

$$x_1(\theta) = x_2(\theta), \quad 0 \leq \theta \leq 2\pi.$$

Moreover, there exists a constant $C = C(m_0, m_1, M, \psi) > 0$ such that

$$\|x_1 - x_2\|_{C[0, 2\pi]} \leq \frac{C}{\left| \log \left\| \frac{\partial u(x_1)}{\partial v} - \frac{\partial u(x_2)}{\partial v} \right\|_{C^1(\Gamma')} \right|} \quad (46)$$

for all $x_1, x_2 \in \mathcal{U}_{m_1, M} \cap \mathcal{Q}_{m_0}$.

The Banach spaces X and Y are fixed here as

$$X = C[0, 2\pi], \quad Y = C^1(\Gamma'),$$

and the forward operator is introduced by the assignment

$$F(x) := \left. \frac{\partial u(x)}{\partial \nu} \right|_{\Gamma'}.$$

Taking into account the intrinsic ill-posedness of this inverse problem, nevertheless, it can be seen that the estimate (46) shows some weak, i.e., logarithmic, stability. This helps to overcome the ill-posedness here again if the admissible set is chosen suitably or the Tikhonov regularization is applied in an appropriate way.

The theory of the preceding sections applies if the functional Φ is chosen as

$$\Phi(x) = \|F(x) - y^\delta\|_Y^2 + \alpha \mathcal{R}(x)$$

with $\mathcal{R}(x)$ as a convex penalty term or if the penalty term is equipped with some stronger norm leading to

$$\Phi(x) = \|F(x) - y^\delta\|_Y^2 + \alpha \|x\|_{\tilde{X}}^2,$$

where $\tilde{X} = Q_{m_0} \cap Z$ and

$$Z = \left\{ x \in C^2[0, 2\pi] : \frac{d^k x}{d\theta^k}(0) = \frac{d^k x}{d\theta^k}(2\pi), k = 0, 1, 2 \right\}.$$

The conditional stability estimation (46) gives the convergence rate

$$\|x_\alpha^\delta - x^\dagger\|_{C[0, 2\pi]} = \mathcal{O}\left(\frac{1}{|\log \delta|}\right) \quad \text{as } \delta \rightarrow 0$$

for the parameter choice $\alpha = \delta^2$.

Similar inverse problems are discussed in the papers [14, 58]. The regularization methods outlined above can be used to treat those inverse problems, too.

Example III (Integral equation of the first kind with analytic kernel). Let D and D_1 be simple connected bounded domains in \mathbb{R}^3 such that $\overline{D} \cap \overline{D}_1 = \emptyset$. Consider an integral equation of the first kind:

$$[F(x)](\eta) := \int_D \frac{x(\zeta)}{|\eta - \zeta|^2} d\zeta = y(\eta), \quad \eta \in D_1. \quad (47)$$

This type of integral equation is derived in the context of models for nondestructive testing (see [36]). In the original inverse problem, there is a nonlinear one. The integral equation (47), however, can be considered as a linearization of the original

problem. It was shown in [36] that the linearized problem (47) is close to the original problem under some assumptions on the size of domain D .

By $\overline{D} \cap \overline{D}_1 = \emptyset$, the kernel $\frac{1}{|\eta - \zeta|^2}$ is analytic in $\eta \in D_1$ and $\zeta \in D$, so that (47) appears as a severely ill-posed linear operator equation.

In the paper [30], it was proved that if there are two functions $x_1, x_2 \in L^2(D)$ such that the corresponding y_1, y_2 satisfy

$$y_1(\eta) = y_2(\eta), \quad \eta \in D_1,$$

then it holds

$$x_1(\zeta) = x_2(\zeta), \quad \zeta \in D.$$

Moreover, the following conditional stability is proved: Fix $q > 3$ and

$$\mathcal{U}_M = \left\{ x \in W_0^{2,q}(D) : \|x\|_{W_0^{2,q}(D)} \leq M \right\}.$$

Then there exists a constant $C = C(q, M, D, D_1) > 0$ such that

$$\|x\|_{L^2(D)} \leq \frac{C}{|\log \|y\|_{H^1(D_1)}|} \tag{48}$$

for all $x \in \mathcal{U}_M$.

The linear forward operator F maps here from the space $X = L^2(D)$ to the space $Y = H^1(D_1)$. In spite of the original ill-posedness of the operator equation, the estimate (48) shows again logarithmic stability after appropriate restriction of the set of admissible solutions.

Variational regularization with the Tikhonov functional

$$\Phi(x) = \|F(x) - y^\delta\|_Y^2 + \alpha\|x - x^*\|_X^2$$

or alternatively with

$$\Phi(x) = \|F(x) - y^\delta\|_Y^2 + \alpha\|x\|_{\tilde{X}}^2$$

for $\tilde{X} = W_0^{2,q}(D)$ allows the application of the general theory to that example. In particular, the conditional stability estimation (48) yields the convergence rate

$$\|x_\alpha^\delta - x^\dagger\|_{L^2(D)} = \mathcal{O}\left(\frac{1}{|\log \delta|}\right) \quad \text{as } \delta \rightarrow 0$$

whenever the a priori choice $\alpha = \delta^2$ of the regularization parameter is used.

Example IV (Identification of wave sources). Let $\Omega \subset \mathbb{R}^n$ be a bounded domain with C^2 -boundary $\partial\Omega$. Consider

$$\begin{cases} \frac{\partial^2 u}{\partial t^2}(\xi, t) = \Delta u(\xi, t) + \lambda(t)x(\xi), & x \in \Omega, 0 < t < T, \\ u(\xi, 0) = \frac{\partial u}{\partial t}(\xi, 0) = 0, & \xi \in \Omega, \\ u(\xi, t) = 0, & \xi \in \partial\Omega, 0 < t < T. \end{cases} \quad (49)$$

Assume that

$$\lambda \in C^\infty[0, \infty), \quad \lambda(0) \neq 0, \quad (50)$$

and fix such λ . Then for any function $x \in L^2(\Omega)$, there exists a unique solution

$$u(x) \in C([0, T]; H^2(\Omega) \cap H_0^1(\Omega)) \cap C^1([0, T]; H_0^1(\Omega)) \cap C^2([0, T]; L^2(\Omega)).$$

The inverse problem under consideration here is the identification of $x = x(\xi)$, $\xi \in \Omega$, from observations y^δ of $y := \frac{\partial u(x)}{\partial \nu}|_{\partial\Omega \times (0, T)}$. Corresponding uniqueness and conditional stability results can be found in [121].

Let

$$\kappa \neq \frac{1}{4}, \frac{3}{4}, \quad 0 \leq \kappa \leq 1,$$

and let $M > 0$ be arbitrarily given. Set

$$X_\kappa = \begin{cases} H^{2\kappa}(\Omega), & 0 \leq \kappa < \frac{1}{4}, \\ H_0^{2\kappa}(\Omega), & \frac{1}{4} < \kappa \leq 1, \kappa \neq \frac{3}{4}, \end{cases}$$

where $H^{2\kappa}(\Omega)$, $H_0^{2\kappa}(\Omega)$ denote the Sobolev spaces, and

$$\mathcal{U}_{M,\kappa} = \{x \in X_\kappa : \|x\|_{H^{2\kappa}(\Omega)} \leq M\}.$$

Furthermore, assume

$$T > \text{diam } \Omega \equiv \sup_{x, x' \in \Omega} |\xi - \xi'|. \quad (51)$$

Then, it is proved that there exists a constant $C = C(\Omega, T, \lambda, \kappa) > 0$ such that

$$\|x_1 - x_2\|_{L^2(\Omega)} \leq CM^{\frac{1}{2\kappa+1}} \left\| \frac{\partial u(x_1)}{\partial \nu} - \frac{\partial u(x_2)}{\partial \nu} \right\|_{L^2(\partial\Omega \times (0, T))}^{\frac{2\kappa}{2\kappa+1}} \quad (52)$$

for all $x_1, x_2 \in \mathcal{U}_{M,\kappa}$.

The definition

$$F(x) = y := \left. \frac{\partial u(x)}{\partial \nu} \right|_{\partial \Omega \times (0, T)}$$

of the forward operator $F : X \rightarrow Y$ is well defined for the Hilbert spaces $X = L^2(\Omega)$ and $Y = L^2(\partial\Omega \times (0, T))$. In contrast to Example I, where also a wave equation is under consideration, F appears here as a linear operator with nonclosed range. However, the estimate (52) shows that this inverse problem possesses even Hölder type stability if we choose the admissible set suitably.

With respect to the regularization methods from the previous sections, the functional Φ can be chosen as

$$\Phi(x) = \|F(x) - y^\delta\|_Y^2 + \alpha\|x - x^*\|_X^2$$

or as

$$\Phi(x) = \|F(x) - y^\delta\|_Y^2 + \alpha\|x\|_{\tilde{X}}^2,$$

where $\tilde{X} = X_\kappa$. Then the conditional stability estimation (52) gives here the Hölder convergence rate

$$\|x_\alpha^\delta - x^\dagger\|_{L^2(\Omega)} = \mathcal{O}\left(\delta^{\frac{2\kappa}{2\kappa+1}}\right) \quad \text{as } \delta \rightarrow 0$$

with the choice $\alpha = \delta^2$.

Example V (Identification of potential in an elliptic equation). Let Ω be a simply connected domain in \mathbb{R}^3 with the C^2 -boundary $\partial\Omega$. Consider the following problem

$$\begin{cases} \Delta u + x \cdot u = 0, & \text{in } \Omega \\ u = f, & \text{on } \partial\Omega \end{cases} \quad (53)$$

with functions $x \in L^2(\Omega)$ and $f \in H^{\frac{1}{2}}(\partial\Omega)$.

Assuming that zero is not the Dirichlet eigenvalue of the Schrödinger operator $\Delta + x$ on the domain Ω ; it is known that there exists unique solution $u \in H^1(\Omega)$ for this problem. Then the Dirichlet-to-Neumann map $\Lambda_x : H^{\frac{1}{2}}(\partial\Omega) \rightarrow H^{-\frac{1}{2}}(\partial\Omega)$ is defined as

$$\Lambda_x f = \left. \frac{\partial u}{\partial \nu} \right|_{\partial\Omega}, \quad (54)$$

where ν is the unit outer normal with respect to $\partial\Omega$.

The inverse problem under consideration here addresses the recovery of the not directly observable potential function $x(\xi)$, for $\xi \in \Omega$, from data y delivered by Λ_x . This is specified as follows: An infinite sequence $\{V_N\}_{N=1}^\infty$ of N -dimensional

subspaces $V_N = \text{span}(f_1, f_2, \dots, f_N)$ is considered generated by a basis $\{f_j\}_{j=1}^\infty$ in $H^1(\partial\Omega)$, i.e.,

$$V_N \subset V_{N+1} \subset H^1(\partial\Omega) \quad \text{and} \quad \bigcup_{N=1}^\infty V_N \text{ is dense in } H^1(\partial\Omega).$$

In this context, it is assumed that the finite dimensional spaces V_N , $N = 1, 2, \dots$, have the following properties:

1. For any $g \in H^1(\partial\Omega)$, there exists a $g_N \in V_N$ and a function $\beta(N)$, which satisfies $\lim_{N \rightarrow \infty} \beta(N) = 0$, such that

$$\|g - g_N\|_{H^{\frac{1}{2}}(\partial\Omega)} \leq \beta(N) \|g\|_{H^1(\partial\Omega)}. \quad (55)$$

2. There exists a constant $C > 0$, which is independent of g , such that

$$\|g_N\|_{H^{\frac{1}{2}}(\partial\Omega)} \leq C \|g\|_{H^{\frac{1}{2}}(\partial\Omega)}. \quad (56)$$

The following result is proved in [29]: Suppose that $x_j \in H^s(\Omega)$, $j = 1, 2$, with $s > \frac{3}{2}$, satisfy

$$\|x_j\|_{H^s(\Omega)} \leq M$$

for some constant $M > 0$. Then there exists a constant $C > 0$, which depends on M , such that

$$\|x_1 - x_2\|_{L^2(\Omega)} \leq C \omega (\|\Lambda_{x_1} - \Lambda_{x_2}\|_{V_N} + \beta(N)) \quad (57)$$

for N large enough and $\|\Lambda_{x_1} - \Lambda_{x_2}\|_{V_N}$ small enough. Precisely, it is here $\omega(t) = \left(\frac{1}{\log^{\frac{1}{\gamma}} t}\right)^\gamma$ with some $0 < \gamma \leq 1$ taking into account that

$$\|\Lambda_{x_1} - \Lambda_{x_2}\|_{V_N} = \sup_{\phi \in V_N, \|\phi\|_{H^{\frac{1}{2}}(\partial\Omega)} = 1} |\langle (\Lambda_{x_1} - \Lambda_{x_2})\phi, \phi \rangle|,$$

where $\langle \cdot, \cdot \rangle$ is the dual pairing between $H^{-\frac{1}{2}}(\partial\Omega)$ to $H^{\frac{1}{2}}(\partial\Omega)$.

Here the forward operator F is defined as

$$F(q) := \Lambda|_{Y_N}.$$

This is a nonlinear operator mapping from the space $X = L^2(\Omega)$ into the space $Y \in \mathcal{L}(L^2(\partial\Omega), H^{\frac{1}{2}}(\partial\Omega))$, which represents the space of bounded linear operators mapping between $L^2(\partial\Omega)$ and $H^{\frac{1}{2}}(\partial\Omega)$. Moreover, consider the restriction $Y_N =$

$Y|_{V_N}$ of Y generated by the subspace V_N . The original problem of finding x from Λ_x data is ill-posed, but even without the uniqueness of the inverse problem, the estimate (57) shows some stability behavior of logarithmic type under the associated restrictions on the expected solution. Again for the Tikhonov regularization with functionals

$$\Phi(x) = \|F(x) - y^\delta\|_{Y_N}^2 + \alpha\|x - x^*\|_X^2$$

or

$$\Phi(x) = \|F(x) - y^\delta\|_{Y_N}^2 + \alpha\|x\|_{\tilde{X}}^2,$$

where $\tilde{X} = H^s$ with $s > \frac{3}{2}$, the theory of sections “Tikhonov Regularization in Hilbert Spaces with Quadratic Misfit and Penalty Terms” and “Variational Regularization in Banach Spaces with Convex Penalty Term” is applicable. From the latter section, with the conditional stability estimation (57), the convergence rate

$$\|x_\alpha^\delta - x^\dagger\|_{L(\Omega)} = \mathcal{O}((\log(1/\delta))^{-\gamma}) \quad \text{as } \delta \rightarrow 0$$

can be derived for the parameter choice $\alpha = \delta^2$.

Example VI (Inverse problems for autoconvolution equations). For the space $X = Y = L^2(0, 1)$ of quadratically integrable real functions defined on the unit interval, consider as first variant of this example the autoconvolution equation $x * x = y$, where with reference to Eq. (1),

$$[F(x)](s) := \int_0^s x(s-t)x(t)dt, \quad 0 \leq s \leq 1 \quad (58)$$

is the corresponding forward operator with $\mathcal{D}(F) = X$. This operator equation of quadratic type occurs in physics of spectra, in optics, and in stochastics, often as part of a more complex task (see, e.g., [11, 70, 108]). A series of studies on deautoconvolution and regularization have been published for the setting (58); see, for example, [34, 100]. Some first basic mathematical analysis of the autoconvolution equation can already be found in the paper [48]. Moreover, a regularization approach for general quadratic operator equations was suggested in the recent paper [43]. Because of their weak nonlinearity, deautoconvolution problems are not seen as difficult, and hence, little attention is paid to them wrongly. However, there is a deficit in convergence rates for regularized solutions x_α^δ obtained by the classical form of Tikhonov regularization in Hilbert spaces as minimizers of the functional (5). It can be shown that Assumption 1 applies and that the inequality (7) from Theorem 2 is satisfied with $L = 2$ and for arbitrary large radii ρ , even as an equation

$$\|F(x) - F(x^\dagger) - F'(x^\dagger)(x - x^\dagger)\|_X = \|x - x^\dagger\|_X^2,$$

where

$$[F'(x)h](s) = 2 \int_0^s x(s-t)h(t)dt, \quad 0 \leq s \leq 1, \quad h \in L^2(0, 1),$$

characterizes the Fréchet derivative of F from (58) at the point x^\dagger . Note that it is very specific phenomenon here that the nonlinear operator F is not compact, but $F'(x^\dagger)$ is a compact linear operator mapping in $L^2(0, 1)$. One consequence of this specific interplay between F and its derivative for the deautoconvolution problem from (58), which is locally ill-posed everywhere, is the fact that the classical convergence rate theory developed for the Tikhonov regularization of nonlinear ill-posed problems reaches its limits if standard source condition

$$x^\dagger - x^* = F'(x^\dagger)^* w, \quad w \in Y,$$

fails. Please refer to [24] for details. On the other hand, convergence rate results based on Hölder source conditions with small Hölder exponent and logarithmic source conditions or on the method of approximate source conditions (cf. [58]) are not applicable since qualified nonlinearity conditions like (36) cannot be proven according to current knowledge.

For a function $x : \mathbb{R} \rightarrow \mathbb{R}$ with support on $[0, 1]$, the autoconvolution $x * x$ is a function with support on $[0, 2]$. Hence, the strength of ill-posedness for the deautoconvolution problem according to the forward operator (58) can be reduced if observations of $[F(x)](s)$ for all $0 \leq s \leq 2$ are taken into account (full data case). Please refer to [46] for details and numerical case studies. In a second variant of this example with applications in laser optics, the full data case is exploited, but for complex functions and with an additional kernel. This variety considers a generalized autoconvolution equation motivated by problems of ultrashort laser pulse characterization arising in the context of the self-diffraction SPIDER method, and the reader is referred to the recent paper [47] for physical details and the experimental setting of this problem. In this variant, the focus is on a kernel-based, complex-valued, and full data analog to (58). Take into account $L^2_{\mathbb{C}}$ -spaces of quadratically integrable complex-valued functions over finite real intervals set for the corresponding normed spaces $X = L^2_{\mathbb{C}}(0, 1)$ and $Y = L^2_{\mathbb{C}}(0, 1)$ and consider for the associated operator equation (1) the nonlinear forward operator

$$[F(x)](s) := \begin{cases} \int_0^s k(s, t)x(s-t)x(t)dt & \text{if } 0 \leq s \leq 1 \\ \int_{s-1}^1 k(s, t)x(s-t)x(t)dt & \text{if } 1 < s \leq 2 \end{cases} \quad (59)$$

mapping from $L^2_{\mathbb{C}}(0, 1)$ to $L^2_{\mathbb{C}}(0, 2)$ with domain $\mathcal{D}(F) = L^2_{\mathbb{C}}(0, 1)$. Every function $x \in L^2_{\mathbb{C}}(0, 1)$ can be represented as $x(t) = A(t) e^{i\phi(t)}$, $0 \leq t \leq 1$, with the nonnegative amplitude (modulus) function $A = |x|$ and the phase function $\phi : [0, 1] \rightarrow \mathbb{R}$. For the SPIDER technology, in particular, the phase function is to be determined from noisy observations of the complex function y , whereas information about the amplitude function can be verified by alternative measurements. In [47] some mathematical studies and a regularization approach for this specific problem have been presented, and further analytic investigations for the specific case of a constant kernel k can be found in [24].

4 Conclusion

This chapter has presented some theoretic results including convergence and convergence rates assertions on direct regularization methods for nonlinear inverse problems formulated in the setting of infinite dimensional Hilbert or Banach spaces. The inverse problems can be written as ill-posed nonlinear operator equations with the consequence that their solutions tend to be unstable with respect to data perturbations. To overcome that drawback, regularization methods use stable auxiliary problems, which are close to the original inverse problem. A regularization parameter controls the trade-off between approximation and stability. For direct regularization methods, the auxiliary problems are mostly minimization problems in abstract spaces, where a weighted sum of a residual term that expresses the data misfit and a stabilizing penalty term expressing expected solution properties has to be minimized. In this context the regularization parameter controls the relative weight of both terms. Furthermore, six examples are given that show the wide range of applicability for such regularization methods in the light of specific inverse problems. More than 120 references at the end of this chapter survey the relevant literature in this field.

1 Introduction

Today *imaging* is rapidly improving by increased specificity and sensitivity of measurement devices. However, even more diagnostic information can be gained by combination of data recorded with different imaging systems.

In particular in medicine, information of different modalities is used for diagnosis. From the various imaging technologies used in medicine, we mention exemplary *positron emission tomography* (PET), *single photon emission computed tomography* (SPECT), *magnetic resonance imaging* (MRI), *magnetic resonance spectroscopy* (MRS), X-ray, and *ultrasound*. Soft tissue can be well visualized in magnetic resonance scans, while bone structures are more easily discernible by X-ray imaging.

Image registration is an appropriate tool to align the information gained from different modalities. Thereby, it is necessary to use similarity measures that are able to compare images of different modalities, such that in a post-processing step the data can be fused and relevant information can be aligned.

The main challenge for computer-assisted comparison of images from different modalities is to define an appropriate distance measure between the images from different modalities.

Similarity measures of images can be categorized as follows:

1. Pixel-wise comparison of intensities.
2. A morphological measure defines the distance between images by the distance between their level sets.
3. Measures based on the image's gray value distributions.

In the following, we review distance measures for images according to the above catalog.

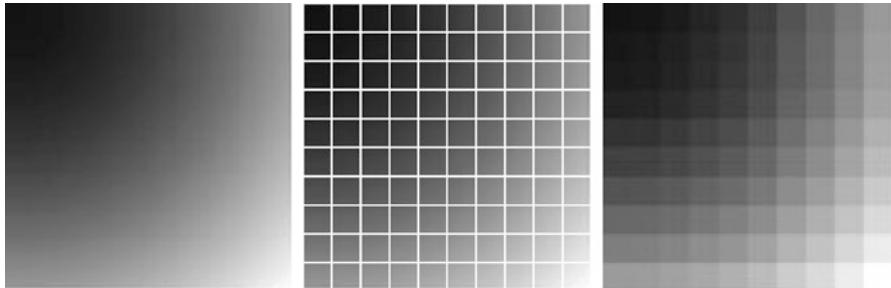

We use the notation Ω for the squared domain $(0, 1)^2$. Images are simultaneously considered as matrices or functions on Ω : A *discrete image* is an $N \times N$ -matrix $U \in \{0, \dots, 255\}^{N \times N}$. Each of the entries of the matrix represents an intensity value at a pixel. Therewith is associated a piecewise constant function

$$u_N(x) = \sum_{i=1}^N \sum_{j=1}^N U^{ij} \chi_{\Omega_{ij}}(x), \quad (1)$$

where

$$\Omega_{ij} := \left(\frac{i-1}{N}, \frac{i}{N} \right] \times \left(\frac{j-1}{N}, \frac{j}{N} \right] \text{ for } 1 \leq i, j \leq N,$$

and $\chi_{\Omega_{ij}}$ is the characteristic function of Ω_{ij} . In the context of image processing, U^{ij} denotes the *pixel intensity* at the *pixel* $\chi_{\Omega_{ij}}$. A *continuous image* is a function $u : \Omega \rightarrow \mathbb{R}$.

We emphasize that the measures for comparing images, presented below, can be applied in a straightforward way to higher-dimensional domains, for example, voxel data. However, here, for the sake of simplicity of notation and readability, we restrict attention to a two-dimensional squared domain Ω . Even more, we restrict attention to intensity data and do not consider vector-valued data, such as color images or tensor data. By this restriction, we exclude, for instance, feature-based intensity measures.

2 Distance Measures

In the following, we review distance measures for comparing discrete and continuous images. We review the standard and a morphological distance measure; both of them are deterministic. Moreover, based on the idea to consider images as random variable, we consider in the last two subsections two statistical approaches.

Deterministic Pixel Measure

The most widely used distance measures for discrete and continuous images are the l^p , L^p distance measures, respectively, in particular $p = 2$; see, for instance, the chapter ▶ [Linear Inverse Problems](#) in this handbook. There, two discrete images U_1 and U_2 are similar, if

$$\begin{aligned}\|U_1 - U_2\|_p &:= \left(\sum_{i=1}^N \sum_{j=1}^N |U_1^{ij} - U_2^{ij}|^p \right)^{\frac{1}{p}}, \quad 1 \leq p < \infty, \\ \|U_2 - U_2\|_\infty &:= \sup_{i,j=1,\dots,N} |U_1^{ij} - U_2^{ij}|, \quad p = \infty,\end{aligned}$$

respectively, is small. Two continuous images $u_1, u_2 : \Omega \rightarrow \mathbb{R}$ are similar if

$$\begin{aligned}\|u_1 - u_2\|_p &:= \left(\int_{\Omega} |u_1(x) - u_2(x)|^p, dx \right)^{\frac{1}{p}} \quad 1 \leq p < \infty, \\ \|u_2 - u_2\|_\infty &:= \text{ess sup}_{x,y} |u_1(x) - u_2(x)|, \quad p = \infty,\end{aligned}$$

is small. Here, ess sup denotes the essential supremum.

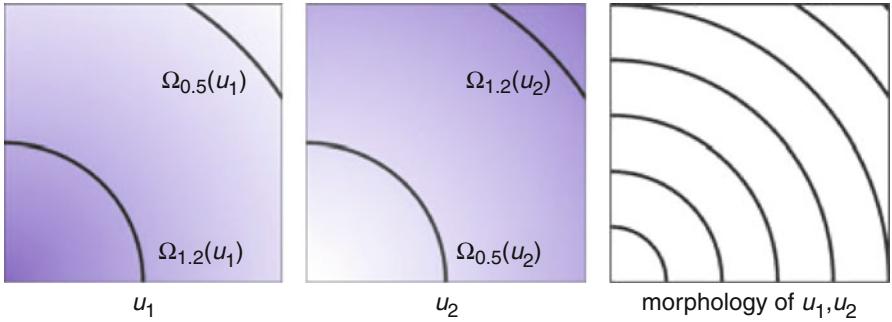

Fig. 1 The gray values of the images are completely different, but the images u_1, u_2 have the same morphology

Morphological Measures

In this subsection, we consider continuous images $u_i : \Omega \rightarrow [0, 255]$, $i = 1, 2$. u_1 and u_2 are *morphologically equivalent* (Fig. 1), if there exists a one-to-one gray value transformation $\beta : [0, 255] \rightarrow [0, 255]$, such that

$$\beta \circ u_1 = u_2.$$

Level sets of a continuous function u are defined as

$$\Omega_t(u) := \{x \in \Omega : u(x) = t\}.$$

The level sets $\Omega_{\mathbb{R}}(u) := \{\Omega_t(u) : t \in [0, 255]\}$ form the objects of an image that remain invariant under gray value transformations. The *normal field* (*Gauss map*) is given by the normals to the level lines and can be written as

$$\begin{aligned} \mathbf{n}(u) : \Omega &\rightarrow \mathbb{R}^d \\ x &\mapsto \begin{cases} 0 & \text{if } \nabla u(x) = 0 \\ \frac{\nabla u(x)}{\|\nabla u(x)\|} & \text{else.} \end{cases} \end{aligned}$$

Droske and Rumpf [7] consider images as similar, if intensity changes occur at the same locations. Therefore, they compare the normal fields of the images with the similarity measure

$$\mathcal{S}_g(u_1, u_2) = \int_{\Omega} g(\mathbf{n}(u_1)(x), \mathbf{n}(u_2)(x)) dx, \quad (2)$$

where they choose the function $g : \mathbb{R}^2 \times \mathbb{R}^2 \rightarrow \mathbb{R} \geq 0$ appropriately. The vectors $\mathbf{n}(u_1)(x), \mathbf{n}(u_2)(x)$ form an angle that is minimal if the images are morphologically equivalent. Therefore, an appropriate choice of the function g is an increasing

function of the minimal angle between v_1 , v_2 , and v_1 , $-v_2$. For instance, setting g to be the cross or the negative dot product, we obtain

$$\begin{aligned}\mathcal{S}_x(u_1, u_2) &= \frac{1}{2} \int_{\Omega} |\mathbf{n}(u_1)(x) \times \mathbf{n}(u_2)(x)|^2 dx \\ \mathcal{S}_o(u_1, u_2) &= \frac{1}{2} \int_{\Omega} (1 - \mathbf{n}(u_1)(x) \cdot \mathbf{n}(u_2)(x))^2 dx.\end{aligned}$$

(The vectors \mathbf{n} have to be embedded in \mathbb{R}^3 in order to calculate the cross product.)

Example 1. Consider the following scaled images $u_i : [0, 1]^2 \rightarrow [0, 1]$,

$$u_1(x) = x_1 x_2, \quad u_2(x) = 1 - x_1 x_2, \quad u_3(x) = (1 - x_1) x_2,$$

with gradients

$$\nabla u_1(x) = \begin{pmatrix} x_2 \\ x_1 \end{pmatrix}, \quad \nabla u_2(x) = \begin{pmatrix} -x_2 \\ -x_1 \end{pmatrix}, \quad \nabla u_3(x) = \begin{pmatrix} -x_2 \\ 1 - x_1 \end{pmatrix}.$$

With $g(u, v) := \frac{1}{2}|u_1 v_2 - u_2 v_1|$, the functional \mathcal{S}_g defined in (2) attains the following values for the particular images:

$$\begin{aligned}\mathcal{S}_g(u_1, u_2) &= \frac{1}{2} \int_{\Omega} |-x_2 x_1 + x_2 x_1| dx = 0 \\ \mathcal{S}_g(u_2, u_3) &= \frac{1}{2} \int_{\Omega} |x_2 x_1 + x_2 x_1| dx = \frac{1}{4} \\ \mathcal{S}_g(u_3, u_1) &= \frac{1}{2} \int_{\Omega} |-x_2 x_1 - (1 - x_1)x_2| dx = \frac{1}{4}.\end{aligned}$$

The similarity measure indicates that u_1 and u_2 are morphologically identical.

The normalized gradient field is set valued in regions where the function is constant. Therefore, the numerical evaluation of the gradient field is highly unstable. To overcome this drawback, Haber and Modersitzki [15] suggested to use regularized normal gradient fields:

$$\begin{aligned}\mathbf{n}_{\epsilon}(u) : \quad \Omega &\rightarrow \quad \mathbb{R}^d \\ x &\mapsto \quad \frac{\nabla u(x)}{\|\nabla u(x)\|_{\epsilon}}\end{aligned}$$

where $\|v\|_{\epsilon} := \sqrt{v^T v + \epsilon^2}$ for every $v \in \mathbb{R}^d$. The parameter ϵ is connected to the estimated noise level in the image. In regions where ϵ is much larger than the gradient, the regularized normalized fields $\mathbf{n}_{\epsilon}(u)$ are almost zero and therefore do not have a significant effect of the measures \mathcal{S}_x or \mathcal{S}_o , respectively. However, in regions where ϵ is much smaller than the gradients, the regularized normal fields are close to the non-regularized ones (Fig. 2).

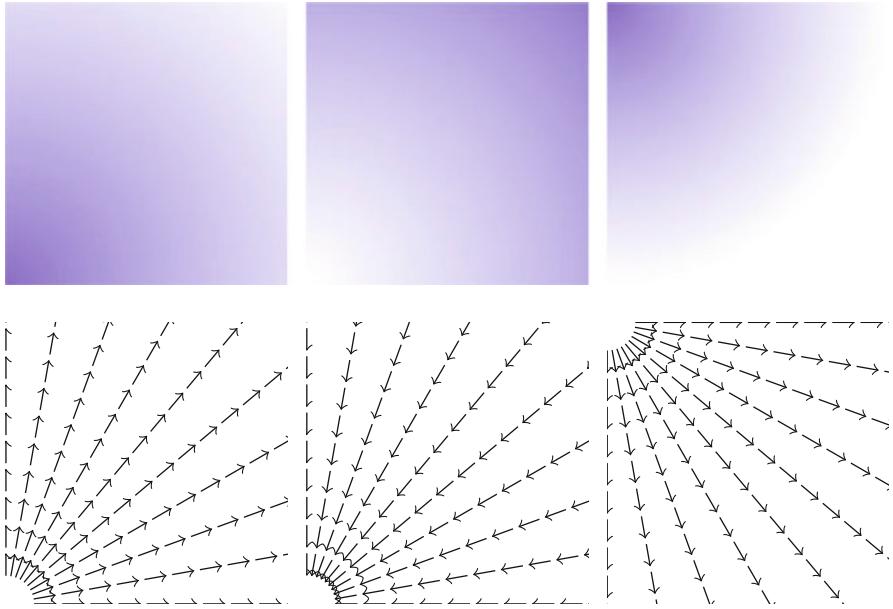

Fig. 2 Top: images u_1, u_2, u_3 . Bottom: $n(u_1), n(u_2), n(u_3)$

Statistical Distance Measures

Several distance measures for pairs of images can be motivated from statistics by considering the images as random variables. In the following, we analyze discrete images from a statistical point of view. For this purpose, we need some elementary statistical definitions. Applications of the following measures are mentioned in section ‘‘Morphological Measures’’:

Correlation Coefficient :

$$\bar{U} := \frac{1}{N^2} \sum_{i,j=1}^N U^{ij} \quad \text{and} \quad \text{Var}(U) = \sum_{i,j=1}^N (U^{ij} - \bar{U})^2$$

denote the *mean intensity* and *variance* of the discrete image U .

$$\text{Cov}(U_1, U_2) = \sum_{i=1}^N \sum_{j=1}^N (U_1^{ij} - \bar{U}_1)(U_2^{ij} - \bar{U}_2)$$

denotes the *covariance* of two images U_1 and U_2 , and the *correlation coefficient* is defined by

$$\rho(U_1, U_2) = \frac{\text{Cov}(U_1, U_2)}{\sqrt{\text{Var}(U_1) \text{Var}(U_2)}}.$$

The correlation coefficient is a measure of *linear dependence* of two images. The range of the correlation coefficient is $[-1, 1]$, and if $\rho(U_1, U_2)$ is close to one, then it indicates that U_1 and U_2 are linearly dependent.

Correlation Ratio: In statistics, the correlation ratio is used to measure the relationship between the statistical dispersion within individual categories and the dispersion across the whole population. The *correlation ratio* is defined by

$$\eta(U_2|U_1) = \frac{\text{Var}(E(U_2|U_1))}{\text{Var}(U_2)},$$

where $E(U_2|U_1)$ is the conditional expectation of U_2 subject to U_1 .

To put this into the context of image comparison, let

$$\Omega_t(U_1) := \{(i, j) | U_1^{ij} = t\}$$

be the discrete level set of intensity $t \in \{0, \dots, 255\}$. Then the expected value of U_2 on the t -th level set of U_1 is given by

$$E(U_2|U_1 = t) := \frac{1}{\#(\Omega_t(U_1))} \sum_{\Omega_t(U_1)} U_2^{ij},$$

where $\#(\Omega_t(U_1))$ denotes the number of pixels in U_1 with gray value t . Moreover, the according conditional variance is defined by

$$V(U_2|U_1 = t) = \frac{1}{\#(\Omega_t(U_1))} \sum_{\Omega_t(U_1)} \left(U_2^{ij} - E(U_2|U_1 = t) \right)^2.$$

The function

$$\begin{aligned} H(U_1) : \{0, \dots, 255\} &\rightarrow \mathbb{N} \\ t &\mapsto \#(\Omega_t(U_1)) \end{aligned}$$

is called the *discrete histogram* of U_1 .

The correlation ratio is nonsymmetric, that is, $\eta(Y|X) \neq \eta(X|Y)$, and takes values in $[0, 1]$. It is a measure of (*non*)*linear dependence* between two images. If $U_1 = U_2$, then the correlation ratio is maximal.

Variance of Intensity Ratio, Ratio Image Uniformity: This measure is based on the definition of similarity that two images are similar, if the factor $R^{ij}(U_1, U_2) = U_1^{ij}/U_2^{ij}$ has a small variance. The *ratio image uniformity* (or normalized variance of the intensity ratio) can be calculated by

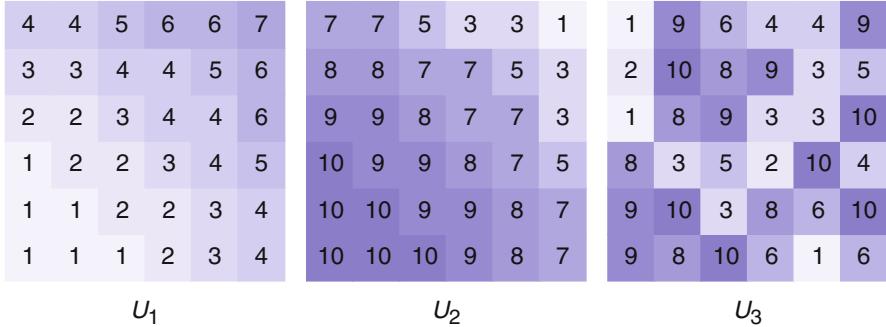

Fig. 3 Images for Examples 2 and 6. Note that there is a dependence between U_1 and U_2 : $U_2 \sim 11 - (U_1)^3$

Table 1 Comparison of the different pixel-based similarity measures. The images U_1 , U_2 are related in a nonlinear way; this is reflected in a correlation ratio of 1. We see that the variance of intensity ratio is not symmetric and not significant to make a statement on a correlation between the images

| | U_1, U_2 | U_2, U_1 | U_2, U_3 | U_3, U_2 | U_3, U_1 | U_1, U_3 |
|-----------------------------|--------------|--------------|------------|------------|-------------|------------|
| Correlation coefficient | -0.98 | -0.98 | 0.10 | 0.10 | -0.14 | -0.14 |
| Correlation ratio | 1.00 | 1.00 | 0.28 | 0.32 | 0.29 | 0.64 |
| Variance of intensity ratio | 1.91 | 2.87 | 2.25 | 1.92 | 3.06 | 0.83 |

$$\text{RIU}(U_1, U_2) = \frac{\text{Var}(R)}{\bar{R}}.$$

It is not symmetric.

Example 2. Consider the discrete images U_1 , U_2 , and U_3 in Fig. 3. Table 1 shows a comparison of the different similarity measures. The variance of the intensity ratio is insignificant and therefore cannot be used to determine similarities. The correlation ratio is maximal for the pairing U_1 , U_2 , and in fact there is a functional dependence of the intensity values of U_1 and U_2 . However, the dependence of the intensity values of U_1 and U_2 is nonlinear; hence, the absolute value of the correlation coefficient (measure of linear dependence) is close to one, but not identical to one.

Statistical Distance Measures (Density Based)

In general, two images of the same object but of different modalities have a large L^p , l^p distance. Hence, the idea is to apply statistical tools that consider images as similar if there is some statistical dependence. Statistical similarity measures are able to compare probability density functions. Hence, we first need to relate images

to density functions. Therefore, we consider an image as a random variable. The basic terminology of random variables is as follows:

Definition 1. A continuous random variable is a real-valued function $X : \Omega^S \rightarrow \mathbb{R}$ defined on the sample space Ω^S . For a sample x , $X(x)$ is called observation.

Remark 1 (Images as Random Variables). When we consider an image $u : \Omega \rightarrow \mathbb{R}$ as a continuous random variable, the sample space is Ω . For a sample $x \in \Omega$, the observation $u(x)$ is the intensity of u at x .

Regarding the intensity values of an image as an observation of a random process allows us to compare images via their intrinsic probability densities. Since the density *cannot* be calculated directly, it has to be estimated. This is outlined in section ‘‘Density Estimation’’. There exists a variety of distance measures for probability densities (see, for instance, [31]). In particular, we review f -divergences in section ‘‘Csiszár-Divergences (f -Divergences)’’ and explain how to use the f -information as an image similarity measure in section ‘‘ f -Information’’.

Density Estimation

This section reviews the problem of *density estimation*, which is the construction of an estimate of the density function from the observed data.

Definition 2. Let $X : \Omega^S \rightarrow \mathbb{R}$ be a random variable, that is, a function mapping the (measurable) sample space Ω^S of a random process to the real numbers.

The *cumulated probability density function* of X is defined by

$$P(t) := \frac{1}{\text{meas}(\Omega^S)} \text{meas}\{x : X(x) \leq t\} \quad t \in \mathbb{R}.$$

The *probability density function* p is the derivative of P .

The *joint cumulated probability density function* of two random variables X_1, X_2 is defined by

$$\hat{P}(t_1, t_2) := \frac{1}{\text{meas}(\Omega^S)^2} \text{meas}\{(x_1, x_2) : X_1(x_1) \leq t_1, X_2(x_2) \leq t_2\} \quad t_1, t_2 \in \mathbb{R}.$$

The *joint probability density function* \hat{p} satisfies

$$\hat{P}(t_1, t_2) = \int_0^{t_1} \int_0^{t_2} \hat{p}(s_1, s_2) ds_1 ds_2.$$

Remark 2. When we consider an image $u : \Omega \rightarrow \mathbb{R}$ a random variable with sample space Ω , we write $p(u)(t)$ for the probability density function of the image u . For the joint probability of two images u_1 and u_2 , we write $\hat{p}(u_1, u_2)(t_1, t_2)$ to emphasize, as above, that the images are considered as random variables.

The terminology of Definition 2 is clarified by the following one-dimensional example:

Example 3. Let $\Omega := [0, 1]$ and

$$\begin{aligned} u : \Omega &\rightarrow [0, 255] \\ x &\rightarrow 255x^2. \end{aligned}$$

The cumulated probability density function

$$P : [0, 255] \rightarrow [0, 1]$$

is obtained by integration:

$$P(t) := \text{meas}\{x : 255x^2 \leq t\} = \text{meas}\left\{x : x \leq \sqrt{\frac{t}{255}}\right\} = \int_0^{\sqrt{\frac{t}{255}}} 1 \, dx = \sqrt{\frac{t}{255}}.$$

The probability density function of u is given by the derivative of P , which is

$$p(u)(t) = \frac{1}{2\sqrt{255}} \frac{1}{\sqrt{t}}.$$

In image processing, it is common to view the discrete image U (or u_N as in (1)) as an approximation of an image u . We aim for the probability density function of u , which is approximated via kernel density estimation using the available information of u , which is U . A kernel histogram is the normalized probability density function according to the discretized image U , where for each pixel a *kernel function* (see (3)) is superimposed. Kernel functions depend on a parameter, which can be used to control the smoothness of the kernel histogram.

We first give a general definition of kernel density estimation:

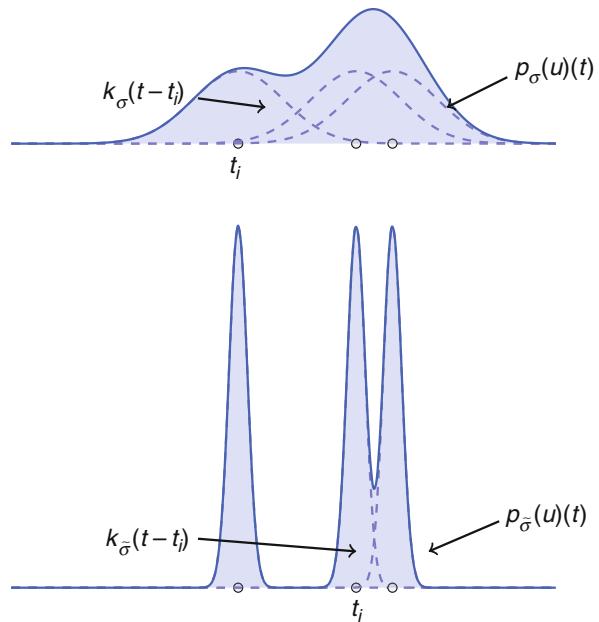

Definition 3 (Kernel Density Estimation). Let t_1, t_2, \dots, t_M be a sample of M independent observations from a measurable real random variable X with probability density function p . A *kernel density approximation* at t is given by

$$p_\sigma(t) = \frac{1}{M} \sum_{i=1}^M k_\sigma(t - t_i), \quad t \in [0, 255]$$

where k_σ is a kernel function with bandwidth σ . p_σ is called *kernel density approximation* with parameter σ .

Let t_1, t_2, \dots, t_M and s_1, s_2, \dots, s_M be samples of M independent observations from measurable real random variables X_1, X_2 with joint probability density function \hat{p} ; then a *joint kernel density approximation* of \hat{p} is given by

Fig. 4 Density estimate for different parameters σ

$$\hat{p}_\sigma(s, t) = \frac{1}{M} \sum_{i=1}^M K_\sigma(s - s_i, t - t_i),$$

where $K_\sigma(s, t)$ is a two-dimensional kernel function.

Remark 3 (Kernel Density Estimation of an Image, Fig. 4). Let u be a continuous image, which is identified with a random variable. Moreover, let U be $N \times N$ samples of u . In analogy to Definition 3, we denote the *kernel density estimation* based on the discrete image U , by

$$p_\sigma(t) = \frac{1}{N^2} \sum_{i,j=1}^N k_\sigma(t - U^{ij})$$

and remark that for u_N as in (1)

$$p_\sigma(u_N)(t) := \int_{\Omega} k_\sigma(t - u_N(x)) dx = \frac{1}{N^2} \sum_{i,j=1}^N k_\sigma(t - U^{ij}). \quad (3)$$

The joint kernel density of two images u_1, u_2 with observations U_1 and U_2 is given by

$$\hat{p}_\sigma(s, t) = \frac{1}{N^2} \sum_{i,j=1}^N K_\sigma(s - U_1^{ij}, t - U_2^{ij}),$$

where $K_\sigma(s, t) = k_\sigma(s)k_\sigma(t)$ is the two-dimensional kernel function. Moreover, we remark that for $u_{1,N}, u_{2,N}$

$$\begin{aligned}\hat{p}_\sigma(u_{1,N}, u_{2,N})(s, t) &:= \int_{\Omega} K_\sigma(s - u_{1,N}(x), t - u_{2,N}(x)) dx \\ &= \frac{1}{N^2} \sum_{i,j=1}^N K_\sigma(s - U_1^{ij}, t - U_2^{ij}).\end{aligned}$$

In the following, we review particular kernel functions and show that standard histograms are kernel density estimations.

Example 4. Assume that $u_i : \Omega \rightarrow [0, 255]$, $i = 1, 2$ are continuous images, with discrete approximations $u_{i,N}$ as in (1):

- We use the joint density kernel $K_\sigma(s, t) := k_\sigma(s)k_\sigma(t)$, where k_σ is the **normalized Gaussian kernel** of variance σ . Then for $i = 1, 2$, the estimates for the marginal densities are given by

$$p_\sigma(u_{i,N})(t) := \int_{\Omega} k_\sigma(u_{i,N}(x) - t) dx = \frac{1}{\sqrt{2\pi\sigma}} \int_{\Omega} \exp\left(\frac{-(u_{i,N}(x) - t)^2}{2\sigma^2}\right) dx,$$

and the joint density approximation reads as follows:

$$\begin{aligned}\hat{p}_\sigma(s, t) &:= \int_{\Omega} K_\sigma((u_1(x), u_2(x)) - (s, t)) dx \\ &= \frac{1}{2\pi\sigma^2} \int_{\Omega} \exp\left(\frac{-(u_1(x) - s)^2}{2\sigma^2}\right) \exp\left(\frac{-(u_2(x) - t)^2}{2\sigma^2}\right) dx\end{aligned}$$

- **Histograms:** Assume that U only takes values in $0, 1, \dots, 255$. When we choose the characteristic function $\chi_{[-\sigma, \sigma]}$, with $\sigma = \frac{1}{2}$ as kernel function, we obtain the density estimate

$$\begin{aligned}p_{\chi, \sigma}(t) &= \int_{\Omega} \chi_{[-\sigma, \sigma]}(u(x) - t) dx \\ &= \text{meas}\{x : t - \sigma \leq u(x) < t + \sigma\} \\ &= \text{size of pixel} \times \text{number of pixels with value } \lfloor t + \sigma \rfloor\end{aligned}$$

Hence, $p_{\chi, \sigma}$ corresponds with the histogram of the discrete image.

Example 5. We return to Example 3. The domain $\Omega = [0, 1]$ is partitioned into N equidistant pieces. Let

$$u_N := \sum_{i=1}^N \left(\int_{\frac{i-1}{N}}^{\frac{i}{N}} u(x) dx \right) \chi_{[\frac{i-1}{N}, \frac{i}{N}]}.$$

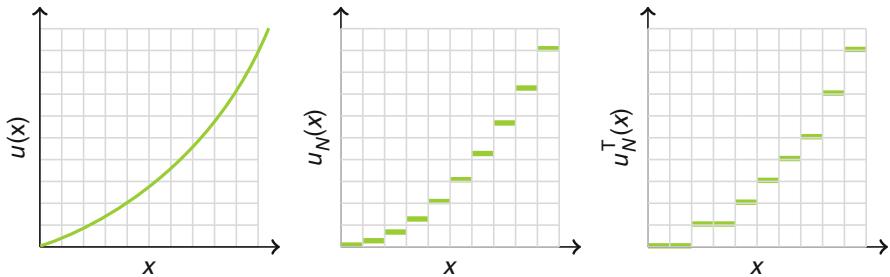

Fig. 5 Original u and discretized versions u_N and u_N^T

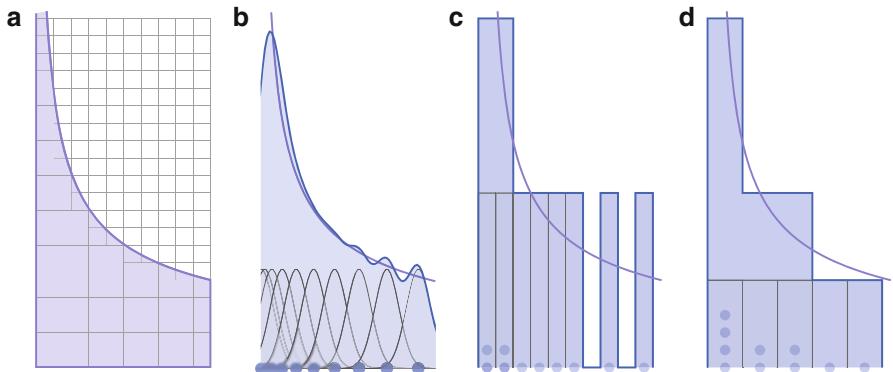

Fig. 6 (a) Density from the original image u . (b) Density estimation with Gaussian-kernel based on u_N ($N = 10$), with $\sigma = 0.07$, (c, d) normalized histogram, based on u_N^T , with $\sigma = 0.05, 0.1$

Moreover, we consider the piecewise function u_N^T represented in Fig. 5. The density according to u , denoted by $p(u)$, and the kernel density estimates of u_N and u_N^T are represented in Fig. 6. They resemble the actual density very well.

Csiszár Divergences (f -Divergences)

The concept of f -divergences has been introduced by Csiszár in [5] as a generalization of Kullback's I -divergence and Rényi's I -divergence and at the same time by Ali and Silvey [1]. In probability calculus, f -divergences are used to measure the distances between probability densities.

Definition 4. Set $\mathcal{F}_0 := \{f : [0, \infty) \rightarrow \mathbb{R} \cup \{\infty\} : f \text{ is convex in } [0, \infty), \text{ continuous at } 0, \text{ and satisfies } f(1) = 0\}$ and

$$V_{\text{pdf}} := \left\{ p \in L^1(\mathbb{R}) : p \geq 0, \int_{\mathbb{R}} p(t) dt = 1 \right\}.$$

Let $g_1, g_2 \in V_{\text{pdf}}$ be probability density functions. The f -divergence between g_1, g_2 is given by

$$\begin{aligned} \mathcal{D}_f : V_{\text{pdf}} \times V_{\text{pdf}} &\rightarrow [0, \infty) \\ (g_1, g_2) &\mapsto \int_{\mathbb{R}} g_2(t) f\left(\frac{g_1(t)}{g_2(t)}\right) dt. \end{aligned} \quad (4)$$

Remark 4.

- In (4), the integrand at positions t where $g_2(t) = 0$ is understood in the following sense:

$$0 f\left(\frac{g_1(t)}{0}\right) := \lim_{\bar{t} \searrow 0} \left(\bar{t} f\left(\frac{g_1(t)}{\bar{t}}\right) \right), \quad t \in \mathbb{R}.$$

- In general, f -divergences are not symmetric, unless there exists some number c such that the generating f satisfies $f(x) = x f\left(\frac{1}{x}\right) + c(x - 1)$.

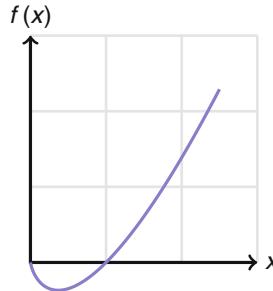

Examples for f -Divergences: We list several f -divergences that have been used in literature (see [6, 12] and references therein).

The Kullback-Leibler divergence is the f -divergence with $f(x) = x \log(x)$

$$\mathcal{D}_f(g_1, g_2) = \int_{\mathbb{R}} g_1(t) \log\left(\frac{g_1(t)}{g_2(t)}\right) dt.$$

Jensen-Shannon divergence is the symmetric Kullback-Leibler divergence:

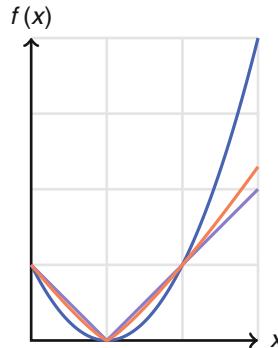

$$\mathcal{D}_f(g_1, g_2) = \int_{\mathbb{R}} \left(g_1(t) \log\left(\frac{g_1(t)}{g_2(t)}\right) + g_2(t) \log\left(\frac{g_2(t)}{g_1(t)}\right) \right) dt.$$

χ^s -Divergences: These divergences are generated by

$$f^s(x) = |x - 1|^s, \quad s \in [1, \infty)$$

and have the form

$$\mathcal{D}_f(g_1, g_2) = \int_{\mathbb{R}} g_2(t) \left| \frac{g_1(t)}{g_2(t)} - 1 \right|^s dt = \int g_2^{1-s}(t) |g_1(t) - g_2(t)|^s dt.$$

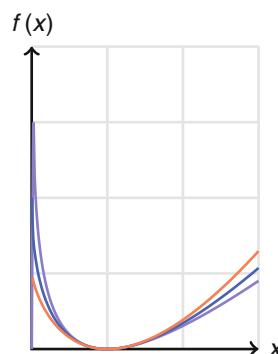

The χ^1 -divergence is a metric. The most widely used out of this family of χ^s divergences is the χ^2 -divergence (Pearson).

Dichotomy Class Divergences: The generating function of this class is given by

$$f(x) = \begin{cases} x - 1 - \ln(x) & \text{for } s = 0, \\ \frac{1}{s(1-s)}(sx + 1 - s - x^s) & \text{for } s \in \mathbb{R} \setminus \{0, 1\}, \\ 1 - x + x \ln(x) & \text{for } s = 1. \end{cases}$$

The parameter $s = \frac{1}{2}$ provides a distance, namely, the Hellinger metric

$$\mathcal{D}_f(g_1, g_2) = 2 \int_{\mathbb{R}} \left(\sqrt{g_1(t)} - \sqrt{g_2(t)} \right)^2 dt.$$

Matsushita's Divergences: The elements of this class, which is generated by the function

$$f(x) = |1 - x^s|^{\frac{1}{s}}, \quad 0 < s \leq 1,$$

are prototypes of metric divergences. The distance is given by

$$d(g_1, g_2) = (\mathcal{D}_f(g_1, g_2))^s$$

where

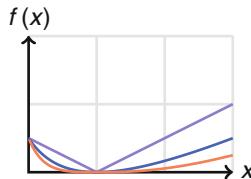

$$\mathcal{D}_f(g_1, g_2) = \int_{\mathbb{R}} g_1(t) \left| 1 - \left(\frac{g_2(t)}{g_1(t)} \right)^s \right|^{\frac{1}{s}} dt.$$

Puri-Vincze Divergences: This class is generated by the functions

$$f(x) = \frac{|1 - x|^s}{2(x + 1)^{s-1}}, \quad s \in [1, \infty).$$

For $s = 2$, we obtain the triangular divergence

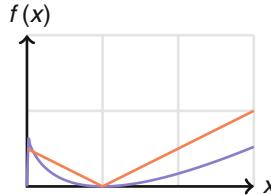

$$\mathcal{D}_f(g_1, g_2) = \int_{\mathbb{R}} \frac{(g_2(t) - g_1(t))^2}{g_2(t) + g_1(t)} dt.$$

Divergences of Arimoto Type: Generated by the functions

$$f(x) = \begin{cases} \frac{s}{s-1} \left((1+x^s)^{\frac{1}{s}} - 2^{\frac{1}{s}-1}(1+x) \right) & \text{for } s \in (0, \infty) \setminus \{1\} \\ (1+x) \ln(2) + x \ln(x) - (1+x) \ln(1+x) & \text{for } s = 1 \\ \frac{1}{2}|1-x| & \text{for } s = \infty. \end{cases}$$

For $s = \infty$, the divergence is proportional to the χ^1 divergence. For $s \in (0, \infty) \setminus \{1\}$, we obtain

$$\mathcal{D}_f(g_1, g_2) = \int_{\mathbb{R}} \frac{s}{s-1} \left(\sqrt[s]{g_1^s(t) + g_2^s(t)} - 2^{\frac{1-s}{s}} (g_1(t) + g_2(t)) \right) dt.$$

Moreover, this class provides the distances

$$d(g_1, g_2) = (\mathcal{D}_f(g_1, g_2))^{\min\{s, \frac{1}{s}\}} \quad \text{for } s \in (0, \infty).$$

f-Information

In the following, we review the *f*-information for measuring the distance between probability densities. The most important *f*-information measure is the *mutual information*.

The notion of *information gain* induced by simultaneously observing two probability measures compared to their separate observations is tightly related to divergences. It results from quantifying the information content of the joint measure in comparison with the product measure.

This motivation leads to the following definition.

Definition 5 (*f*-Information for Images). For $f \in \mathcal{F}_0$ (see Definition 4), we define the ***f*-information** of $u_1, u_2 \in L^\infty(\Omega)$ by

$$I_f(u_1, u_2) := \mathcal{D}_f(p(u_1)p(u_2), p(u_1, u_2)),$$

where the $p(u_i)$ is the probability density of u_i , as introduced in section ‘‘Density Estimation.’’

Additionally, we define the ***f*-entropy** of an image u_1 by

$$H_f(u_1) := I_f(u_1, u_1).$$

In analogy to independent probability densities, we call two images u_1, u_2 **independent** if there is no information gain, that is,

$$p(u_1, u_2) = p(u_1)p(u_2).$$

Remark 5. The f -information has the following properties:

- **Symmetry:** $I_f(u_1, u_2) = I_f(u_2, u_1)$.
- **Bounds:** $0 \leq I_f(u_1, u_2) \leq \min\{H_f(u_1), H_f(u_2)\}$.
- $I_f(u_1, u_2) = 0$ if and only if u_1, u_2 are mutually independent.

The definition of f -information does not make assumptions on the relationship between the image intensities (see [38] for discussion). It does neither assume a linear nor a functional correlation but only a predictable relationship. For more information on f -information, see [36].

Example 6. The most famous examples of f -informations are the following:

Mutual/Shannon Information: For $f(x) = x \ln x$, we obtain

$$I_f(u_1, u_2) = \int_{\mathbb{R}} \int_{\mathbb{R}} p(u_1, u_2)(t_1, t_2) \ln \left(\frac{p(u_1, u_2)(t_1, t_2)}{p(u_1)(t_1)p(u_2)(t_2)} \right) dt_1 dt_2,$$

with Shannon entropy

$$H_f(u) = \int_{\mathbb{R}} p(u)(t) \ln \left(\frac{1}{p(u)(t)} \right) dt,$$

joint entropy

$$H_f(u_1, u_2) = - \int_{\mathbb{R}} \int_{\mathbb{R}} p(u_1, u_2)(t_1, t_2) \ln(p(u_1, u_2)(t_1, t_2)) dt_1 dt_2,$$

conditional entropy

$$H_f(u_2|u_1) = \int_{\mathbb{R}} p(u_1)(t) H_f(u_2|u_1 = t) dt,$$

and relative entropy (the Kullback-Leibler divergence)

$$H_f(u_1|u_2) = \int_{\mathbb{R}} p(u_1)(t) \ln \left(\frac{p(u_1)}{p(u_2)} \right).$$

The relative entropy is not symmetric. Maes et al. [25] and Studholme et al. [35] both suggested the use of joint entropy for multimodal image registration. Maes et al. demonstrate the robustness of registration, using mutual information with respect to partial overlap and image degradation, such as noise and intensity inhomogeneities.

Hellinger Information: For $f(x) = 2x - 2 - 4\sqrt{x}$ (see also Dichotomy Class in section “Csiszár-Divergences (f -Divergences)”), we obtain

$$I_f(u_1, u_2) = \int_{\mathbb{R}} \int_{\mathbb{R}} \left(\sqrt{p(u_1, u_2)(t_1, t_2)} - \sqrt{p(u_1)(t_1)p(u_2)(t_2)} \right)^2 dt_1 dt_2,$$

with Hellinger entropy

$$H_f(u) = 2 \left(1 - \int_{\mathbb{R}} (p(u)(t))^{\frac{3}{2}} dt \right).$$

Both are bounded from above by 2.

For measuring the distance between discrete images U_1 and U_2 , it is common to map the images via kernel estimation to continuous estimates of their intensity value densities $p_\sigma(u_{i,N})$, where $p_\sigma(u_{i,N})$ is as defined in (3). The difference between images is then measured via the distance between the associated estimated probability densities.

Example 7. For $U_i, i = 1, 2, 3$ as in Fig. 3, let $u_{i,N}$ be the corresponding piecewise constant functions. Note that U_1 and U_2 are somehow related. In other words, they are highly dependent on each other, so we can expect a low information value. Comparing the images point-wise with least squares shows a higher similarity value for U_2 and U_3 than for U_1 and U_2 .

For the ease of presentation, we work with histograms. Recall that the estimated probability function $p_\sigma(u_{i,N})$ is equal to the normalized histogram of U_i . The histograms (connected to the marginal density densities) are given by

| | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|----------|---|---|---|---|---|---|---|---|---|----|
| $H(U_1)$ | 6 | 7 | 6 | 9 | 3 | 4 | 1 | 0 | 0 | 0 |
| $H(U_2)$ | 1 | 0 | 4 | 0 | 3 | 0 | 9 | 6 | 7 | 6 |
| $H(U_3)$ | 3 | 2 | 5 | 3 | 2 | 4 | 0 | 5 | 6 | 6 |

In order to calculate the information measures, we calculate the joint histograms of U_1, U_2, U_3 , that is, $JH(U_1, U_2) : (s, t) \rightarrow$ number of pixels such that $U_1^{ij} = s$ and $U_2^{ij} = t$ (see Tables 2 and 3).

The entries in the joint histogram of U_1, U_2 are located along a diagonal, whereas the entries of the other two joint histograms are spread all over. Hence, we can observe the dependence of $p_\sigma(u_{1,N}), p_\sigma(u_{2,N})$ already by looking at the joint histogram. Next, we calculate the Hellinger and the mutual information. For the f -entropies, we obtain

| | U_1 | U_2 | U_3 |
|-------------------|-------|-------|-------|
| Mutual entropy | 1.91 | 1.91 | 2.13 |
| Hellinger entropy | 1.17 | 1.17 | 1.30 |

Table 2 Joint histograms of U_2 , U_3 and U_3 , U_1 . The entries are disperse; this will be reflected in a lower f -information as in the case for U_1 , U_2

| $JH(U_1, U_2)$ | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | $H(U_2)$ |
|----------------|---|---|---|---|---|---|---|---|---|----|----------|
| $H(U_1)$ | 6 | 7 | 6 | 9 | 3 | 4 | 1 | 0 | 0 | 0 | 6 |

and for the f -information measures:

| | (U_1, U_2) | (U_2, U_3) | (U_3, U_1) |
|-----------------------|--------------|--------------|--------------|
| Mutual information | 1.91 | 0.74 | 0.74 |
| Hellinger information | 1.17 | 0.57 | 0.57 |
| Sum of least squares | 31.44 | 14.56 | 21.56 |

Indeed, in both cases (Hellinger and mutual information), U_1 , U_2 (high f -information value) can be considered as more similar than U_1 and U_3 , whereas the least squares value between U_1 , U_2 is the highest, meaning that they differ at most.

We can observe in Example 7 that the values of f -information differ a lot by different choices of the function f . Moreover, it is not easy to interpret the values; hence, one is interested in calculating normalized values:

Normalized Mutual Information: Studholme [35] proposed a normalized measure of mutual information. Normalized f -information is defined by

$$\text{NI}_f(u_1, u_2) := \frac{H_f(u_1) + H_f(u_2)}{I_f(u_1, u_2)}.$$

If $u_1 = u_2$, then the normalized f -information is minimal with value 2.

Entropy Correlation Coefficient: Collignon and Maes [25] suggested the use of the entropy correlation coefficient, another form of normalized f -information (Table 4):

$$H_f\text{CC}(u_1, u_2) = \frac{2I_f(u_1, u_2)}{H_f(u_1) + H_f(u_2)} = 2 - \frac{2}{\text{NI}_f(u_1, u_2)}.$$

The entropy correlation coefficient is one if $u_1 = u_2$ and zero if u_1 and u_2 are completely independent.

Exclusive f -Information: It is defined by

$$EI_f(u_1, u_2) := H_f(u_1) + H_f(u_2) - 2I_f(u_1, u_2).$$

Note that the exclusive f -information is **minimal** for $u_1 = u_2$.

Distance Measures Including Statistical Prior Information

Most multimodal measures used in literature do not consider the underlying image context or other statistical prior information on the image modalities. Recently, several groups developed similarity measures that incorporate such information:

- Leventon and Grimson [23] proposed to learn *prior information* from training data (registered multimodal images) by estimating the joint intensity distributions

Table 4 Comparison of measures composed by f -information and f -entropies

| Mutual information | (u_1, u_2) | (u_2, u_3) | (u_3, u_1) |
|---------------------------------|--------------|--------------|--------------|
| Normalized ^a | 2.00 | 5.32 | 5.32 |
| Entropy correlation coefficient | 1.00 | 0.38 | 0.38 |
| Exclusive ^a | 0.00 | 2.46 | 2.46 |
| Hellinger information | (u_1, u_2) | (u_2, u_3) | (u_3, u_1) |
| Normalized ^a | 2.00 | 4.36 | 4.36 |
| Entropy correlation coefficient | 1.00 | 0.46 | 0.46 |
| Exclusive ^a | 0.00 | 1.34 | 1.34 |

^aNormalized and exclusive informations are minimal if the images are equal, whereas the entropy correlation coefficient is maximal

of the training images. Based on this paper, Chung et al. [4] proposed to use the Kullback-Leibler distance to compare the learned joint intensity distribution, with the joint intensity distribution of the images, in order to compare multimodal images. This idea was extended by Guetter et al. [14], who combine mutual information with the incorporation of learned prior knowledge with a Kullback-Leibler term.

As a follow-up of their ideas, we suggest the following type of generalized similarity measures: Let p_σ^l be the learned joint intensity density (learned from the training data set) and $\alpha \in [0, 1]$. For $f \in \mathcal{F}_0$, define

$$\mathcal{S}_{\alpha,\sigma}(u_1, u_2) := \alpha \mathcal{D}_f(p_\sigma^l, p_\sigma(u_1, u_2)) + (1 - \alpha) \underbrace{\mathcal{D}_f(p_\sigma(u_1, u_2), p_\sigma(u_1)p_\sigma(u_2))}_{I_f(u_1, u_2)}.$$

- Instead of using a universal but a priori fixed similarity measure, one can *learn a similarity* measure in a discriminative manner. The methodology proposed by Lee et al. [22] uses a learning algorithm that constructs a similarity measure based on a set of preregistered images.

3 Mathematical Models for Variational Imaging

In the following, we proceed with an abstract setting. We are given a physical model F , which in mathematical terms is an operator between spaces U and V . For given data $v \in V$, we aim for solving the operator equation

$$F(\Phi) = v.$$

In general, the solution is not unique, and we aim for finding the solution with *minimal energy*, that is, we aim for a minimizer of the constraint optimization problem

$$\mathcal{R}(\Phi) \rightarrow \min \text{ subject to } F(\Phi) = v.$$

In practice, a complication of this problem is that only approximate (noisy) data $v^\delta \in V$ of v is available. To take into account uncertainty of the data, it is then intuitive to consider the following constrained optimization problem instead:

$$\mathcal{R}(\Phi) \rightarrow \min \text{ subject to } \|F(\Phi) - v^\delta\|^2 \leq \delta, \quad (5)$$

where δ is an upper bound for the approximation error $v - v^\delta$. It is known that solving (5) is equivalent to minimizing the Tikhonov functional,

$$\Phi \rightarrow \frac{1}{2} \|F(\Phi) - v^\delta\|^2 + \alpha \mathcal{R}(\Phi), \quad (6)$$

where $\alpha > 0$ is chosen according to Morozov's discrepancy principle [19].

For the formulation of the constrained optimization problem, the Tikhonov method, respectively, it is essential that $F(\Phi)$ and v , v^δ , respectively, represent data of the same modality. If $F(\Phi)$ and the data, which we denote now by w , are of different kind, then it is intuitive to use a multimodal similarity measure \mathcal{S}^r , instead of the least squares distance, which allows for comparison of $F(\Phi)$ and w . Consequently, we consider the multimodal variational method, which consists in minimization of

$$\Phi \rightarrow \mathcal{T}_{\alpha, w^\delta}(\Phi) := \mathcal{S}^r(F(\Phi), w^\delta) + \alpha \mathcal{R}(\Phi), \quad \alpha > 0.$$

In the limiting case, that is, for $\delta \rightarrow 0$, one aims for recovering an \mathcal{RS}^r -minimizing solution Φ^\dagger if

$$\mathcal{R}(\Phi^\dagger) = \min\{\mathcal{R}(\Phi) : \Phi \in \mathcal{A}\} \text{ where } \mathcal{A} = \{\Phi : \Phi = \arg \min\{\mathcal{S}^r(F(\cdot), w)\}\}.$$

To take into account priors in the Tikhonov regularization, the standard way is again by a least squares approach. In this case, for regularization the least squares functional

$$\Phi \rightarrow \mathcal{R}_1(\Phi) = \frac{1}{2} \|\Phi - \Phi_0\|^2$$

is added to $\frac{1}{2} \|F(\Phi) - v^\delta\|^2$ (see, e.g., [8]). In analogy, we consider the regularization functional (6) and incorporate priors by adding generalization of the functional $\mathcal{R}_1(\Phi)$. Taking into account prior information Ψ_0 , which might come, for instance, from another modality, this leads to the following class of generalized Tikhonov functionals:

$$\mathcal{T}_{\alpha, \beta}^{w^\delta, \Psi_0}(\Phi) := \mathcal{S}^r(F(\Phi), w^\delta) + \alpha \mathcal{R}(\Phi) + \beta \mathcal{S}^p(\Phi, \Psi_0).$$

Here \mathcal{S}^p is an appropriate multimodal similarity measure. In the limiting case, that is, for $\delta \rightarrow 0$, one aims for recovering an $\gamma - \mathcal{RS}^r \mathcal{S}^p$ -minimizing solution Φ^\dagger if

$$\begin{aligned} \mathcal{R}(\Phi^\dagger) + \gamma \mathcal{S}^p(\Phi^\dagger, \Psi_0) &= \min\{\mathcal{R}(\Phi) + \gamma \mathcal{S}^p(\Phi^\dagger, \Psi_0) : \Phi \in \mathcal{A}\} \text{ where} \\ \mathcal{A} &= \{\Phi : \Phi = \arg \min\{\mathcal{S}^r(F(\cdot), w)\}\}. \end{aligned}$$

The γ -parameter balances between the amount of prior information and regularization and satisfies $\gamma = \lim_{\alpha, \beta \rightarrow 0} \frac{\beta}{\alpha}$. For theoretical results on existence of minimizing elements of the functionals and convergence, we refer to [11, 30].

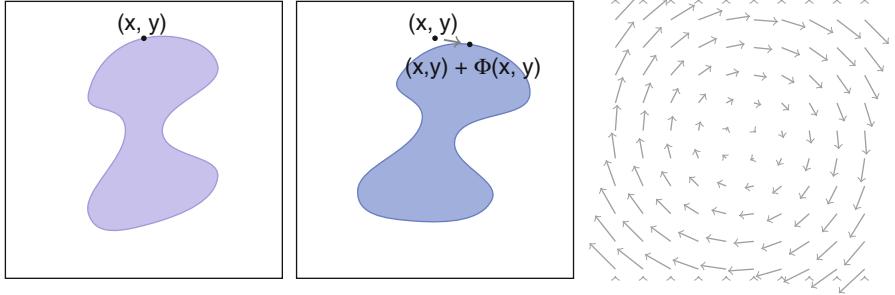

Fig. 7 *Left:* images u_R, u_T , *right:* deformation field Φ

4 Registration

In this section, we review variational methods for *image registration*. This problem consists in determining a spatial transformation (vector field) Φ that aligns pixels of two images u_R and u_T in an optimal way (Fig. 7). We use the terminology *reference image* for u_R and *template image* for u_T , where both are assumed to be compactly supported functions in Ω . That is, we consider the problem of determining the optimal transformation, which minimizes the functional

$$u \rightarrow \mathcal{S}^r(u_T \circ (id + \Phi), u_R). \quad (7)$$

To establish the context to the inverse problem setting, we use the setting $F(\Phi) = u_T(id + \Phi)$ and $w^\delta = u_R$. In general, the problem of minimizing (7) is ill posed. The Tikhonov-type variational regularization for registration then consists in minimization of the functional

$$\Phi \rightarrow \mathcal{S}^r(u_T \circ (id + \Phi), u_R) + \alpha \mathcal{R}(\Phi) \quad (8)$$

(we do not consider constrained registration here, but concentrate on the Tikhonov regularization).

Image registration (also of voxel (3D) data) is widely used in medical imaging, for instance, for monitoring and evaluating tumor growth, disease development, and therapy evaluation.

Variational methods for registration differ by the choice of the regularization functional \mathcal{R} and the similarity measure \mathcal{S}^r . There exists a variety of similarity measures that are used in practice. For some surveys, we refer to [17, 27, 32].

The regularization functional \mathcal{R} typically involves differential operators. In particular, for nonrigid registration, energy functionals from elasticity theory and fluid dynamics are used for regularization.

The optimality condition for a minimizer of (8) reads as follows:

$$\alpha D_\Phi(\mathcal{R}(\Phi), \Psi) + D_\Phi(\mathcal{S}^r(u_T \circ (id + \Phi), u_R), \Psi) = 0 \quad \text{for all } \Psi \in U, \quad (9)$$

where $D_\Phi(\mathcal{T}, \Psi)$ denotes the directional derivative of a functional \mathcal{T} in direction Ψ . The left-hand side of the equation is the steepest descent functional of the energy functional (8). In the following, we highlight some steepest descent functionals according to variational registration methods.

Example 8 (Elastic Registration with L^2 -Norm-Based Distance Function). Set $\alpha = 1$, $\mathcal{S}^r(v_1, v_2) = \frac{1}{2} \|v_1 - v_2\|_{L^2}^2$. We consider an elastic regularization functional of the form

$$\mathcal{R}(\Phi) = \int_{\Omega} \sum_{i=1}^2 \sum_{j=1}^2 \left(\frac{\lambda}{2} \frac{\partial}{\partial x_i} \Phi^i \frac{\partial}{\partial x_j} \Phi^j + \frac{\mu}{4} \left(\frac{\partial}{\partial x_j} \Phi^i + \frac{\partial}{\partial x_i} \Phi^j \right)^2 \right),$$

where $\lambda, \mu \geq 0$ are Lamé parameters and $\Phi = (\Phi^1, \Phi^2)$. λ is adjusted to control the rate of growth or shrinkage of local regions within the deforming template, and μ is adjusted to control shearing between adjacent regions of the template [3]. In this case, the optimality condition for minimizing $\alpha\mathcal{R}(\Phi) + \mathcal{S}^r(u_T \circ (id + \Phi))$, given by (9), is satisfied if Φ solves the following PDE:

$$\mu \Delta \Phi(x) + (\mu + \lambda) \nabla(\nabla \cdot \Phi(x)) = \underbrace{-\frac{1}{\alpha} (u_T(x + \Phi(x)) - u_R(x)) \nabla u_T(x + \Phi(x))}_{\frac{\partial}{\partial \Phi} \mathcal{S}^r}.$$

Here $\Delta \Phi = (\Delta \Phi^1, \Delta \Phi^2)$ and $D_\Phi(\mathcal{S}^r(u_T \circ (id + \Phi), u_R), \Psi) = \int_{\Omega} \frac{\partial}{\partial \Phi} \mathcal{S}^r \cdot \Psi$. This partial differential equation is known as linear elastic equation and is derived assuming small angles of rotation and small linear deformations. When large displacements are inherent, it is not applicable [2, 13, 18, 24, 29, 40].

Example 9 (Elastic Registration with f -Information). Assume that $k_\sigma \in \mathcal{C}^1(\mathbb{R}, \mathbb{R})$ is some kernel density function. Moreover, let $K_\sigma(s, t) = k_\sigma(s)k_\sigma(t)$. We pose the similarity measure as the f -information between the template and the reference image:

$$\mathcal{S}^r(u_T \circ (id + \Phi), u_R) = H_f(u_R) - I_f(u_T \circ (id + \Phi), u_R),$$

and set α and \mathcal{R} as in the previous example. In order to write the derivative of I_f in a compact way, we use the abbreviations $\tilde{\Phi} := id + \Phi$. The derivative of $p_\sigma(u_T \circ \tilde{\Phi})$ with respect to $\tilde{\Phi}$, in direction Ψ , is given by

$$D_{\tilde{\Phi}}(p_\sigma(u_T \circ \tilde{\Phi}), \Psi)(t) = \int_{\Omega} k'_\sigma(t - u_T(\tilde{\Phi}(x))) \nabla u_T(\tilde{\Phi}(x)) \cdot \Psi(x) dx$$

and

$$\begin{aligned} D_{\tilde{\Phi}}(\hat{p}_\sigma(u_T \circ \tilde{\Phi}, u_R), \Psi)(s, t) \\ = \int_{\Omega} k'_\sigma(s - u_T(\tilde{\Phi}(x))) k_\sigma(t - u_R(x)) (\nabla u_T(\tilde{\Phi}(x)) \cdot \Psi(x)) \, dx. \end{aligned}$$

We use the following abbreviations:

$$g_1(s, t) := \frac{p_\sigma(u_T \circ \tilde{\Phi})(s) p_\sigma(u_R)(t)}{p_\sigma(u_T \circ \tilde{\Phi}, u_R)(s, t)}, \quad g_2(s, t) := \frac{p_\sigma(u_R)(t)}{(\hat{p}_\sigma(u_T \circ \tilde{\Phi}, u_R)(s, t))^2},$$

and

$$g_3(s, t) := D_{\tilde{\Phi}}(p_\sigma(u_T \circ \tilde{\Phi}), \Psi)(s) \hat{p}_\sigma(u_T \circ \tilde{\Phi}, u_R)(s, t) + p_\sigma(u_T \circ \tilde{\Phi})(s) D_{\tilde{\Phi}}(\hat{p}_\sigma(u_T \circ \tilde{\Phi}, u_R), \Psi)(s, t).$$

With this, we can calculate the derivative of the f -information to be

$$\begin{aligned} D_{\tilde{\Phi}}(I_f(u_T \circ \tilde{\Phi}, u_R), \Psi) \\ = \int_{\mathbb{R}} \int_{\mathbb{R}} D_{\tilde{\Phi}}(p_\sigma(u_T \circ \tilde{\Phi}), \Psi)(s) p_\sigma(u_R)(t) f(g_1(s, t)) \\ + p_\sigma(u_T \circ \tilde{\Phi})(s) p_\sigma(u_R)(t) f'(g_1(s, t)) g_2(s, t) g_3(s, t) \, dt \, ds. \end{aligned}$$

For mutual information, this simplifies to

$$\begin{aligned} D_{\tilde{\Phi}}(MI(u_T \circ \tilde{\Phi}, u_R), \Psi) &= \int_{\mathbb{R}} \int_{\mathbb{R}} \left(D_{\tilde{\Phi}}(\hat{p}_\sigma(u_T \circ \tilde{\Phi}, u_R), \Psi)(s, t) \ln \left(\frac{1}{g_1(s, t)} \right) \right. \\ &\quad \left. + \frac{D_{\tilde{\Phi}}(\hat{p}_\sigma(u_T \circ \tilde{\Phi}, u_R), \Psi)(s, t)}{p_\sigma(u_T \circ \tilde{\Phi})(s) p_\sigma(u_R)(t)} \right) \, ds \, dt. \end{aligned}$$

A detailed exposition on elastic registration with mutual information can be found in [9, 11, 16].

In this section, we have presented a general framework on variational-based techniques for nonconstrained multimodal image registration. Below we give a short overview on relevant literature on this topic.

Kim and Fessler [21] describe an intensity based image registration technique that uses a robust correlation coefficient as a similarity measure for images. It is less sensitive to outliers that are present in one image, but not in the other. Kaneko [20] proposed the selective correlation coefficient, as an extension of the correlation coefficient. Van Elsen et al. investigated similarity measures for MR and CT images.

She proposed to calculate the correlation coefficient of geometrical features [37]. Alternatively to the correlation coefficient, one could calculate Spearman's rank correlation coefficient (also known as Spearman's ρ), which is a nonparametric measure of correlation [10], but not very popular in multimodal imaging. Roche et al. [33, 34] tested the correlation ratio to align MR, CT, and PET images. Woods et al. [42] developed an algorithm based on this measure for automated aligning and re-slicing PET images. Independently, several groups realized that the problem of registering two different image modalities can be cast in an information theoretic framework. Collignon et al. [25] and Studholme et al. [35] both suggested using the joint entropy of the combined images as a registration potential. Pluim et al. [28] investigated in more general f -informations. For MR-CT registrations, the learned similarity measure by Lee et al. outperforms all standard measures. Experimental results for learning similarity measures for multimodal images can be found in [22].

5 Recommended Reading

For recent results on divergences and information measures, we refer to *Computational Information Geometry*. Website: <http://informationgeometry.wordpress.com/> (last accessed 5 June 2014).

Comparison and evaluation of different similarity measures for CT, MR, and PET brain images can be found in [41].

It is worth mentioning the *Retrospective Image Registration Evaluation Project*. It is designed to compare different multimodal registration techniques. It involves the use of a database of image volumes, commonly known as the “Vanderbilt Database,” on which the registrations are to be performed. Moreover, it provides a training data set for multimodal image registration. Link: <http://www.insight-journal.org/fire/> (last accessed 5 June 2014). For a collection of databases, we refer to the Validation of Medical Image Registration page <http://www.vmip.org> (last accessed 5 June 2014).

A number of image registration software tools have been developed in the last decade. The following support multimodal image comparison:

- ITK is an open-source, cross-platform system that provides developers with an extensive suite of software tools for image analysis. It supports the following similarity measures: mean squares metric, normalized cross-correlation metric, mean reciprocal square differences, mutual information (different implementations [26, 39]), the Kullback-Leibler distance, normalized mutual information, correlation coefficient, kappa statistics (for binary images), and gradient difference metric. Website: www.itk.org/ (last accessed 2 June 2014).
- FLIRT is a robust and accurate automated linear (affine) registration tool based around a multi-start, multi-resolution global optimization method. It can be used for inter- and intra-modal registration with 2D or 3D images. Websites: <http://fsl.fmrib.ox.ac.uk/fsl/fslwiki/FLIRT> (last accessed 2 June 2014).

- FAIR, FLIRT are toolboxes for fast and flexible image registration. Both have been developed by the SAFIR-research group in Lübeck. They include the sum of squared differences, mutual information, and normalized gradient fields. Websites: <http://www.mic.uni-luebeck.de/de/people/jan-modersitzki/software.html> (last accessed 4 June 2014).
- AIR stands for automated image registration. It supports standard deviation of ratio images, least squares, and least squares with global intensity rescaling. Website: <http://bishopw.loni.ucla.edu/AIR5/> (last accessed 5 June 2014).
- RView: This software integrates a number of 3D/4D data display and fusion routines together with three-dimensional rigid volume registration using normalized mutual information. It also contains many interactive volume segmentation and painting functions for structural data analysis. Website: <http://www.colin-studholme.net/software/software.html> (last accessed 5 June 2014).

6 Conclusion

A number of different similarity measures which are used for comparison of multimodal images are listed in this survey. These measures can be grouped into four different categories depending on the way the images are interpreted: If images are represented by pixel intensities (for instance, representing photon counts), one can apply standard L^p , L^p -norms for comparison. However, these distance measures are not recommendable for multimodal images. Viewing images as random variables, distance measures from statistics can be utilized. Other common measures are based on image morphology (level lines or gradient fields), which have the advantage that they are less sensitive (or even blind) to gray-level transformations. In applications, images of different modalities neither reveal the same morphology nor the positions of edges are matching. Thus, none of the above mentioned distance measures are useful. For these applications, comparison measures for the gray value distributions of the images were proposed, and in order to obtain estimates of these distributions, kernel density estimations have been implemented on top. Then, one can either compare the distributions of the images directly or alternatively quantify the information content of the joint measures in comparison with the product measures. Such distances are called information measures. Recent approaches are concerned with learning similarity measures with statistical prior information. Variational image registration is discussed, where the appropriate distance measure is important in recovering the right local transformation parameters.

Abstract

Energy minimization methods are a very popular tool in image and signal processing. This chapter deals with images defined on a discrete finite set. The energies under consideration can be differentiable or not or convex or not. Analytical results on the minimizers of different energies are provided that reveal salient features of the images recovered in this way, as a function of the shape of the energy itself. An intrinsic mutual relationship between energy minimization and modeling via the choice of the energy is thus established. Examples and illustrations corroborate the presented results. Applications that take benefit from these results are presented as well.

1 Introduction

In numerous applications, an unknown image or a signal $u_o \in \mathbb{R}^p$ is represented by data $v \in \mathbb{R}^q$ according to an observation model, called also forward model

$$v = A(u_o) \text{ with noise,} \quad (1)$$

where $A : \mathbb{R}^p \rightarrow \mathbb{R}^q$ is a (linear or nonlinear) transform. When u is an $m \times n$ image, its pixels are arranged columnwise into a p -length real vector, where $p = mn$ and the original $u[i, j]$ is identified with $u[(i-1)m + j]$. Some typical applications are, for instance, denoising, deblurring, segmentation, zooming and super-resolution, reconstruction in inverse problems, coding and compression, feature selection, and compressive sensing. In all these cases, recovering a good estimate \hat{u} for u_o needs to combine the observation along with a prior and desiderata on the unknown u_o . A common way to define such an estimate is

$$\text{Find } \hat{u} \text{ such that } \mathcal{F}(\hat{u}, v) = \min_{u \in U} \mathcal{F}(u, v), \quad (2)$$

$$\mathcal{F}(u, v) = \Psi(u, v) + \beta \Phi(u), \quad (3)$$

where $\mathcal{F} : \mathbb{R}^p \times \mathbb{R}^q \rightarrow \mathbb{R}$ is called an energy (or an objective), $U \subset \mathbb{R}^p$ is a set of constraints, Ψ is a data-fidelity term, Φ brings prior information on u_o , and $\beta > 0$ is a parameter which controls the trade-off between Ψ and Φ .

The term Ψ ensures that \hat{u} satisfies (1) quite faithfully according to an appropriate measure. The noise n is random and a natural way to derive Ψ from (1) is to use probabilities; see, e.g., [7, 32, 37, 56]. More precisely, if $\pi(v|u)$ is the likelihood of data v , the usual choice is

$$\Psi(u, v) = -\log \pi(v|u). \quad (4)$$

For instance, if A is a linear operator and $v = Au + n$ where n is additive independent and identically distributed (i.i.d.) zero-mean Gaussian noise, one finds that

$$\Psi(u, v) \propto \|Au - v\|_2^2. \quad (5)$$

This remains quite a common choice partly because it simplifies calculations.

The role of Φ in (3) is to push the solution to exhibit some a priori known or desired features. It is called prior or regularization or penalty term. In many image processing applications, Φ is of the form

$$\Phi(u) = \sum_{i=1}^r \phi(\|\mathbf{D}_i u\|), \quad (6)$$

where for any $i \in \{1, \dots, r\}$, $\mathbf{D}_i : \mathbb{R}^p \rightarrow \mathbb{R}^s$, for s an integer $s \geq 1$, are linear operators and $\|\cdot\|$ is usually the ℓ_1 or the ℓ_2 norm. For instance, the family $\{\mathbf{D}_i\} \equiv \{\mathbf{D}_i : i \in \{1, \dots, r\}\}$ can represent the discrete approximation of the gradient or the Laplacian operator on u or the finite differences of various orders or the combination of any of these with the synthesis operator of a frame transform or the vectors of the canonical basis of \mathbb{R}^r . Note that $s = 1$ if $\{\mathbf{D}_i\}$ are finite differences or a discrete Laplacian; then

$$s = 1 \Rightarrow \phi(\|\mathbf{D}_i u\|) = \phi(|\mathbf{D}_i u|).$$

And if $\{\mathbf{D}_i\}$ are the basis vectors of \mathbb{R}^r , one has $\phi(|\mathbf{D}_i u|) = \phi(|u[i]|)$. In (6), $\phi : \mathbb{R}_+ \mapsto \mathbb{R}$ is quite a “general” function, often called a *potential function (PF)*. A very standard assumption is that

H1 $\phi : \mathbb{R}_+ \rightarrow \mathbb{R}$ is proper, lower semicontinuous (l.s.c.) and increasing on \mathbb{R}_+ , with $\phi(t) > \phi(0)$ for any $t > 0$.

Some typical examples for ϕ are given in Table 1 and their plots in Fig. 1.

Remark 1. If $\phi'(0^+) > 0$ the function $t \rightarrow \phi(|t|)$ is nonsmooth at zero in which case Φ is nonsmooth on $\cup_{i=1}^r [w \in \mathbb{R}^p : \mathbf{D}_i w = 0]$. Conversely, $\phi'(0^+) = 0$ leads to a smooth at zero $t \rightarrow \phi(|t|)$. With the PF (f13), Φ leads to the counting function, commonly called the ℓ_0 -norm.

For the human vision, *an important requirement is that the prior Φ promotes smoothing inside homogeneous regions but preserves sharp edges*. According to a fine analysis conducted in the 1990s and summarized in [7], ϕ preserves edges if H1 holds as if H2, stated below, holds true as well:

H2 $\lim_{t \rightarrow \infty} \frac{\phi'(t)}{t} = 0$.

This assumption is satisfied by all PFs in Table 1 except for (f1) in case if $\alpha = 2$. Note that there are numerous other heuristics for edge preservation.

Table 1 Commonly used PFs $\phi : \mathbb{R}_+ \rightarrow \mathbb{R}$ where $\alpha > 0$ is a parameter. Note that among the nonconvex PFs, (f8), (f10), and (f12) are coercive, while the remaining PFs, namely, (f6), (f7), (f9), (f11), and (f13), are bounded. And all nonconvex PFs with $\phi'(0^+) > 0$ are *concave* on \mathbb{R}_+ . Recall that (f6) is the discrete equivalent of the Mumford-Shah (MS) prior [17, 72]

| Convex PFs | |
|--|---|
| $\phi'(0^+) = 0$ | $\phi'(0^+) > 0$ |
| (f1) $\phi(t) = t^\alpha$, $1 < \alpha \leq 2$ | (f5) $\phi(t) = t$ |
| (f2) $\phi(t) = \sqrt{\alpha + t^2}$ | |
| (f3) $\phi(t) = \log(\cosh(\alpha t))$ | |
| (f4) $\phi(t) = t/\alpha - \log(1 + t/\alpha)$ | |
| Nonconvex PFs | |
| $\phi'(0^+) = 0$ | $\phi'(0^+) > 0$ |
| (f6) $\phi(t) = \min\{\alpha t^2, 1\}$ | (f10) $\phi(t) = t^\alpha$, $0 < \alpha < 1$ |
| (f7) $\phi(t) = \frac{\alpha t^2}{1 + \alpha t^2}$ | (f11) $\phi(t) = \frac{\alpha t}{1 + \alpha t}$ |
| (f8) $\phi(t) = \log(\alpha t^2 + 1)$ | (f12) $\phi(t) = \log(\alpha t + 1)$ |
| (f9) $\phi(t) = 1 - \exp(-\alpha t^2)$ | (f13) $\phi(0) = 0$, $\phi(t) = 1$ if $t \neq 0$ |

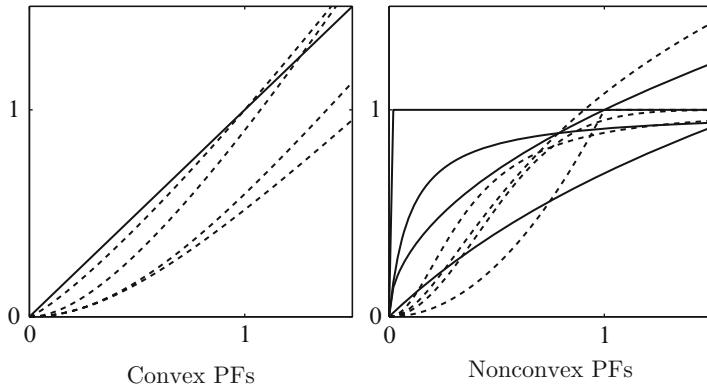

Fig. 1 Plots of the PFs given in Table 1. PFs with $\phi'(0^+) = 0$ (---), PFs with $\phi'(0^+) > 0$ (—)

Background

Energy minimization methods, as described here, are *at the crossroad of several well-established methodologies* that are briefly sketched below.

- Bayesian maximum a posteriori (MAP) estimation using Markov random field (MRF) priors. Such an estimation is based on the maximization of the posterior distribution $\pi(u|v) = \pi(v|u)\pi(u)/Z$, where $\pi(u)$ is the prior model for u_o and $Z = \pi(v)$ can be seen as a constant. Equivalently, \hat{u} minimizes with respect to u the energy

$$\mathcal{F}(u, v) = -\ln \pi(v|u) - \ln \pi(u).$$

Identifying these first term above with $\Psi(\cdot, v)$ and the second one with Φ shows the basis of the equivalence. Classical papers on MAP energies using MRF priors are [14–16, 20, 51, 56]. Since the pioneering work of Geman and Geman [56], various *nonconvex* PFs ϕ were explored in order to produce images involving neat edges; see, e.g., [54, 55, 65]. MAP energies involving MRF priors are also considered in many books, such as [32, 53, 64]. For a pedagogical account, see [96].

- Regularization for ill-posed inverse problems was initiated in the book of Tikhonov and Arsenin [93] in 1977. The main idea can be stated in terms of the stabilization of this kind of problems. Useful textbooks in this direction are, e.g., [61, 69, 94] and especially the recent [91]. This methodology and its most recent achievements are nicely discussed from quite a general point of view in Chapter ▶ [Regularization Methods for Ill-Posed Problems](#) in this handbook.
- Variational methods are related to PDE restoration methods and are naturally developed for signals and images defined on a continuous subset $\Omega \subset \mathbb{R}^d$, $d = 1, 2, \dots$; for images $d = 2$. Originally, the data-fidelity term is of the form (5) for $A = \text{Id}$ and $\Phi(u) = \int_{\Omega} \phi(\|Du\|_2)dx$, where ϕ is a convex function as those given in Table 1 (top). Since the beginning of the 1990s, a remarkable effort was done to find heuristics on ϕ that enable *to recover edges and breakpoints in restored images and signals while smoothing the regions between them*; see, e.g., [7, 13, 26, 31, 59, 64, 73, 85, 87]. One of the most successful is the *Total Variation* (TV) regularization corresponding to $\phi(t) = t$, which was proposed by Rudin, Osher, and Fatemi in [87]. Variational methods were rapidly applied along with data-fidelity terms Ψ . The use of differential operators D^k of various orders $k \geq 2$ in the prior Φ has been recently investigated; see, e.g., [22, 23]. More details on variational methods for image processing can be found in several textbooks like [3, 7, 91].

For numerical implementation, the variational functional is discretized and Φ takes the form of (6). Different discretization approaches are considered; see, e.g., [2, 27, 95]

The *equivalence between these approaches* has been considered in several seminal papers; see, e.g., [37, 63]. The state of the art and the relationship among all these methodologies are nicely outlined in the recent book of Scherzer et al. [91]. This book gives a brief historical overview of these methodologies and attaches a great importance to the functional analysis of the presented results.

The Main Features of the Minimizers as a Function of the Energy

Pushing curiosity ahead leads to various additional questions. One observes that frequently data fidelity and priors are modeled separately. It is hence necessary to check if the minimizer \hat{u} of $\mathcal{F}(\cdot, v)$ obeys all information contained in the data model Ψ as well as in the prior Φ . Hence the question: how the prior Φ and the data-fidelity Ψ are effectively involved in \hat{u} – a minimizer of $\mathcal{F}(\cdot, v)$. This leads to formulate the following *inverse modeling problem*:

Analyze the mutual relationship between the salient features exhibited by the minimizers \hat{u} of an energy $\mathcal{F}(\cdot, v)$ and the shape of the energy itself. (7)

This problem was posed in a systematic way and studied since [74, 75]. The *point of view* provided by (7) is actually adopted by many authors. Problem (7) is totally general and involves crucial stakes:

- It yields rigorous and strong results on the minimizers \hat{u} .
- Such a knowledge enables a real control on the solution – the reconstructed image or signal \hat{u} .
- Conversely, it opens *new perspectives for modeling*.
- It enables the conception of specialized energies \mathcal{F} that fulfill the requirements in applications.
- This kind of results can help to derive numerical schemes using knowledge on the solutions.

Problem (7) remains open. The results presented here concern images, signals, and data living on finite grids. In this practical framework, the results in this chapter are quite general since they hold for *energies \mathcal{F} which can be convex or nonconvex or smooth or nonsmooth, and results address local and global minimizers*.

Organization of the Chapter

Some preliminary notions and results that help the reading of the chapter are sketched in Sect. 2. Section 3 is devoted to the regularity of the (local) minimizers of $\mathcal{F}(\cdot, v)$ with a special focus on nonconvex regularization. Section 4 shows how edges are enhanced using nonconvex regularization. In Sect. 5 it is shown that nonsmooth regularization leads typically to minimizers that are sparse in the space spanned by $\{D_i\}$. Conversely, Sect. 6 exhibits that the minimizers relevant to nonsmooth data fidelity achieve an exact fit for numerous data samples. Section 7 considers results when both Ψ and Φ are nonsmooth. Illustrations and applications are presented.

2 Preliminaries

In this section we set the notations and recall some classical definitions and results on minimization problems.

Notation

We systematically denote by \hat{u} a (local) minimizer of $\mathcal{F}(\cdot, v)$. It is explicitly specified when \hat{u} is a global minimizer.

- D_j^n – The differential operator of order n with respect to the j th component of a function.
- $v[i]$ – The i th entry of vector v .
- $\#J$ – The cardinality of the set J .
- $J^c = I \setminus J$ – The complement of $J \subset I$ in I where I is a set.
- K^\perp – The orthogonal complement of a sub-vector space $K \subset \mathbb{R}^n$.
- A^* – The transpose of a matrix (or a vector) where A is real valued.
- $A > 0$ ($A \succeq 0$) – The matrix A is positive definite (positive semi-definite).
- $\mathbb{1}_n \in \mathbb{R}^n$ – The n -length vector composed of ones, i.e., $\mathbb{1}_n[i] = 1$, $1 \leq i \leq n$.
- \mathbb{L}^n – The Lebesgue measure on \mathbb{R}^n .
- Id – The identity operator.
- $\|\cdot\|_\rho$ – A vector or a matrix ρ -norm.
- $\mathbb{R}_+ \stackrel{\text{def}}{=} \{t \in \mathbb{R} : t \geq 0\}$ and $\mathbb{R}_+^* \stackrel{\text{def}}{=} \{t \in \mathbb{R} : t > 0\}$.
- TV – Total Variation.
- $\{e_1, \dots, e_n\}$ – The canonical basis of \mathbb{R}^n , i.e., $e_i[i] = 1$ and $e_i[j] = 0$ if $i \neq j$.

Reminders and Definitions

Definition 1. A function $\mathcal{F} : \mathbb{R}^p \rightarrow \mathbb{R}$ is coercive if $\lim_{\|u\| \rightarrow \infty} \mathcal{F}(u) = +\infty$.

A special attention being dedicated to nonsmooth functions, we recall some basic facts.

Definition 2. Given $v \in \mathbb{R}^q$, the function $\mathcal{F}(\cdot, v) : \mathbb{R}^p \rightarrow \mathbb{R}$ admits at $\hat{u} \in \mathbb{R}^p$ a *one-sided derivative* in a direction $w \in \mathbb{R}^p$, denoted $\delta_1 \mathcal{F}(\hat{u}, v)(w)$, if the following limit exists:

$$\delta_1 \mathcal{F}(\hat{u}, v)(w) = \lim_{t \searrow 0} \frac{\mathcal{F}(\hat{u} + tw, v) - \mathcal{F}(\hat{u}, v)}{t},$$

where the index 1 in δ_1 means that derivatives with respect to the first variable of \mathcal{F} are addressed.

Here $\delta_1 \mathcal{F}(\hat{u}, v)(w)$ is a *right-side* derivative; the *left-side* derivative is $-\delta_1 \mathcal{F}(\hat{u}, v)(-w)$. If $\mathcal{F}(\cdot, v)$ is differentiable at \hat{u} , then $\delta_1 \mathcal{F}(\hat{u}, v)(w) = D_1 \mathcal{F}(\hat{u}, v)w$ where D_1 stands for differential with respect to the first variable (see paragraph “Notation”). For $\phi : \mathbb{R}_+ \rightarrow \mathbb{R}$, we denote by $\phi'(t^-)$ and $\phi'(t^+)$ its left-side and right-side derivatives, respectively.

The classical necessary condition for a local minimum of a (nonsmooth) function is recalled [60, 86]:

Theorem 1. *If $\mathcal{F}(\cdot, v)$ has a local minimum at $\hat{u} \in \mathbb{R}^p$, then $\delta_1 \mathcal{F}(\hat{u}, v)(w) \geq 0$, for every $w \in \mathbb{R}^p$.*

If $\mathcal{F}(\cdot, v)$ is Fréchet differentiable at \hat{u} , one finds $D_1\mathcal{F}(\hat{u}, v) = 0$.

Rademacher's theorem states that if \mathcal{F} is proper and Lipschitz continuous on \mathbb{R}^p , then the set of points in \mathbb{R}^p at which \mathcal{F} is *not* Fréchet differentiable form a set of Lebesgue measure zero [60, 86]. Hence $\mathcal{F}(\cdot, v)$ is differentiable at almost every u . However, when $\mathcal{F}(\cdot, v)$ is nondifferentiable, its minimizers are typically located at points where $\mathcal{F}(\cdot, v)$ is nondifferentiable; see, e.g., Example 1 below.

Example 1. Consider $\mathcal{F}(u, v) = \frac{1}{2}\|u - v\|^2 + \beta|u|$ for $\beta > 0$ and $u, v \in \mathbb{R}$. The minimizer \hat{u} of $\mathcal{F}(\cdot, v)$ reads as

$$\hat{u} = \begin{cases} 0 & \text{if } |v| \leq \beta \\ v - \text{sign}(v)\beta & \text{if } |v| > \beta \end{cases} \quad (\hat{u} \text{ is shrunk w.r.t. } v.)$$

Clearly, $\mathcal{F}(\cdot, v)$ is not Fréchet differentiable *only at zero*. For any $|v| \leq \beta$, the minimizer of $\mathcal{F}(\cdot, v)$ is located *precisely at zero*.

The next corollary shows what can happen if the necessary condition in Theorem 1 fails.

Corollary 1. *Let \mathcal{F} be differentiable on $(\mathbb{R}^p \times \mathbb{R}^q) \setminus \Theta_0$ where*

$$\Theta_0 \stackrel{\text{def}}{=} \{(u, v) \in \mathbb{R}^p \times \mathbb{R}^q : \exists w \in \mathbb{R}^p, -\delta_1\mathcal{F}(u, v)(-w) > \delta_1\mathcal{F}(u, v)(w)\}. \quad (8)$$

Given $v \in \mathbb{R}^q$, if \hat{u} is a (local) minimizer of $\mathcal{F}(\cdot, v)$ then

$$(\hat{u}, v) \notin \Theta_0.$$

Proof. If \hat{u} is a local minimizer, then by Theorem 1, $\delta_1\mathcal{F}(\hat{u}, v)(-w) \geq 0$, hence

$$-\delta_1\mathcal{F}(\hat{u}, v)(-w) \leq 0 \leq \delta_1\mathcal{F}(\hat{u}, v)(w), \quad \forall w \in \mathbb{R}^p. \quad (9)$$

If $(\hat{u}, v) \in \Theta_0$, the necessary condition (9) cannot hold. \square

Example 2. Suppose that Ψ in (3) is a differentiable function for any $v \in \mathbb{R}^q$. For a finite set of positive numbers, say $\theta_1, \dots, \theta_k$, suppose that the PF ϕ is differentiable on $\mathbb{R}_+ \setminus \cup_{j=1}^k \theta_j$ and that

$$\phi'(\theta_j^-) > \phi'(\theta_j^+), \quad 1 \leq j \leq k. \quad (10)$$

Given a (local) minimizer \hat{u} , denote

$$I = \{1, \dots, r\} \quad \text{and} \quad I_{\hat{u}} = \{i \in I : \|D_i \hat{u}\|_2 = \theta_j, 1 \leq j \leq k\}.$$

Define $F(\hat{u}, v) = \Psi(\hat{u}, v) + \beta \sum_{i \in I \setminus I_{\hat{u}}} \phi(\|D_i \hat{u}\|_2)$, which is differentiable at \hat{u} .

Clearly, $\mathcal{F}(\hat{u}, v) = F(\hat{u}, v) + \beta \sum_{i \in I_{\hat{u}}} \phi(\|D_i \hat{u}\|_2)$. Applying the necessary condition (9) for $w = \hat{u}$ yields

$$\beta \sum_{i \in I_{\hat{u}}} \phi'(\|D_i \hat{u}\|_2^-) \leq -D_i F(\hat{u}, v)(\hat{u}) \leq \beta \sum_{i \in I_{\hat{u}}} \phi'(\|D_i \hat{u}\|_2^+).$$

In particular, one has $\sum_{i \in I_{\hat{u}}} \phi'(\|D_i \hat{u}\|_2^-) \leq \sum_{i \in I_{\hat{u}}} \phi'(\|D_i \hat{u}\|_2^+)$, which contradicts the assumption on ϕ' in (10). It follows that if \hat{u} is a (local) minimizer of $\mathcal{F}(\cdot, v)$, then $I_{\hat{u}} = \emptyset$ and

$$\|D_i \hat{u}\|_2 \neq \theta_j, \quad 1 \leq j \leq k, \quad \forall i \in I.$$

A typical case is the PF (f6) in Table 1, namely, $\phi(t) = \min\{\alpha t^2, 1\}$. Then $k = 1$ and $\theta_1 = \frac{1}{\sqrt{\alpha}}$.

The following existence theorem can be found, e.g., in the textbook [35].

Theorem 2. For $v \in \mathbb{R}^q$, let $U \subset \mathbb{R}^p$ be a nonempty and closed subset and $\mathcal{F}(\cdot, v) : U \rightarrow \mathbb{R}$ a lower semicontinuous (l.s.c.) proper function. If U is unbounded (with possibly $U = \mathbb{R}^p$), suppose that $\mathcal{F}(\cdot, v)$ is coercive. Then there exists $\hat{u} \in U$ such that $\mathcal{F}(\hat{u}, v) = \inf_{u \in U} \mathcal{F}(u, v)$.

This theorem gives only *sufficient conditions* for the existence of a minimizer. They are *not* necessary, as seen in the example below.

Example 3. Let $\mathcal{F} : \mathbb{R}^2 \times \mathbb{R}^2 \rightarrow \mathbb{R}$ involve (f6) in Table 1 and read

$$\mathcal{F}(u, v) = (u[1] - v[1])^2 + \beta \phi(|u[1] - u[2]|) \text{ for } \phi(t) = \max\{\alpha t^2, 1\}, \quad 0 < \beta < \infty.$$

For any v , $\mathcal{F}(\cdot, v)$ is not coercive since it is bounded by β in the direction spanned by $\{(0, u[2])\}$. However, its global minimum is strict and is reached for $\hat{u}[1] = \hat{u}[2] = v[1]$ with $\mathcal{F}(\hat{u}, v) = 0$.

To prove the existence of optimal solutions for more general energies, we refer to the textbook [9].

Most of the results summarized in this chapter exhibit the behavior of the minimizer points \hat{u} of $\mathcal{F}(\cdot, v)$ under variations of v . In words, they deal with local minimizer functions.

Definition 3. Let $\mathcal{F} : \mathbb{R}^p \times \mathbb{R}^q \rightarrow \mathbb{R}$ and $O \subseteq \mathbb{R}^q$. We say that $\mathcal{U} : O \rightarrow \mathbb{R}^p$ is a *local minimizer function* for the family of functions $\mathcal{F}(\cdot, O) = \{\mathcal{F}(\cdot, v) : v \in O\}$ if for any $v \in O$, the function $\mathcal{F}(\cdot, v)$ reaches a *strict local minimum at $\mathcal{U}(v)$* .

When $\mathcal{F}(\cdot, v)$ is proper, l.s.c., and convex, the standard results below can be evoked; see [35, 49].

Theorem 3. Let $\mathcal{F}(\cdot, v) : \mathbb{R}^p \rightarrow \mathbb{R}$ be proper, convex, l.s.c., and coercive for every $v \in \mathbb{R}^q$.

- (i) Then $\mathcal{F}(\cdot, v)$ has a unique (global) minimum which is reached for a closed convex set of minimizers $\{\hat{\mathcal{U}}(v)\} \stackrel{\text{def}}{=} \left\{ \hat{u} \in \mathbb{R}^p : \mathcal{F}(\hat{u}, v) = \inf_{u \in U} \mathcal{F}(u, v) \right\}$.
- (ii) If in addition $\mathcal{F}(\cdot, v)$ is strictly convex, then there is a unique minimizer $\hat{u} = \mathcal{U}(v)$ (which is also global). So $\mathcal{F}(\mathbb{R}^p, v)$ has a unique minimizer function $v \mapsto \mathcal{U}(v)$.

The next lemma, which can be found, e.g., in [52], addresses the regularity of the local minimizer functions when \mathcal{F} is smooth. It can be seen as a variant of the implicit functions theorem.

Lemma 1. Let \mathcal{F} be \mathcal{C}^m , $m \geq 2$, on a neighborhood of $(\hat{u}, v) \in \mathbb{R}^p \times \mathbb{R}^q$. Suppose that $\mathcal{F}(\cdot, v)$ reaches at \hat{u} a local minimum such that $D_1^2 \mathcal{F}(\hat{u}, v) \succ 0$. Then there are a neighborhood $O \subset \mathbb{R}^q$ containing v and a unique \mathcal{C}^{m-1} local minimizer function $\mathcal{U} : O \rightarrow \mathbb{R}^p$, such that $D_1^2 \mathcal{F}(\mathcal{U}(v), v) \succ 0$ for every $v \in O$ and $\mathcal{U}(v) = \hat{u}$.

This lemma is extended in several directions in this chapter.

Definition 4. Let $\phi : [0, +\infty) \rightarrow \mathbb{R}$ and $m \geq 0$ an integer. We say that ϕ is \mathcal{C}^m on \mathbb{R}_+ , or equivalently that $\phi \in \mathcal{C}^m(\mathbb{R}_+)$, if and only if $t \mapsto \phi(|t|)$ is \mathcal{C}^m on \mathbb{R} .

By this definition, $\phi'(0) = 0$. In Table 1, left, $\phi \in \mathcal{C}^1(\mathbb{R}_+)$ for (f1) if $\alpha < 2$, $\phi \in \mathcal{C}^2(\mathbb{R}_+)$ for (f4), while for (f2), (f3), and (f7)–(f9) we find $\phi \in \mathcal{C}^\infty(\mathbb{R}_+)$.

3 Regularity Results

Here, we focus on the regularity of the minimizers of $\mathcal{F} : \mathbb{R}^p \times \mathbb{R}^q \rightarrow \mathbb{R}$ of the form

$$\mathcal{F}(u, v) = \|Au - v\|_2^2 + \beta \sum_{i \in I} \phi(\|\mathbf{D}_i u\|_2), \quad (11)$$

$$I \stackrel{\text{def}}{=} \{1, \dots, r\},$$

where $A \in \mathbb{R}^{q \times p}$ and for any $i \in I$ we have $\mathbf{D}_i \in \mathbb{R}^{s \times p}$ for $s \geq 1$. Let us denote by \mathbf{D} the following $rs \times p$ matrix:

$$\mathbf{D} \stackrel{\text{def}}{=} \begin{bmatrix} \mathbf{D}_1 \\ \vdots \\ \mathbf{D}_r \end{bmatrix}.$$

When A in (11) is not injective, a standard assumption in order to have regularization is

$$\mathbf{H3} \quad \ker(A) \cap \ker(D) = \{0\}.$$

$\mathbf{H3}$ is trivial if $\text{rank } A = p$ or $\text{rank } D = p$. Often, $\ker(D) = \text{span}(\mathbb{1}_p)$ and $A\mathbb{1}_p \neq 0$, so $\mathbf{H3}$ holds.

Some General Results

We first verify the conditions on $\mathcal{F}(\cdot, v)$ in (11) that enable Theorems 2 and 3 to be applied. Since $\mathbf{H1}$ holds, $\mathcal{F}(\cdot, v)$ in (11) is *l.s.c. and proper*.

1. $\mathcal{F}(\cdot, v)$ in (11) is *coercive* for any $v \in \mathbb{R}^q$ at least in *one* of the following cases:

- $\text{Rank}(A) = p$ and $\phi : \mathbb{R}_+ \mapsto \mathbb{R}_+$ is nondecreasing.
- $\mathbf{H1}$ and $\mathbf{H3}$ hold and $\lim_{t \nearrow \infty} \phi(t) = \infty$ (e.g., (f1)–(f5), (f8), (f10), and (f12) in Table 1).

By Theorem 2, $\mathcal{F}(\cdot, v)$ has minimizers.

2. For any $v \in \mathbb{R}^q$, the energy $\mathcal{F}(\cdot, v)$ in (11) is *convex and coercive* if $\mathbf{H1}$ and $\mathbf{H3}$ hold for a *convex* ϕ . Then the claim in Theorem 3(3) holds true.
3. Further, $\mathcal{F}(\cdot, v)$ in (11) is *strictly convex and coercive* for any $v \in \mathbb{R}^q$ if ϕ satisfies $\mathbf{H1}$ and if *one* of the following assumptions holds:

- $\text{Rank}(A) = p$ and ϕ is convex.
- $\mathbf{H3}$ holds and ϕ is strictly convex.

Then the claim in Theorem 3(3) holds. Further, if \mathcal{F} is \mathcal{C}^m for $m \geq 2$, then the minimizer function $\mathcal{U} : \mathbb{R}^q \rightarrow \mathbb{R}^p$ (see Definition 3) is \mathcal{C}^{m-1} by Lemma 1.

However, the PFs involved in (11) used for signal and image processing are often nonconvex, bounded, or nondifferentiable. One extension of the standard results is given in the next section.

Stability of the Minimizers of Energies with Possibly Nonconvex Priors

Related questions have been considered in critical point theory, sometimes in semi-definite programming; the well-posedness of some classes of *smooth* optimization problems was addressed in [42]. Other results have been established on the stability of the local minimizers of general *smooth* energies [52]. Typically, these results are quite abstract to be applied directly to energies of the form (11).

Here the assumptions stated below are considered.

H4 The operator A in (11) satisfies $\text{rank } A = p$, i.e., A^*A is invertible.

H5 The PF ϕ in (11) is $C^0(\mathbb{R}_+)$ and C^m , $m \geq 2$, on \mathbb{R}_+^* with $0 \leq \phi'(0^+) < \infty$.

Under H1, H2, H4, and H5, the prior Φ (and hence $\mathcal{F}(\cdot, v)$) in (11) can be *nonconvex and in addition nonsmooth*. By H1 and H4, $\mathcal{F}(\cdot, v)$ in (11) admits a global minimum $v \in \mathbb{R}^q$ – see Item 1 in section “Some General Results.” However, $\mathcal{F}(\cdot, v)$ can present *numerous local minima*.

- Energies \mathcal{F} with nonconvex and possibly nondifferentiable PFs ϕ are frequently used in engineering problems since they were observed to give rise to high-quality solutions \hat{u} . It is hence important to have good knowledge on the stability of the obtained solutions.

The results summarized in this section provide the state of the art for energies of the form (11).

Local Minimizers

The stability of local minimizers is an important matter in its own right for several reasons. Often, a nonconvex energy is minimized only locally, in the vicinity of some initial guess. Second, the minimization schemes that guarantee the finding of the global minimum of a nonconvex objective function are exceptional. The practically obtained solutions are usually only local minimizers.

The statements below are a simplified version of the results established in [44].

Theorem 4. Let $\mathcal{F}(\cdot, v)$ in (11) satisfy H1, H2, H4, and H5. Then there exists a closed subset $\Theta \subset \mathbb{R}^q$ whose Lebesgue measure is $\mathbb{L}^q(\Theta) = 0$ such that for any $v \in \mathbb{R}^q \setminus \Theta$, there exists an open subset $O \subset \mathbb{R}^q$ with $v \in O$ and a local minimizer function (see Definition 3) $\mathcal{U} : O \rightarrow \mathbb{R}^p$ which is C^{m-1} on O and fulfills $\hat{u} = \mathcal{U}(v)$.

Since Θ is closed in \mathbb{R}^q and $\mathbb{L}^q(\Theta) = 0$, the stated properties are *generic*.

Commentary on the Assumptions

All assumptions H1, H2, and H5 bearing on the PF ϕ are nonrestrictive; they address all PFs in Table 1 except for (f13) which is discontinuous at zero. The assumption H4 cannot be avoided, as seen in Example 4.

Example 4. Consider $\mathcal{F} : \mathbb{R}^2 \times \mathbb{R} \rightarrow \mathbb{R}$ given by

$$\mathcal{F}(u, v) = (u[1] - u[2] - v)^2 + |u[1]| + |u[2]|,$$

where $v \equiv v[1]$. The minimum is obtained after a simple computation.

$$v > \frac{1}{2} \quad \hat{u} = \left(c, c - v + \frac{1}{2} \right) \text{ for any } c \in \left[0, v - \frac{1}{2} \right] \text{ (nonstrict minimizer).}$$

$$|v| \leq \frac{1}{2} \quad \hat{u} = 0 \quad (\text{unique minimizer})$$

$$v < -\frac{1}{2} \quad \hat{u} = \left(c, c - v - \frac{1}{2} \right) \quad \text{for any } c \in \left[v + \frac{1}{2}, 0 \right] \quad (\text{nonstrict minimizer}).$$

In this case, assumption H4 fails and there is a local minimizer function only for $v \in \left[-\frac{1}{2}, \frac{1}{2} \right]$.

Other Results

The derivations in [44] reveal several other practical results.

1. If $\phi \in C^2(\mathbb{R}_+)$, see Definition 4, then $\forall v \in \mathbb{R}^q \setminus \Theta$, every local minimizer \hat{u} of $\mathcal{F}(u, v)$ is strict and $D_1^2 \mathcal{F}(\hat{u}, v) \succ 0$. Consequently, Lemma 1 is extended since the statement holds true $\forall v \in \mathbb{R}^q \setminus \Theta$.
 - ▶ For real data v – a random sample of \mathbb{R}^q – whenever $\mathcal{F}(\cdot, v)$ is differentiable and satisfies the assumptions of Theorem 4, it is a generic property that local minimizers \hat{u} are strict and their Hessians $D_1^2 \mathcal{F}(\hat{u}, v)$ are positive definite.
2. Using Corollary 1, the statement of Theorem 4 holds true if $\phi'(0^+) = 0$ and if there is $\tau > 0$ such that $\phi'(\tau^-) > \phi'(\tau^+)$. This is the case of the PF (f6) in Table 1.
3. If $\phi'(0^+) > 0$, define

$$\hat{J} \stackrel{\text{def}}{=} \{i \in I : D_i \hat{u} = 0\} \quad \text{and} \quad K_{\hat{J}} \stackrel{\text{def}}{=} \left\{ w \in \mathbb{R}^p : D_i w = 0, \forall i \in \hat{J} \right\}. \quad (12)$$

Then $\forall v \in \mathbb{R}^q \setminus \Theta$, every local minimizer \hat{u} of $\mathcal{F}(u, v)$ is strict and

- (a) $D_1 \mathcal{F}|_{K_{\hat{J}}}(\hat{u}, v) = 0$ and $D_1^2 \mathcal{F}|_{K_{\hat{J}}}(\hat{u}, v) \succ 0$ – a sufficient condition for a strict minimum on $K_{\hat{J}}$.
- (b) $\delta_1 \mathcal{F}(\hat{u}, v)(w) > 0, \forall w \in K_{\hat{J}}^\perp \setminus \{0\}$ – a sufficient condition for a strict minimum on $K_{\hat{J}}^\perp$.

- ▶ Here (a) and (b) provide a sufficient condition for a strict (local) minimum of $\mathcal{F}(\cdot, v)$ at \hat{u} (a direct consequence of [80, Theorem 1]). These conditions are satisfied at the (local) minimizers \hat{u} of $\mathcal{F}(\cdot, v)$ for every $v \in \mathbb{R}^q$, except for a negligible subset of \mathbb{R}^q , in which case Lemma 1 can be applied.

One can interpret these results as follows:

- ▶ Under the assumptions H1, H2, H4, and H5, given real data $v \in \mathbb{R}^q$, the chance to get a nonstrict (local) minimizer or a (local) minimizer of the energy in (11) that does not result from a C^{m-1} local minimizer function is null.

Global Minimizers of Energies with for Possibly Nonconvex Priors

The results on the global minimizers of (11) presented next are extracted from [45].

Theorem 5. Assume that $\mathcal{F}(\cdot, v)$ in (11) satisfy H1, H2, H4, and H5. Then there exists a subset $\hat{\Theta} \subset \mathbb{R}^q$ such that $\mathbb{L}^q(\hat{\Theta}) = 0$ and the interior of $\mathbb{R}^q \setminus \hat{\Theta}$ is dense in \mathbb{R}^q , and for any $v \in \mathbb{R}^q \setminus \hat{\Theta}$ the energy $\mathcal{F}(\cdot, v)$ has a unique global minimizer. Furthermore, the global minimizer function $\hat{U} : \mathbb{R}^q \setminus \hat{\Theta} \rightarrow \mathbb{R}^p$ is \mathcal{C}^{m-1} on an open subset of $\mathbb{R}^q \setminus \hat{\Theta}$ which is dense in \mathbb{R}^q .

- ▶ Otherwise said, in a real-world problem there is no chance of getting data v such that the energy $\mathcal{F}(\cdot, v)$ (11) has more than one global minimizer.

Nonetheless, $\hat{\Theta}$ plays a crucial role for the recovery of edges; this issue is developed in Sect. 4.

Nonasymptotic Bounds on Minimizers

The aim here is to give *nonasymptotic* analytical bounds on the local and the global minimizers \hat{u} of $\mathcal{F}(\cdot, v)$ in (11) that hold for all PFs ϕ in Table 1. Related questions have mainly been considered in particular cases or asymptotically; see, e.g., [4, 71, 92]. In [51] the mean and the variance of the minimizers \hat{u} for strictly convex and differentiable functions ϕ have been explored.

The bounds provided below are of practical interest for the initialization and the convergence analysis of numerical schemes. The statements given below are extracted from [82].

Bounds on the restored data. One compares the “restored” data $A\hat{u}$ with the given data v .

H6 Consider the alternative assumptions:

- $\phi'(0^+) = 0$ and $\phi \in \mathcal{C}^1(\mathbb{R}_+ \setminus \Theta_0)$ where the set $\Theta_0 = \{t > 0 : \phi'(t^-) > \phi'(t^+)\}$ is at most finite.
- $\phi'(0^+) > 0$ and ϕ is \mathcal{C}^1 on \mathbb{R}_+^* .

The set Θ_0 allows us to address the PF given in (f6). Let us emphasize that under H1 and H6, the PF ϕ can be convex or nonconvex.

Theorem 6. Consider $\mathcal{F}(\cdot, v)$ of the form (11) where H1, H3, and H6 hold. For every $v \in \mathbb{R}^q$, if $\mathcal{F}(\cdot, v)$ has a (local) minimum at \hat{u} , then

$$\|A\hat{u}\|_2 \leq \|v\|_2.$$

Comments on the results. This bound holds for every (local) minimizer of $\mathcal{F}(\cdot, v)$. If A is a uniform tight frame (i.e., $A^*A = \text{Id}$), one has

$$\|\hat{u}\|_2 \leq \|v\|_2.$$

The mean of restored data. In many applications, the noise corrupting the data can be supposed to have a mean equal to zero. When $A = \text{Id}$, it is well known that $\text{mean}(\hat{u}) = \text{mean}(v)$; see, e.g., [7]. However, for a general A one has

$$A\mathbb{1}_p \propto \mathbb{1}_q \quad \Rightarrow \quad \text{mean}(\hat{u}) = \text{mean}(v). \quad (13)$$

The requirement $A\mathbb{1}_p \propto \mathbb{1}_q$ is quite restrictive. In the simple case when $\phi(t) = t^2$, $\ker(D) = \mathbb{1}_{rs}$ and A is square and invertible, it is easy to see that this is also a sufficient condition. Finally, if $A \neq \text{Id}$, then generally $\text{mean}(\hat{u}) \neq \text{mean}(v)$.

The residuals for edge-preserving regularization. A bound on the data-fidelity term at a (local) minimizer \hat{u} of $\mathcal{F}(\cdot, v)$ shall be given. The edge-preserving H2 (see Sect. 1) is replaced by a stronger edge-preserving assumption:

$$\mathbf{H7} \quad \|\phi'\|_\infty \stackrel{\text{def}}{=} \max \left\{ \sup_{t \geq 0} |\phi'(t^+)|, \sup_{t > 0} |\phi'(t^-)| \right\} < \infty.$$

Except for (f1) and (f13), all other PFs in Table 1 satisfy H7. Note that when $\phi'(0^+) > 0$ and H7 hold, one usually has $\|\phi'\|_\infty = \phi'(0^+)$.

Theorem 7. Let $\mathcal{F}(\cdot, v)$ be of the form (11) where $\text{rank}(A) = q \leq p$, and H1, H3, H6, and H7 hold. For every $v \in \mathbb{R}^q$, if $\mathcal{F}(\cdot, v)$ has a (local) minimum at \hat{u} , then

$$\|A\hat{u} - v\|_\infty \leq \frac{\beta}{2} \|\phi'\|_\infty \|AA^*\|^{-1} \|A\|_\infty \|D\|_1. \quad (14)$$

Let us emphasize that the bound in (14) is *independent of data v* and that it is satisfied for *any local or global minimizer \hat{u} of $\mathcal{F}(\cdot, v)$* . (Recall that for a real matrix C with entries $C[i, j]$, one has $\|C\|_1 = \max_j \sum_i |C[i, j]|$ and $\|C\|_\infty = \max_i \sum_j |C[i, j]|$; see, e.g., [35].)

If D corresponds to a discrete gradient operator for a two-dimensional image, $\|D\|_1 = 4$. If in addition $A = \text{Id}$, (14) yields

$$\|v - \hat{u}\|_\infty \leq 2\beta \|\phi'\|_\infty.$$

The result of this theorem may seem surprising. In a statistical setting, the quadratic data-fidelity term $\|Au - v\|_2^2$ in (11) corresponds to white Gaussian noise on the data, which is unbounded. However, if ϕ is edge preserving according to H7, any (local) minimizer \hat{u} of $\mathcal{F}(\cdot, v)$ gives rise to a *noise estimate* $(v - A\hat{u})[i]$, $1 \leq i \leq q$ that is tightly bounded as stated in (14).

- Hence the model for Gaussian noise on the data v is distorted by the solution \hat{u} .

- When $\mathcal{F}(\cdot, v)$ is convex and coercive, (14) shows that a good initialization for a minimization algorithm should be a point u_0 such that $Au_0 = v$, e.g., the minimum norm solution of $\|v - \hat{u}\|_2$ given by $u_0 = A^*(AA^*)^{-1}v$.

4 Nonconvex Regularization

Motivation

A permanent requirement is that the energy \mathcal{F} favors the recovery of neat edges. Since the pioneering work of Geman and Geman [56], various *nonconvex* Φ in (3) have been proposed [15, 54, 55, 64, 68, 72, 85]. Indeed, the relevant minimizers exhibit neat edges between homogeneous regions. However, these nonconvex energies are tiresome to control and to minimize (only few algorithms are proved to find the global minimizer in particular cases). In order to avoid these numerical intricacies, since the 1990s, an important effort was done to derive *convex* edge-preserving PFs; see, e.g., [20, 31, 57, 64, 87] and [7] for an overview. The most popular convex edge-preserving PF was derived by Rudin, Osher, and Fatemi [87]: it amounts to $\phi = t$, for $\{D_i\}$ yielding the discrete gradient operator, the ℓ_2 -norm in (6) (see Sect. 1), and the relevant Φ is called *the Total Variation (TV) regularization*.

In Fig. 2 one sees that the height of the edges is better recovered when ϕ is nonconvex, compared to the convex TV regularization. The same effect can also be observed, e.g., in Figs. 7, 8, and 10.

A considerable progress in nonconvex minimization has been realized. For energies of the form (2)–(3) we refer to [5, 19, 88, 89].

- This section is devoted to explain why edges are nicely recovered using a nonconvex ϕ .

Assumptions on Potential Functions ϕ

Consider $\mathcal{F}(\cdot, v)$ of the form (11) where $D_i : \mathbb{R}^p \rightarrow \mathbb{R}^1$, $i \in I = \{1, \dots, r\}$, i.e.,

$$\mathcal{F}(u, v) = \|Au - v\|_2^2 + \beta \sum_{i \in I} \phi(|D_i u|), \quad (15)$$

and $\phi : \mathbb{R}_+ \rightarrow \mathbb{R}_+$ satisfies H1 (see Sect. 1), H6 section “Nonasymptotic Bounds on Minimizers,” and H8 given below

H8 ϕ is C^2 and $\phi'(t) \geq 0$ on \mathbb{R}_+^* , and $\inf_{t \in \mathbb{R}_+^*} \phi''(t) < 0$ with $\lim_{t \rightarrow \infty} \phi''(t) = 0$;

as well as *one* of the following assumptions:

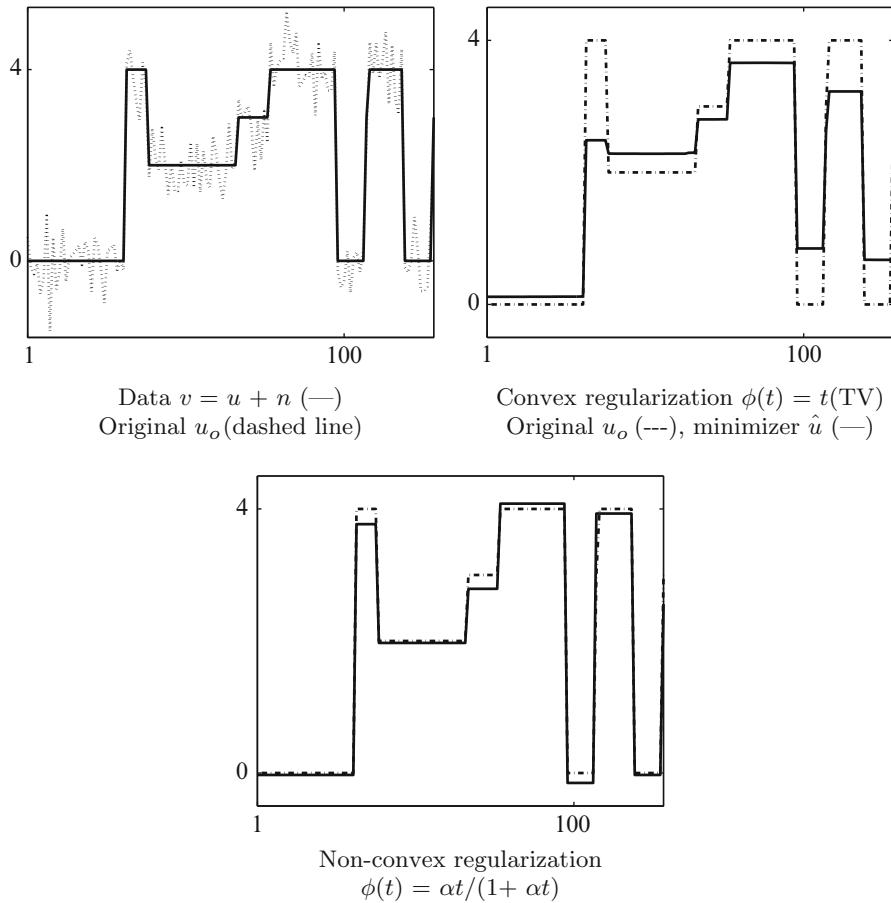

Fig. 2 Minimizers of $\mathcal{F}(u, v) = \|u - v\|_2^2 + \beta \sum_{i=1}^{p-1} \phi(|u[i] - u[i+1]|)$

H9 $\phi'(0^+) = 0$, and there are two numbers $\tau > 0$ and $\mathcal{T} \in (\tau, \infty)$ such that $\phi''(t) \geq 0$ on $[0, \tau]$, $\phi''(t) < 0$ on (τ, ∞) , $\phi''(t)$ decreases on (τ, \mathcal{T}) and increases on (\mathcal{T}, ∞) .

H10 $\phi'(0^+) > 0$, and $\lim_{t \rightarrow 0} \phi''(t) < 0$ is well defined and $\phi''(t) < 0$ strictly increases on $(0, \infty)$.

These assumptions are illustrated in Fig. 3. They hold for all nonconvex PFs in Table 1, except for (f6) and (f13) which are presented separately. Further, these assumptions are easy to relax.

The results presented below come from [81].

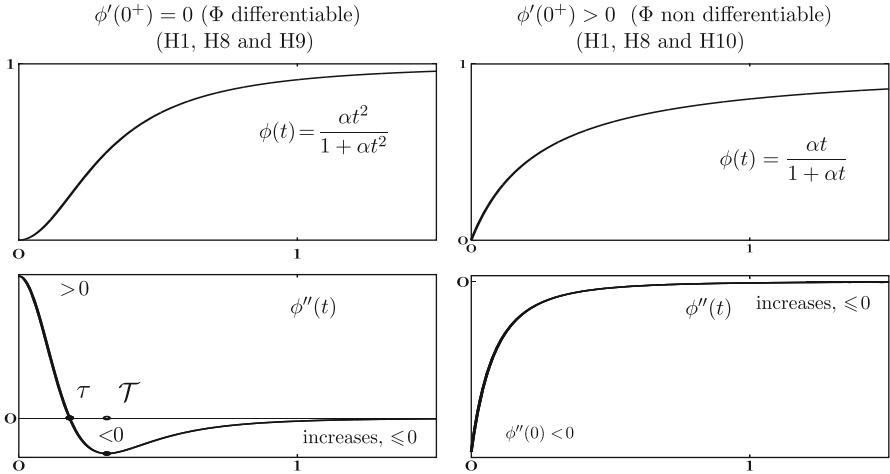

Fig. 3 Illustration of the assumptions in two typical cases – (f7) and (f11) – in Table 1

How It Works on \mathbb{R}

- This example illustrates the main facts that explain why edges are enhanced when ϕ is nonconvex, satisfying H1, and H8 along with either H9 or H10.

Let $\mathcal{F} : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}$ be given by

$$\mathcal{F}(u, v)$$

$$= \frac{1}{2}(u - v)^2 + \beta\phi(u) \text{ for } \begin{cases} \beta > \frac{1}{|\phi''(\mathcal{T})|} & \text{if } \phi'(0^+) = 0 \text{ (H1, H8 and H9)} \\ \beta > \frac{1}{|\lim_{t \searrow 0} \phi''(t)|} & \text{if } \phi'(0^+) > 0 \text{ (H1, H8 and H10)} \end{cases}$$

The (local) minimality conditions for \hat{u} of $\mathcal{F}(\cdot, v)$ read as

- If $\phi'(0^+) = 0$ or $[\phi'(0^+) > 0 \text{ and } \hat{u} \neq 0]$: $\hat{u} + \beta\phi'(\hat{u}) = v$ and $1 + \beta\phi''(\hat{u}) \geq 0$.
- If $\phi'(0^+) > 0$ and $\hat{u} = 0$: $|v| \leq \beta\phi'(0^+)$.

To simplify, we assume that $v \geq 0$. Define

$$\theta_0 = \inf C_\beta \text{ and } \theta_1 = \sup C_\beta,$$

$$\text{for } C_\beta = \{u \in \mathbb{R}_+^* : D_1^2 \mathcal{F}(u, v) < 0\} = \{u \in \mathbb{R}_+^* : \phi''(u) < -1/\beta\}.$$

One has $\theta_0 = 0$ if $\phi'(0^+) > 0$ and $0 < \theta_0 < \mathcal{T} < \theta_1$ if $\phi'(0^+) = 0$. A few calculations yield

1. For every $v \in \mathbb{R}_+$ no minimizer lives in (θ_0, θ_1) (cf. Fig. 4).
2. One computes $0 < \xi_0 < \xi_1$ such that (cf. Fig. 4)
 - a. If $0 \leq v \leq \xi_1$, $\mathcal{F}(\cdot, v)$ has a (local) minimizer $\hat{u}_0 \in [0, \theta_0]$, hence \hat{u}_0 is subject to a strong smoothing.
 - b. If $v \geq \xi_1$, $\mathcal{F}(\cdot, v)$ has a (local) minimizer $\hat{u}_1 \geq \theta_1$, hence \hat{u}_1 is subject to a weak smoothing.
 - c. If $v \in [\xi_0, \xi_1]$ then $\mathcal{F}(\cdot, v)$ has two local minimizers, \hat{u}_0 and \hat{u}_1 .
3. There is $\xi \in (\xi_0, \xi_1)$ such that $\mathcal{F}(\cdot, \xi)$ has two global minimizers, $\mathcal{F}(\hat{u}_0, \xi) = \mathcal{F}(\hat{u}_1, \xi)$, as seen in Fig. 5;
 - a. If $0 < v < \xi$, the unique global minimizer is $\hat{u} = \hat{u}_0$.
 - b. If $v > \xi$, the unique global minimizer is $\hat{u} = \hat{u}_1$.
4. The global minimizer function $v \mapsto \mathcal{U}(v)$ is discontinuous at ξ and C^1 -smooth on $\mathbb{R}_+ \setminus \{\xi\}$.

Item 1 is the key for the recovery of either homogeneous regions or high edges. The minimizer \hat{u}_0 (see Items 2a and 3a) corresponds to the restoration of homogeneous regions, while \hat{u}_1 (see Items 2b and 3b) corresponds to edges. Item 3 corresponds to a decision for the presence of an edge at the global minimizer. Since $\{\xi\}$ is closed and $\mathbb{L}^1\{\xi\} = 0$, Item 4 confirms the results of section “Global Minimizers of Energies with for Possibly Nonconvex Priors.”

Either Smoothing or Edge Enhancement

(A) Case $\phi'(0^+) = 0$. Below the case depicted in Figs. 4, left, and 5, left, is extended to \mathbb{R}^p .

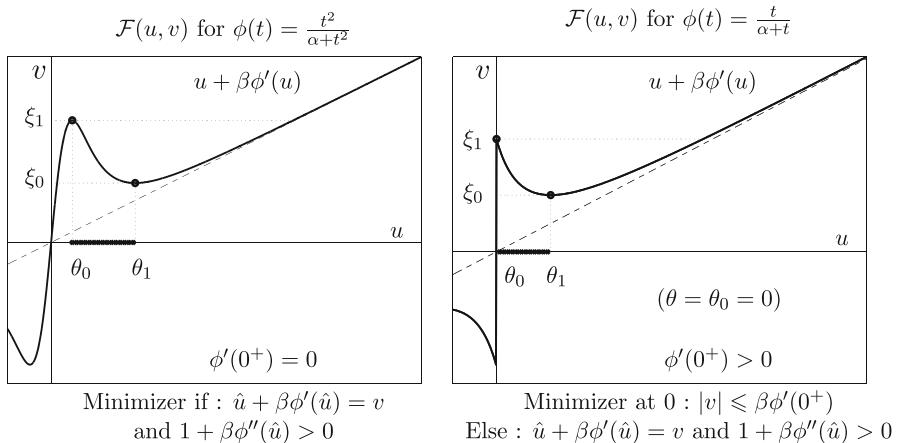

Fig. 4 The curve of $u \mapsto (D_1\mathcal{F}(u, v) - v)$ on $\mathbb{R} \setminus \{0\}$. All assumptions mentioned before hold

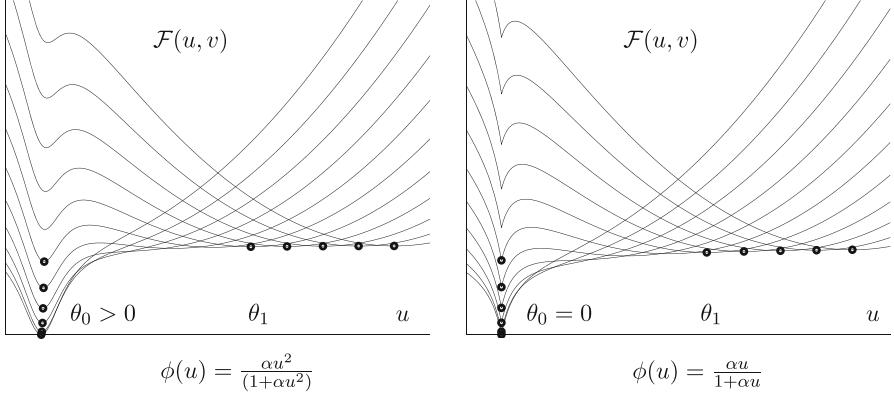

Fig. 5 Each curve represents $\mathcal{F}(u, v) = \frac{1}{2}(u-v)^2 + \beta\phi(u)$ for an increasing sequence $v \in [0, \xi_1]$. The global minimizer of each $\mathcal{F}(\cdot, v)$ is marked with “•.” No (local) minimizer lives in (θ_0, θ_1)

Theorem 8. Let $\mathcal{F}(\cdot, v)$ be of the form (15) where H1, H3, H8, and H9 hold, and $\{\mathbf{D}_i : i \in I\}$ are linearly independent. Set $\mu \stackrel{\text{def}}{=} \max_{1 \leq i \leq r} \|\mathbf{D}^*(\mathbf{D}\mathbf{D}^*)^{-1}\mathbf{e}_i\|_2$. For $\beta > \frac{2\mu^2 \|A^* A\|_2}{|\phi''(\mathcal{T})|}$, there are $\theta_0 \in (\tau, \mathcal{T})$ and $\theta_1 \in (\mathcal{T}, \infty)$ such that $\forall v \in \mathbb{R}^q$, if \hat{u} is a (local) minimizer of $\mathcal{F}(\cdot, v)$, then

$$\text{either } |\mathbf{D}_i \hat{u}| \leq \theta_0, \quad \text{or} \quad |\mathbf{D}_i \hat{u}| \geq \theta_1, \quad \forall i \in I. \quad (16)$$

In many imaging problems, $\{\mathbf{D}_i\}$ are not linearly independent. If $\{\mathbf{D}_i\}$ are linearly dependent, the result (16) holds true for all (local) minimizers \hat{u} that are locally homogeneous on regions that are connected with respect to $\{\mathbf{D}_i\}$. Otherwise, one recovers both high edges and smooth transitions, as seen in Fig. 8a. When ϕ is convex, all edges are smoothed, as one can observe in Fig. 7a.

The PF $\phi(t) = \min\{\alpha t^2, 1\}$ (f6) in Table 1 does not satisfy assumptions H8 and H9. From Corollary 1 and Example 2 (section “Reminders and Definitions”), any (local) minimizer \hat{u} of $\mathcal{F}(\cdot, v)$ obeys

$$|\mathbf{D}_i \hat{u}| \neq \frac{1}{\sqrt{\alpha}}, \quad \forall i \in I.$$

Proposition 1 below addresses only the *global minimizers* of $\mathcal{F}(\cdot, v)$.

Proposition 1. Let $\mathcal{F}(\cdot, v)$ be given by (15) where $\phi(t) = \min\{\alpha t^2, 1\}$, $\{\mathbf{D} : i \in I\}$ are linearly independent and $\text{rank}(A) \geq p - r \geq 1$. If $\mathcal{F}(\cdot, v)$ has a global minimizer at \hat{u} , then

$$\text{either } |\mathbf{D}_i \hat{u}| \leq \frac{1}{\sqrt{\alpha}} \Gamma_i, \quad \text{or} \quad |\mathbf{D}_i \hat{u}| \geq \frac{1}{\sqrt{\alpha}} \Gamma_i,$$

$$\text{for } \Gamma_i = \sqrt{\frac{\|Be_i\|_2^2}{\|Be_i\|_2^2 + \alpha\beta}} < 1, \quad \forall i \in I, \quad (17)$$

where B is a matrix depending only on A and D .

If $D = \text{Id}$, then $B = A$. If u one-dimensional signal and $D_i u = u[i] - u[i+1]$, $1 \leq i \leq p-1$, one has $B = (\text{Id} - \frac{1}{p}\mathbb{1}\mathbb{1}^T)AH$ where $H \in \mathbb{R}^{p \times p}$ is upper triangular composed of ones.

In Proposition 1, set $\theta_0 = \frac{\gamma}{\sqrt{\alpha}}$ and $\theta_1 = \frac{1}{\sqrt{\alpha}\gamma}$ for $\gamma \stackrel{\text{def}}{=} \max_{i \in I} \Gamma_i < 1$.

Let us define the following subsets:

$$\hat{J}_0 \stackrel{\text{def}}{=} \{i \in I : |D_i \hat{u}| \leq \theta_0\} \quad \text{and} \quad \hat{J}_1 \stackrel{\text{def}}{=} I \setminus \hat{J}_0 = \{i \in I : |D_i \hat{u}| \geq \theta_1\}. \quad (18)$$

One can interpret the results of Theorem 8 and Proposition 1 as follows:

- The pixels in \hat{J}_0 form homogeneous regions with respect to $\{D_i\}$, whereas the pixels in \hat{J}_1 are break points.

In particular, if $\{D_i\}$ correspond to first-order differences, \hat{J}_0 addresses smoothly varying regions where $|D_i \hat{u}| \leq \theta_0$, while \hat{J}_1 corresponds to edges higher than $\theta_1 - \theta_0$.

(B) Case $\phi'(0^+) > 0$. Here the results are stronger without assumptions on $\{D_i\}$. This case corresponds to Figs. 4, right, and 5, right.

Theorem 9. Consider $\mathcal{F}(\cdot, v)$ of the form (15) where H3 holds and ϕ satisfies H1, H8, and H10. Let $\beta > \frac{2\mu^2 \|A^* A\|_2}{|\lim_{t \searrow 0} \phi''(t)|}$, where $\mu > 0$ is a constant depending only on $\{D_i\}$. Then $\exists \theta_1 > 0$ such that $\forall v \in \mathbb{R}^q$, every (local) minimizer \hat{u} of $\mathcal{F}(\cdot, v)$ satisfies

$$\text{either } |D_i \hat{u}| = 0, \quad \text{or } |D_i \hat{u}| \geq \theta_1, \quad \forall i \in I. \quad (19)$$

The results of Theorem 9 were extended to energies involving box constraints in [33].

The “0-1” PF (f13) in Table 1 does not satisfy H8 and H10 since it is discontinuous at 0.

Proposition 2. Let $\mathcal{F}(\cdot, v)$ in (15) be defined for $\phi(0) = 0$, $\phi(t) = 1$ if $t > 0$, i.e., (f13), $\{D_i\}$ be linearly independent and $\text{rank } A \geq p-r \geq 1$. If $\mathcal{F}(\cdot, v)$ has a global minimum at \hat{u} , then

$$\text{either } |D_i \hat{u}| = 0 \quad \text{or } |D_i \hat{u}| \geq \frac{\sqrt{\beta}}{\|Be_i\|_2}, \quad \forall i \in I, \quad (20)$$

where the matrix B depends only on D and on A .

In (20), B is the same as in Proposition 1. For $\theta_1 \stackrel{\text{def}}{=} \min_{i \in I} \frac{\sqrt{\beta}}{\|Be_i\|}$, it is clear that (20) holds.

Let

$$\hat{J}_0 \stackrel{\text{def}}{=} \{i : |D_i \hat{u}| = 0\} \text{ and } \hat{J}_1 \stackrel{\text{def}}{=} I \setminus \hat{J}_0 = \{i : |D_i \hat{u}| \geq \theta_1\}.$$

Using this notation, the results of Theorem 9 and Proposition 2 show that:

- ▶ The indexes in \hat{J}_0 address regions in \hat{u} that can be called *strongly homogeneous* (since $|D_i \hat{u}| = 0$), while \hat{J}_1 addresses breakpoints where $|D_i \hat{u}| \geq \theta_1$.
If $\{D_i\}$ are first-order differences, \hat{u} is *neatly segmented*: \hat{J}_0 corresponds to *constant* regions, while \hat{J}_1 describes all edges and they are higher than θ_1 .

Direct segmentation of an image from data transformed via a general (nondiagonal) operator A remains a difficult task using standard methods. The result in (19), Theorem 9, tells us that such a segmentation is naturally involved in the minimizers \hat{u} of $\mathcal{F}(\cdot, v)$, for any operator A . This effect can be observed, e.g., on Figs. 8b, d and 11d.

(C) Illustration: Deblurring of an image from noisy data. The original image u_o in Fig. 6a presents smoothly varying regions, constant regions, and sharp edges. Data in Fig. 6b correspond to $v = a * u_o + n$, where a is a blur with entries $a_{i,j} = \exp(-(i^2 + j^2)/12.5)$ for $-4 \leq i, j \leq 4$, and n is white Gaussian noise yielding 20 dB of SNR. The amplitudes of the original image are in the range of [0, 1.32] and those of the data in [-5, 50]. In all restored images, $\{D_i\}$ correspond to the first-order differences of each pixel with its 8 nearest neighbors. In all figures, the obtained minimizers are displayed on the top. Just below, the sections corresponding to rows 54 and 90 of the restored images are compared with the same rows of the original image.

The restorations in Fig. 7 are obtained using *convex* PFs ϕ while those in Fig. 8 using *nonconvex* PFs ϕ . Edges are sharp and high in Fig. 8 where ϕ is nonconvex, which corroborates the results in paragraphs (A) and (B). In Fig. 8b, d ϕ is nonconvex and $\phi'(0^+) > 0$ in addition. As stated in Theorem 9, in spite of the fact that A is nondiagonal (and ill-conditioned), the restored images are fully segmented and the edges between constant pieces are high.

5 Nonsmooth Regularization

- ▶ Observe that the minimizers corresponding to $\phi'(0^+) > 0$ (nonsmooth regularization) in Figs. 2b, c, 7b, 8b, d, 10a–c, and 11d are constant on numerous regions. This section is aimed to explain and to generalize this observation.

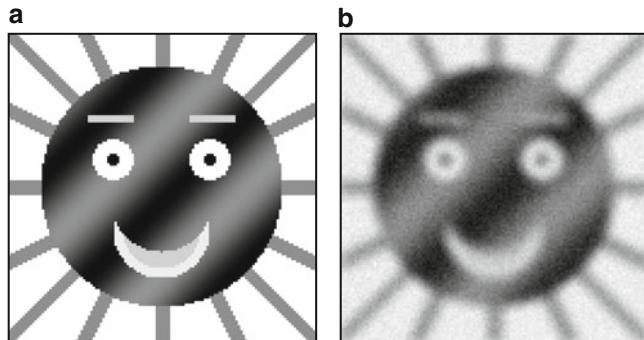

Fig. 6 Data $v = a \star u_o + n$, where a is a blur and n is white Gaussian noise, 20 dB of SNR. (a) Original image. (b) Data $v = \text{blur} + \text{noise}$

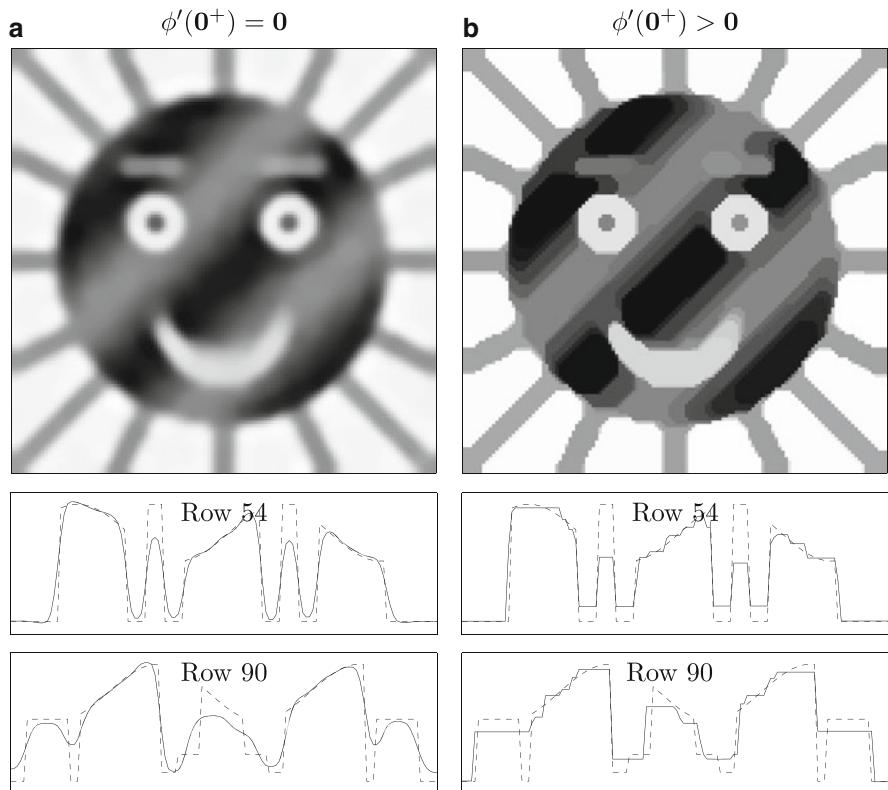

Fig. 7 Restoration using convex PFs. (a) $\phi(t) = t^\alpha$ for $\alpha = 1.4, \beta = 40$. (b) $\phi(t) = t$ for $\beta = 100$

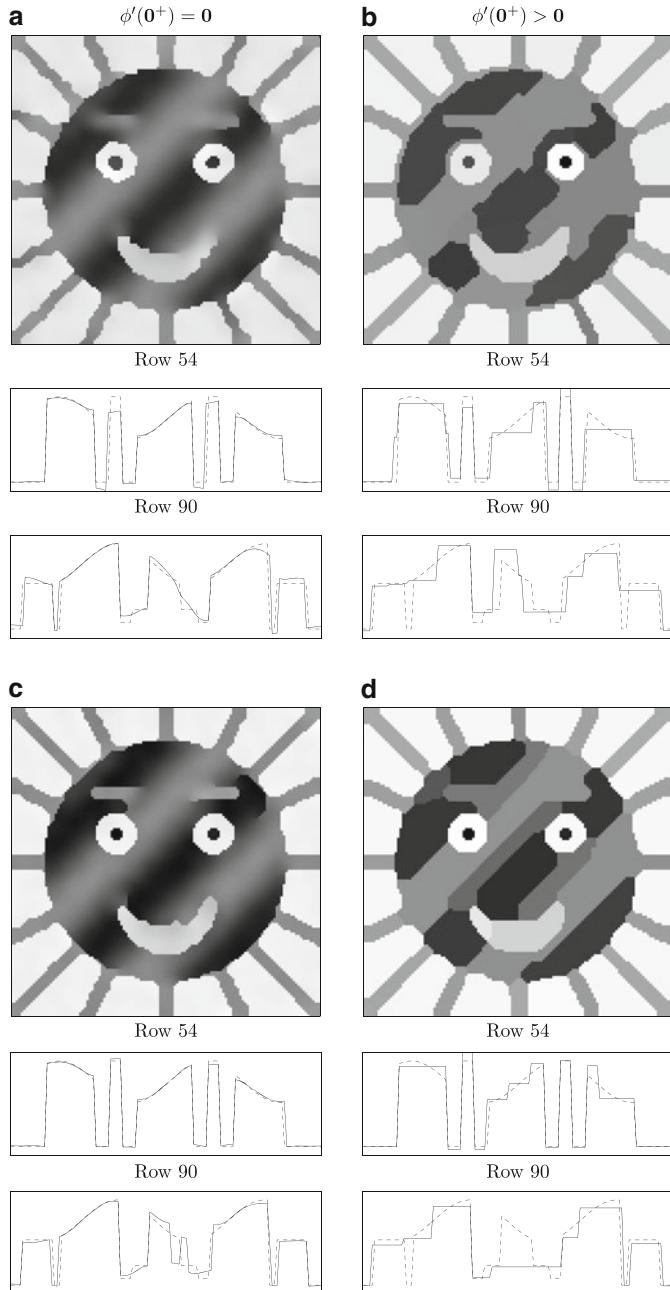

Fig. 8 Restoration using nonconvex PFs. **(a)** $\phi(t) = \frac{\alpha t^2}{1 + \alpha t^2}$ for $\alpha = 25, \beta = 35$. **(b)** $\phi(t) = \frac{\alpha t}{1 + \alpha t}$ for $\alpha = 20, \beta = 100$. **(c)** $\phi(t) = \min\{\alpha t^2, 1\}$ for $\alpha = 60, \beta = 10$. **(d)** $\phi(0) = 0, \phi(t) = 1, t > 0$ for $\beta = 25$

Consider

$$\mathcal{F}(u, v) = \Psi(u, v) + \beta\Phi(u) \quad (21)$$

$$\Phi(u) = \sum_{i=1}^r \phi(\|D_i u\|_2), \quad (22)$$

where $\Psi : \mathbb{R}^p \times \mathbb{R}^q \rightarrow \mathbb{R}$ is *any explicit or implicit* C^m -smooth function for $m \geq 2$ and $D_i : \mathbb{R}^p \mapsto \mathbb{R}^s$, $\forall i \in I = \{1, \dots, r\}$, are general linear operators for any integer $s \geq 1$. It is assumed that ϕ satisfies H1 along with

H11 ϕ is C^2 -smooth on \mathbb{R}_+^* and $\phi'(0^+) > 0$.

Note that Ψ and ϕ can be convex or nonconvex. Let us define the set-valued function \mathcal{J} on \mathbb{R}^p by

$$\mathcal{J}(u) = \left\{ i \in I : \|D_i u\|_2 = 0 \right\}. \quad (23)$$

Given $u \in \mathbb{R}^p$, $\mathcal{J}(u)$ indicates all regions where $D_i u = 0$. Such regions are called *strongly homogeneous* with respect to $\{D_i\}$. (The adverb “strongly” is used to emphasize the difference with just “homogeneous regions” where $\|D_i u\|_2 \approx 0$.) In particular, if $\{D_i\}$ correspond to first-order differences between neighboring samples of u or to discrete gradients, $\mathcal{J}(u)$ indicates all constant regions in u .

Main Theoretical Result

The results presented below are extracted from [80].

Theorem 10. Given $v \in \mathbb{R}^q$, assume that $\mathcal{F}(\cdot, v)$ in (21)–(22) is such that Ψ is C^m , $m \geq 2$ on $\mathbb{R}^p \times \mathbb{R}^q$, and that ϕ satisfies H1 and H11. Let $\hat{u} \in \mathbb{R}^p$ be a (local) minimizer of $\mathcal{F}(\cdot, v)$. For $\hat{J} \stackrel{\text{def}}{=} \mathcal{J}(\hat{u})$, let $K_{\hat{J}}$ be the vector subspace

$$K_{\hat{J}} = \left\{ u \in \mathbb{R}^p : D_i u = 0, \forall i \in \hat{J} \right\}. \quad (24)$$

Suppose also that

- (a) $\delta_1 \mathcal{F}(\hat{u}, v)(w) > 0$, for every $w \in K_{\hat{J}}^\perp \setminus \{0\}$.
- (b) There is an open subset $O'_{\hat{J}} \subset \mathbb{R}^q$ such that $\mathcal{F}|_{K_{\hat{J}}}(\cdot, O'_{\hat{J}})$ has a local minimizer function $\mathcal{U}_{\hat{J}} : O'_{\hat{J}} \rightarrow K_{\hat{J}}$ which is C^{m-1} continuous and $\hat{u} = \mathcal{U}_{\hat{J}}(v)$.

Then there is an open neighborhood $O_{\hat{J}} \subset O'_{\hat{J}}$ of v such that $\mathcal{F}(\cdot, O_{\hat{J}})$ admits a C^{m-1} local minimizer function $\mathcal{U} : O_{\hat{J}} \rightarrow \mathbb{R}^p$ which satisfies $\mathcal{U}(v) = \hat{u}$, $\mathcal{U}|_{K_{\hat{J}}} = \mathcal{U}_{\hat{J}}$ and

$$v \in O_{\hat{J}} \Rightarrow D_i \mathcal{U}(v) = 0, \text{ for all } i \in \hat{J}. \quad (25)$$

Note that \hat{J} and $K_{\hat{J}}$ are the same as those introduced in (12) section ‘‘Local Minimizers.’’

Commentary on the assumptions. Since $\mathcal{F}(\cdot, v)$ has a local minimum at \hat{u} , by Theorem 1 one has $\delta_1 \mathcal{F}(\hat{u}, v)(w) \geq 0$, for all $w \in K_{\hat{J}}^\perp \setminus \{0\}$, and if for some w the inequality becomes inequality, then the inequality is strict for $-w$. So (a) is not a strong requirement. Condition (b) amounts to Lemma 1 (section ‘‘Reminders and Definitions’’) applied to $\mathcal{F}|_{K_{\hat{J}}}$ which is C^m on a neighborhood of (\hat{u}, v) belonging to $K_{\hat{J}} \times \mathbb{R}^q$.

If $\mathcal{F}(\cdot, v)$ (possibly nonconvex) is of the form (11) and assumption H4 (section ‘‘Stability of the Minimizers of Energies with Possibly Nonconvex Priors’’) holds, Theorem 4 and the other results given next show that (a) and (b) are satisfied for any $v \in \mathbb{R}^q \setminus \Theta$ where Θ is closed and $\mathbb{L}^q(\Theta) = 0$.

Significance of the results. Using the definition of \mathcal{J} in (23), the conclusion of the theorem can be reformulated as

$$v \in O_{\hat{J}} \Rightarrow \mathcal{J}(\mathcal{U}(v)) \supseteq \hat{J} \Leftrightarrow \mathcal{U}(v) \in K_{\hat{J}}. \quad (26)$$

Minimizers involving large subsets \hat{J} are observed in Figs. 2b, c, 7b, 8b, d, 10a–c, and 11d. It was seen in Examples 1 and 4, as well as in section ‘‘How It Works on \mathbb{R}^n ’’ (case $\phi'(0^+) > 0$), that \hat{J} is nonempty for data v living in an open $O_{\hat{J}}$. Note also that there is an open subset $\tilde{O}_{\hat{J}} \subset O_{\hat{J}}$ such that $\mathcal{J}(\mathcal{U}(v)) = \hat{J}$ for all $v \in \tilde{O}_{\hat{J}}$. These sets $\tilde{O}_{\hat{J}}$ are described in Example 5.

Observe that (26) is a severe restriction since $K_{\hat{J}}$ is a closed and negligible subset of \mathbb{R}^p , whereas data v vary on open subsets $O_{\hat{J}}$ of \mathbb{R}^q .

Focus on a (local) minimizer function $\mathcal{U} : O \rightarrow \mathbb{R}^p$ for $\mathcal{F}(\cdot, O)$ and put $\hat{J} = \mathcal{J}(\mathcal{U}(v))$ for some $v \in O$. By Theorem 10, the sets $O_{\hat{J}}$ and $\tilde{O}_{\hat{J}}$ are of positive measure in \mathbb{R}^q . When data v range over O , the set-valued function $(\mathcal{J} \circ \mathcal{U})$ generally takes several distinct values, say $\{J_j\}$. Thus, with a (local) minimizer function \mathcal{U} , defined on an open set O , there is associated a family of subsets $\{\tilde{O}_{J_j}\}$ which form a covering of O . When $v \in \tilde{O}_{J_j}$, we find a minimizer $\hat{u} = \mathcal{U}(v)$ satisfying $\mathcal{J}(\hat{u}) = J_j$.

- ▶ Energies with nonsmooth regularization terms, as those considered here, exhibit local minimizers which *generically* satisfy constraints of the form $\mathcal{J}(\hat{u}) \neq \emptyset$.

In particular, if $\{D_i\}$ are discrete gradients or first-order difference operators, minimizers \hat{u} are typically constant on many regions. For example, if $\phi(t) = t$, we have $\Phi(u) = \text{TV}(u)$, and this explains the stair-casing effect observed in TV methods on discrete images and signals [30, 39].

Examples and Discussion

The subsection begins with an illustration of Theorem 10 and its meaning.

Restoration of a noisy signal. Figure 9 shows a piecewise constant signal u_o corrupted with two different noises.

Figure 10 depicts the restoration from these two noisy data samples by minimizing an energy of the form $\mathcal{F}(u, v) = \|u - v\|^2 + \beta \sum_{i=1}^{p-1} \phi(|u[i] - u[i+1]|)$. The minimizers shown in Fig. 10a–c correspond to functions ϕ such that $\phi'(0^+) > 0$ and they are constant on large segments. The reader is invited to compare the subsets where these minimizers are constant. The function ϕ in Fig. 10d satisfies $\phi'(0^+) = 0$ and the resultant minimizers are nowhere constant.

Example 5 below gives a rich geometric interpretation of Theorem 25.

Example 5 (1D TV Regularization). Let $\mathcal{F} : \mathbb{R}^p \times \mathbb{R}^p \rightarrow \mathbb{R}$ be given by

$$\mathcal{F}(u, v) = \|Au - v\|_2^2 + \beta \sum_{i=1}^{p-1} |u[i] - u[i+1]|, \quad \beta > 0, \quad (27)$$

where $A \in \mathbb{R}^{p \times p}$ is invertible. Clearly, there is a unique minimizer function \mathcal{U} for $\mathcal{F}(\cdot, \mathbb{R}^p)$. Two striking phenomena concerning the sets $\tilde{\mathcal{O}}_J$ are described next:

1. For every point $\hat{u} \in \mathbb{R}^p$, there is a polyhedron $Q_{\hat{u}} \subset \mathbb{R}^p$ of dimension $\#\mathcal{J}(\hat{u})$, such that for every $v \in Q_{\hat{u}}$, the same point $\mathcal{U}(v) = \hat{u}$ is the unique minimizer of $\mathcal{F}(\cdot, v)$.
2. For every $J \subset \{1, \dots, p-1\}$, there is a subset $\tilde{\mathcal{O}}_J \subset \mathbb{R}^p$, composed of $2^{p-\#J-1}$ unbounded polyhedra (of dimension p) of \mathbb{R}^p such that for every $v \in \tilde{\mathcal{O}}_J$, the

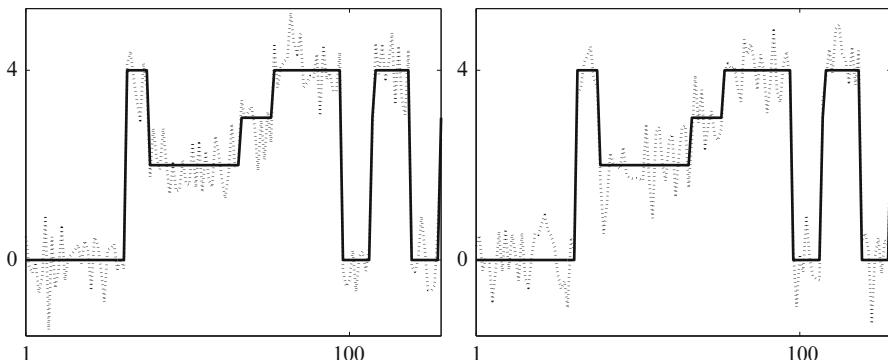

Fig. 9 Data $v = u_o + n$ (—) corresponding to the original u_o (---) contaminated with two different noise samples n on the left and on the right

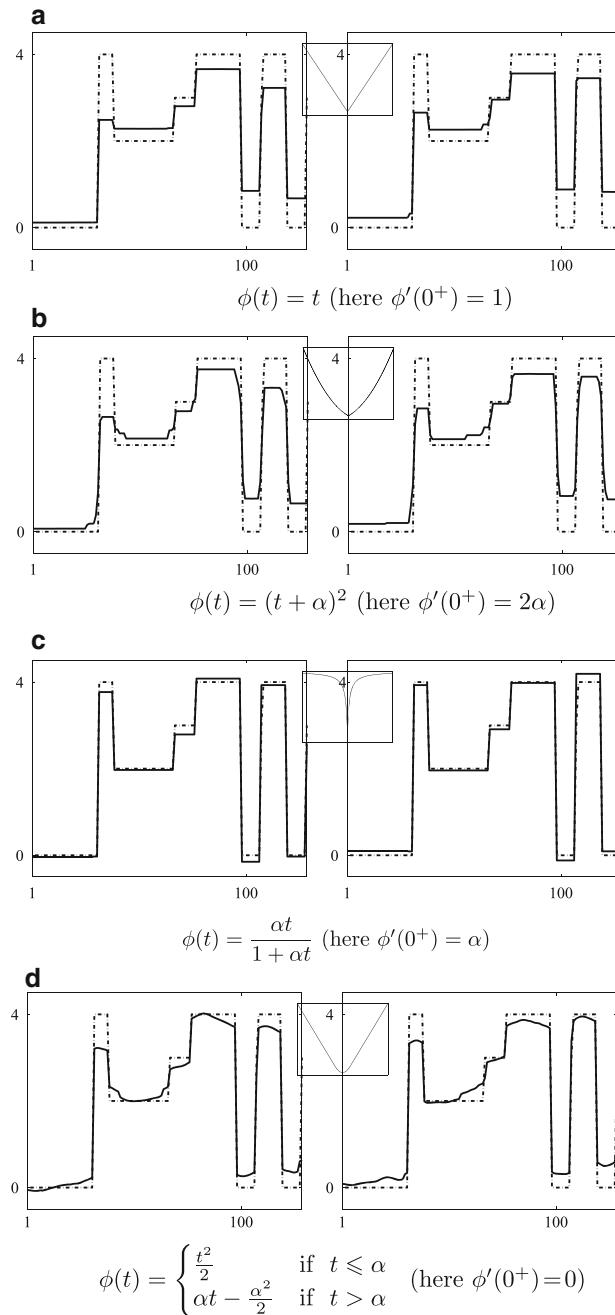

Fig. 10 Restoration using different functions ϕ . Original u_o (-.-), minimizer \hat{u} (—). Each figure from (a) to (d) shows the two minimizers \hat{u} corresponding to the two data sets in Fig. 9 (left and right), while the shape of ϕ is plotted in the middle

minimizer \hat{u} of $\mathcal{F}(\cdot, v)$ satisfies $\hat{u}_i = \hat{u}_{i+1}$ for all $i \in J$ and $\hat{u}_i \neq \hat{u}_{i+1}$ for all $i \in J^c$. Their closure forms a covering of \mathbb{R}^p .

The next Remark 2 deserves to be combined with the conclusions of section “Nonsymptotic Bounds on Minimizers.”

Remark 2. The energy in (27) has a straightforward Bayesian interpretation in terms of *maximum a posteriori* (MAP) estimation (see section “Background,” first item). The quadratic data-fidelity term corresponds to an observation model of the form $v = Au_o + n$ where n is independent identically distributed (i.i.d.) Gaussian noise with mean zero and variance denoted by σ^2 . The likelihood reads $\pi(v|u) = \exp\left(-\frac{1}{2\sigma^2}\|Au - v\|_2^2\right)$. The regularization term corresponds to an i.i.d. Laplacian prior on each difference $u[i] - u[i+1]$, $1 \leq i \leq p-1$, that is, $\exp(-\lambda|t|)$ for $\lambda = \frac{\beta}{2\sigma^2}$. Since this density is continuous on \mathbb{R} , the probability to get a null sample, $t = u[i] - u[i+1] = 0$, is equal to zero. However, the results presented above show that for the minimizer \hat{u} of $\mathcal{F}(\cdot, v)$, the probability to have $\hat{u}[i] - \hat{u}[i+1] = 0$ for a certain amount of indexes i is *strictly positive*. This means that the Laplacian prior on the differences $u[i] - u[i+1]$ is far from being incorporated in the MAP solution \hat{u} .

Applications

The use of nondifferentiable (and also nonconvex) regularization in compressive sensing is actually extremely abundant; readers can check, e.g., the textbook [50].

Image reconstruction is computed tomography. The concentration of an isotope in a part of the body provides an image characterizing metabolic functions and local blood flow [21, 62]. In emission computed tomography (ECT), a radioactive drug is introduced in a region of the body and the emitted photons are recorded around it. Data are formed by the number of photons $v[i] \geq 0$ reaching each detector, $i = 1, \dots, q$. The observed photon counts v have a Poissonian distribution [21, 90]. Their mean is determined using projection operators $\{a_i, i = 1, 2, \dots, q\}$ and a constant $\rho > 0$. The data-fidelity Ψ derived from the log-likelihood function is nonstrictly convex and reads:

$$\Psi(u, v) = \rho \left\langle \sum_{i=1}^q a_i, u \right\rangle - \sum_{i=1}^q v[i] \ln (\langle a_i, u \rangle). \quad (28)$$

Figure 11 presents image reconstruction from simulated ECT data by minimizing and energy of the forms (21) and (22) where Ψ is given by (28) and $\{D_i\}$ yield the first-order differences between each pixel and its eight nearest neighbors. One observes, yet again, that a PF ϕ which is nonconvex with $\phi'(0^+) > 0$ leads to a nicely segmented piecewise constant reconstruction.

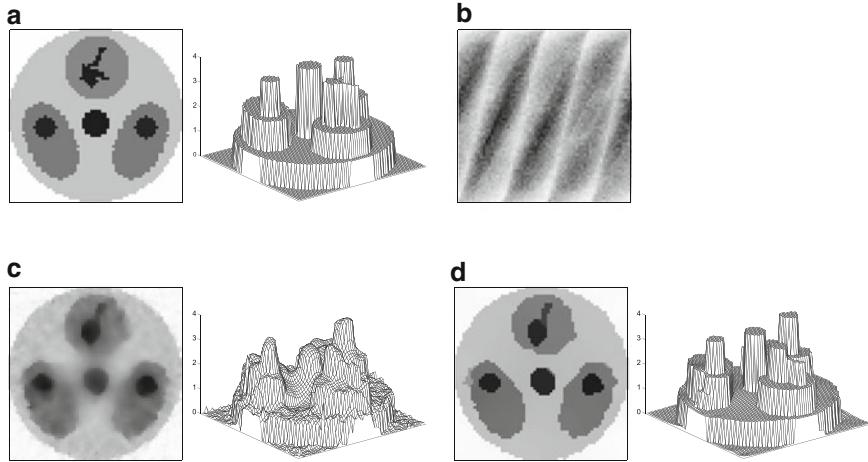

Fig. 11 ECT. $\mathcal{F}(u, v) = \Psi(u, v) + \beta \sum_{i \in I} \phi(|D_i u|)$. (a) Original phantom. (b) ECT simulated data. (c) $\phi'(0) = 0$, edge preserving. (d) $\phi(t) = t/(\alpha + t)$ ($\phi'(0^+) > 0$, nonconvex)

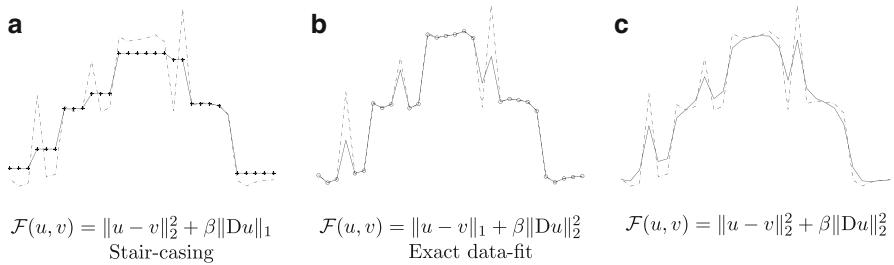

Fig. 12 D is a first-order difference operator, i.e., $D_i u = u[i] - u[i+1]$, $1 \leq i \leq p-1$. Data (- - -), restored signal (—). Constant pieces in (a) are emphasized using “*,” while data samples that are equal to the relevant samples of the minimizer in (b) are emphasized using “o”

6 Nonsmooth Data Fidelity

- Figure 12 shows that there is a striking distinction in the behavior of the minimizers relevant to nonsmooth data-fidelity terms (b) with respect to nonsmooth regularization (a). More precisely, many data samples are *fitted exactly* when the data-fidelity term is nonsmooth. This particular behavior is explained and generalized in the present section.

Consider

$$\mathcal{F}(u, v) = \Psi(u, v) + \beta \Phi(u), \quad (29)$$

$$\Psi(u, v) = \sum_{i=1}^q \psi(|\langle a_i, u \rangle - v[i]|), \quad (30)$$

where $a_i \in \mathbb{R}^p$ for all $i \in \{1, \dots, q\}$ and $\psi : \mathbb{R}_+ \rightarrow \mathbb{R}_+$ is a function satisfying

H12 ψ is C^m , $m \geq 2$ on \mathbb{R}_+^* and $\psi'(0^+) > 0$ is finite.

By this condition, $t \mapsto \psi(|t|)$ is continuous on \mathbb{R} . Let $A \in \mathbb{R}^{q \times p}$ denote the matrix such that for any $i = 1, \dots, q$, its i th row reads a_i^* .

Nonsmooth data-fidelity terms Ψ in energies of the form (29) and (30) were introduced in *image processing* in 2001 [77].

General Results

Here we present some results on the minimizers \hat{u} of \mathcal{F} as given in (29) and (30), where Ψ is *nondifferentiable*, obtained in [78, 79]. An additional assumption is that

H13 The regularization term $\Phi : \mathbb{R}^p \rightarrow \mathbb{R}$ in (29) is C^m , $m \geq 2$.

Note that Φ in (29) can be convex or nonconvex. To analyze the observation in Fig. 12b, the following set-valued function \mathcal{J} will be useful:

$$(u, v) \in (\mathbb{R}^p \times \mathbb{R}^q) \mapsto \mathcal{J}(u, v) = \left\{ i \in \{1, \dots, q\} : \langle a_i, u \rangle = v[i] \right\}. \quad (31)$$

Given v and a (local) minimizer \hat{u} of $\mathcal{F}(\cdot, v)$, the set of all data entries $v[i]$ that are fitted exactly by $(A\hat{u})[i]$ reads $\hat{J} = \mathcal{J}(\hat{u}, v)$. Its complement is $\hat{J}^c = \{1, \dots, q\} \setminus \hat{J}$.

Theorem 11. Let \mathcal{F} be of the form (29)–(30) where assumptions H12 and H13 hold. Given $v \in \mathbb{R}^q$, let $\hat{u} \in \mathbb{R}^p$ be a (local) minimizer of $\mathcal{F}(\cdot, v)$. For $\hat{J} = \mathcal{J}(\hat{u}, v)$, where \mathcal{J} is defined according to (31), let

$$\mathcal{K}_{\hat{J}}(v) = \{u \in \mathbb{R}^p : \langle a_i, u \rangle = v[i] \forall i \in \hat{J} \text{ and } \langle a_i, u \rangle \neq v[i] \forall i \in \hat{J}^c\},$$

and let $K_{\hat{J}}$ be its tangent. Suppose the following:

1. The set $\{a_i : i \in \hat{J}\}$ is linearly independent.
2. $\forall w \in K_{\hat{J}} \setminus \{0\}$ we have $D_1(\mathcal{F}|_{\overline{\mathcal{K}_{\hat{J}}(v)}})(\hat{u}, v)w = 0$ and $D_1^2(\mathcal{F}|_{\overline{\mathcal{K}_{\hat{J}}(v)}})(\hat{u}, v)(w, w) > 0$.
3. $\forall w \in K_{\hat{J}}^\perp \setminus \{0\}$ we have $\delta_1 \mathcal{F}(\hat{u}, v)(w) > 0$.

Then there are a neighborhood $O_{\hat{J}} \subset \mathbb{R}^q$ containing v and a C^{m-1} local minimizer function $\mathcal{U} : O_{\hat{J}} \rightarrow \mathbb{R}^p$ relevant to $\mathcal{F}(\cdot, O_{\hat{J}})$, yielding in particular $\hat{u} = \mathcal{U}(v)$, and

$$v \in O_{\hat{J}} \Rightarrow \begin{cases} \langle a_i, \mathcal{U}(v) \rangle = v[i] \text{ if } i \in \hat{J}, \\ \langle a_i, \mathcal{U}(v) \rangle \neq v[i] \text{ if } i \in \hat{J}^c. \end{cases} \quad (32)$$

The result in (32) means that $\mathcal{J}(\mathcal{U}(v), v) = \hat{J}$ is constant on $O_{\hat{J}}$.

Note that for every v and $J \neq \emptyset$, the set $\mathcal{K}_J(v)$ is a finite union of connected components, whereas its closure $\overline{\mathcal{K}_J(v)}$ is an affine subspace. Its tangent $K_{\hat{J}}$ reads

$$K_{\hat{J}} = \{u \in \mathbb{R}^p : \langle a_i, u \rangle = 0 \ \forall i \in \hat{J}\}.$$

A comparison with $K_{\hat{J}}$ in (24) may be instructive. Compare also (b) and (c) in Theorem 11 with (a) and (b) in Theorem 10. By the way, conditions (b) and (c) in Theorem 11 ensure that $\mathcal{F}(\cdot, v)$ reaches a strict minimum at \hat{u} [78, Proposition 1]. Observe that this sufficient condition for strict minimum involves the behavior of $\mathcal{F}(\cdot, v)$ on two orthogonal subspaces separately. This occurs because of the nonsmoothness of $t \mapsto \psi(|t|)$ at zero. It can be useful to note that at a minimizer \hat{u} ,

$$\begin{aligned} \delta_1 \mathcal{F}(\hat{u}, v)(w) &= \phi'(0^+) \sum_{i \in \hat{J}} |\langle a_i, w \rangle| + \sum_{i \in \hat{J}^c} \psi'(\langle a_i, \hat{u} \rangle - v[i]) \langle a_i, w \rangle \\ &\quad + \beta D\Phi(\hat{u})w \geq 0, \text{ for any } w \in \mathbb{R}^p \end{aligned} \quad (33)$$

Commentary on the assumptions. Assumption (a) does not require the independence of the whole set $\{a_i : i \in \{1, \dots, q\}\}$. It is easy to check that this assumption fails to hold only for some v is included in a subspace of dimension strictly smaller than q . Hence, assumption (a) is satisfied for almost all $v \in \mathbb{R}^q$ and the theorem addresses *any matrix A*, whether it be singular or invertible.

Assumption (b) is the classical sufficient condition for a strict local minimum of a smooth function over an affine subspace; see Lemma 1 (section ‘‘Reminders and Definitions’’). If an arbitrary function $\mathcal{F}(\cdot, v) : \mathbb{R}^p \rightarrow \mathbb{R}$ has a minimum at \hat{u} , then necessarily $\delta_1 \mathcal{F}(\hat{u}, v)(w) \geq 0$ for all $w \in K_{\hat{J}}^\perp$; see Theorem 1. In comparison, (c) requires only that the latter inequality be strict.

It will be interesting to characterize the sets of data v for which (b) and (c) may fail at some (local) minimizers. Some ideas from section ‘‘Local Minimizers’’ can provide a starting point.

Corollary 2. *Let \mathcal{F} be of the form (29)–(30) where $p = q$, and H12 and H13 hold true. Given $v \in \mathbb{R}^q$, let $\hat{u} \in \mathbb{R}^p$ be a (local) minimizer of $\mathcal{F}(\cdot, v)$. Suppose the following:*

- (a) *The set $\{a_i : 1 \leq i \leq q\}$ is linearly independent.*
- (b) *$\forall w \in \mathbb{R}^q$ satisfying $\|w\|_2 = 1$ we have $\beta |D\Phi(\hat{u})w| < \psi'(0^+) \sum_{i=1}^q |\langle a_i, w \rangle|$.*

Then

$$\hat{J} = \{1, \dots, q\}$$

and there are a neighborhood $O_{\hat{J}} \subset \mathbb{R}^q$ containing v and a \mathcal{C}^{m-1} local minimizer function $\mathcal{U} : O_{\hat{J}} \rightarrow \mathbb{R}^p$ relevant to $\mathcal{F}(\cdot, O_{\hat{J}})$, yielding in particular $\hat{u} = \mathcal{U}(v)$, and

$$v \in O_{\hat{J}} \Rightarrow \langle a_i, \mathcal{U}(v) \rangle = v[i] \quad \forall i \in \hat{J} = \{1, \dots, q\}. \quad (34)$$

More precisely, $\mathcal{U}(v) = A^{-1}v$ for any $v \in O_{\hat{J}}$.

In the context of Corollary 2, A is invertible. Combining this with (33) and (b) shows that

$$\begin{aligned} \mathcal{K}_{\hat{J}}(v) &= \{u \in \mathbb{R}^p : Au = v\} = A^{-1}v, \\ K_{\hat{J}} &= \ker(A) = \{0\}. \end{aligned}$$

Then

$$\begin{aligned} &\left\{ v \in \mathbb{R}^q : \beta |D\Phi(A^{-1}v)w| < \psi'(0^+) \sum_{i=1}^q |\langle a_i, w \rangle|, \forall w \in \mathbb{R}^q \setminus \{0\}, \|w\|_2 = 1 \right\} \\ &\subset O_{\hat{J}} \equiv O_{\{1, \dots, q\}}. \end{aligned}$$

The subset on the left contains an open subset of \mathbb{R}^q by the continuity of $v \mapsto D\Phi(A^{-1}v)$ combined with (b).

Significance of the results. Consider that $\#J \geq 1$. The result in (32) means that the set-valued function $v \rightarrow \mathcal{J}(\mathcal{U}(v), v)$ is constant on $O_{\hat{J}}$, i.e., that \mathcal{J} is constant under small perturbations of v . Equivalently, all residuals $\langle a_i, \mathcal{U}(v) \rangle - v[i]$ for $i \in \hat{J}$ are null on $O_{\hat{J}}$.

Theorem 11 shows that \mathbb{R}^q contains *volumes of positive measure* composed of data that lead to local minimizers which fit exactly the data entries belonging to the same set. In general, there are volumes corresponding to various \hat{J} so that noisy data come across them. That is why *nonsmooth data-fidelity terms generically yield minimizers fitting exactly a certain number of the data entries*. The resultant numerical effect is observed in Fig. 12b as well as in Figs. 14 and 15.

Remark 3 (Stability of Minimizers). The fact that there is a C^{m-1} local minimizer function shows that, in spite of the nonsmoothness of \mathcal{F} , for any v , all local minimizers of $\mathcal{F}(\cdot, v)$ which satisfy the conditions of the theorem are *stable under weak perturbations of data v* . This result extends Lemma 1.

Example 6. Let \mathcal{F} read

$$\mathcal{F}(u, v) = \sum_{i=1}^q |u[i] - v[i]| + \frac{\beta}{2} \sum_{i=1}^q (u[i])^2, \quad \beta > 0.$$

It is easy to see that there is a unique local minimizer function \mathcal{U} which is given by

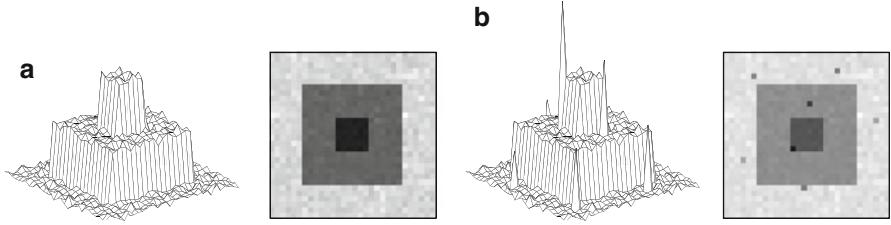

Fig. 13 Original u_o and data v degraded by outliers. **(a)** Original u_o . **(b)** Data $v = u \cdot$ outliers

$$\mathcal{U}(v)[i] = \frac{1}{\beta} \text{sign}(v[i]) \quad \text{if} \quad |v[i]| > \frac{1}{\beta},$$

$$\mathcal{U}(v)[i] = v[i] \quad \text{if} \quad |v[i]| \leq \frac{1}{\beta}.$$

Condition (c) in Theorem 11 fails to hold only for $\left\{v \in \mathbb{R}^q : |v[i]| = \frac{1}{\beta}, \forall i \in \hat{J}\right\}$. This set is of Lebesgue measure zero in \mathbb{R}^q . For any $J \in \{1, \dots, q\}$ put

$$O_J = \left\{v \in \mathbb{R}^q : |v[i]| \leq \frac{1}{\beta}, \forall i \in J \quad \text{and} \quad |v[i]| > \frac{1}{\beta}, \forall i \in J^c\right\}.$$

Obviously, every $v \in O_J$ gives rise to a minimizer \hat{u} satisfying

$$\hat{u}[i] = v[i], \quad \forall i \in J \quad \text{and} \quad \hat{u}[i] \neq v[i], \quad \forall i \in J^c.$$

Each set O_J has a positive Lebesgue measure in \mathbb{R}^q . Moreover, the union of all O_J when J ranges on all subsets $J \subset \{1, \dots, q\}$ (including the empty set) forms a partition of \mathbb{R}^q .

Numerical experiment. The original image u_o is shown in Fig. 13a. Data v in Fig. 13b are obtained by replacing some pixels of u_o by aberrant impulsions, called *outliers*.

In all Figs. 14–17, $\{D_i\}$ correspond to the first-order differences between each pixel and its four nearest neighbors. Figure 14a corresponds to an ℓ_1 data-fidelity term for $\beta = 0.14$. The outliers are well visible although their amplitudes are clearly reduced. The image of the residuals $v - \hat{u}$, shown in Fig. 14b, is null everywhere except at the positions of the outliers in v . The pixels corresponding to nonzero residuals (i.e., the elements of \hat{J}^c) provide a good estimate of the locations of the outliers in v . Figure 15a shows a minimizer \hat{u} of the same $\mathcal{F}(\cdot, v)$ obtained for $\beta = 0.25$. This minimizer does not contain visible outliers and is very close to the original image u_o . The image of the residuals $v - \hat{u}$ in Fig. 15b is null only on restricted areas but has a very small magnitude everywhere beyond the outliers.

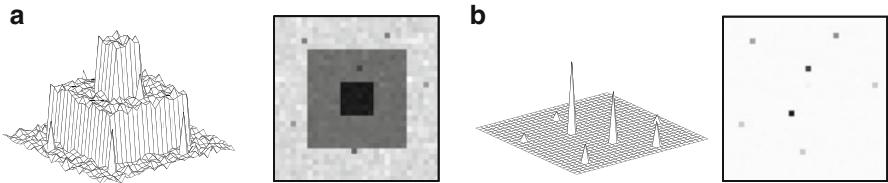

Fig. 14 Restoration using $\mathcal{F}(u, v) = \sum_i |u[i] - v[i]| + \beta \sum_{i \in I} |\mathbf{D}_i u|^\alpha$ $\alpha = 1.1$ and $\beta = 0.14$. **(a)** Restoration \hat{u} for $\beta = 0.14$. **(b)** Residual $v - \hat{u}$

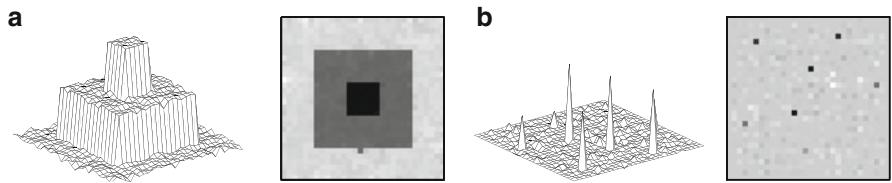

Fig. 15 Restoration using $\mathcal{F}(u, v) = \sum_i |u[i] - v[i]| + \beta \sum_{i \in I} |\mathbf{D}_i u|^\alpha$ for $\alpha = 1.1$ and $\beta = 0.25$. **(a)** Restoration \hat{u} for $\beta = 0.25$. **(b)** Residual $v - \hat{u}$

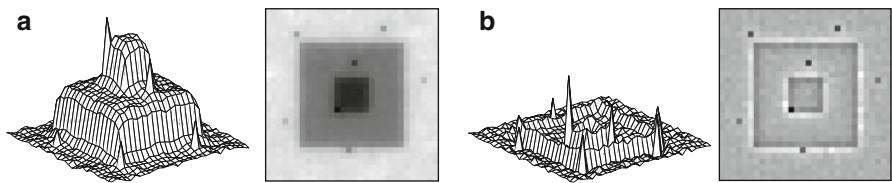

Fig. 16 Restoration using a smooth energy, $\mathcal{F}(u, v) = \sum_i (u[i] - v[i])^2 + \beta \sum_i (|\mathbf{D}_i u|)^2$, $\beta = 0.2$. **(a)** Restoration \hat{u} for $\beta = 0.2$. **(b)** Residual $v - \hat{u}$

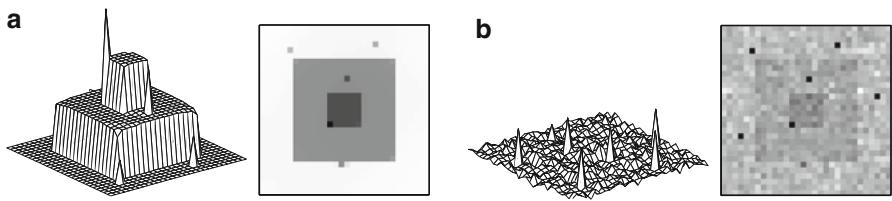

Fig. 17 Restoration using nonsmooth regularization $\mathcal{F}(u, v) = \sum_i (u[i] - v[i])^2 + \beta \sum_i |\mathbf{D}_i u|$, $\beta = 0.2$. **(a)** Restoration \hat{u} for $\beta = 0.2$. **(b)** Residual $v - \hat{u}$

The minimizers of two different cost-functions \mathcal{F} involving a *smooth* data-fidelity term Ψ , shown in Figs. 16 and 17, do not fit any data entry. In particular, the restoration in Fig. 17 corresponds to a nonsmooth regularization and it is constant over large regions; this effect was explained in Sect. 5.

Applications

The possibility to keep some data samples unchanged by using nonsmooth data fidelity is a precious property in various application fields. Nonsmooth data fidelities are good to detect and smooth outliers. This property was exploited for deblurring under impulse noise contamination; see, e.g., [10–12].

Denoising of frame coefficients. Consider the recovery of an original (unknown) $u_o \in \mathbb{R}^p$ – a signal or an image containing smooth zones and edges – from noisy data

$$v = u_o + n,$$

where n represents a perturbation. As discussed in Sect. 4, a systematic default of the images and signals restored using convex edge-preserving PFs ϕ is that the amplitude of edges is underestimated.

Shrinkage estimators operate on a decomposition of data v into a frame of ℓ^2 , say $\{w_i : i \in J\}$ where J is a set of indexes. Let W be the corresponding frame operator, i.e., $(Wv)[i] = \langle v, w_i \rangle$, $\forall i \in J$, and \tilde{W} be a left inverse of W , giving rise to the dual frame $\{\tilde{w}_i : i \in J\}$. The frame coefficients of v read $y = Wv$ and are contaminated with noise Wn . The inaugural work of Donoho and Johnstone [40] considers two different shrinkage estimators: given $T > 0$, *hard thresholding* corresponds to

$$y_T[i] = \begin{cases} y[i] & \text{if } i \in J_1, \\ 0 & \text{if } i \in J_0, \end{cases} \quad \text{where} \quad \begin{cases} J_0 = \{i \in J : |y[i]| \leq T\}; \\ J_1 = J \setminus J_0, \end{cases} \quad (35)$$

while in soft thresholding one takes $y_T[i] = y[i] - T \text{sign}(y[i])$ if $i \in J_1$ and $y_T[i] = 0$ if $i \in J_0$. Both soft and hard thresholding are asymptotically optimal in the minimax sense if n is white Gaussian noise of standard deviation σ and

$$T = \sigma \sqrt{2 \log_e p}. \quad (36)$$

This threshold is difficult to use in practice because it increases with the size of u . Numerous improvements were realized; see, e.g., [4, 13, 24, 34, 38, 66, 70]. In all cases, the main problem is that smoothing large coefficients oversmooths edges, while thresholding small coefficients can generate Gibbs-like oscillations near edges; see Fig. 18c, d. If shrinkage is weak, noisy coefficients (outliers) remain almost unchanged and produce artifacts having the shape of $\{\tilde{w}_i\}$; see Fig. 18c–e.

In order to alleviate these difficulties, several authors proposed *hybrid methods* where the information contained in important coefficients $y[i]$ is combined with priors in the domain of the sought-after signal or image [18, 25, 36, 43, 67]. A critical analysis was presented in [46].

A specialized hybrid method involving ℓ_1 data fidelity on frame coefficients is proposed in [46]. Data are initially hard thresholded – see (35) – using a *suboptimal*

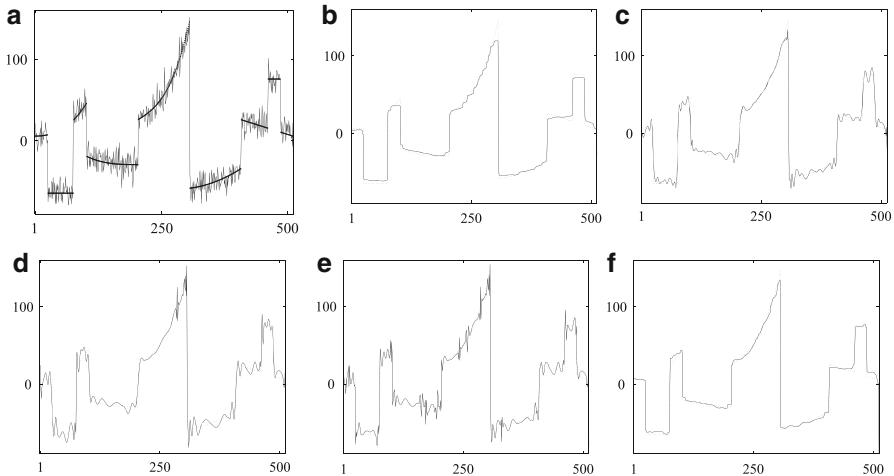

Fig. 18 Methods to restore the noisy signal in (a). Restored signal (—), original signal (---). (a) Original and data corrupted with white Gaussian noise. (b) TV regularization. (c) Sure-shrink. (d) $T = 35$ optimal, $\hat{u}_T = \sum_i y_T[i] \tilde{w}_i$. (e) y_T , $T = 23$, $\hat{u}_T = \sum_i y_T[i] \tilde{w}_i$. (f) The proposed method

threshold T in order to keep as much as possible information. (The use of another shrinkage estimator would alter all coefficients, which is not desired.) Then

1. J_1 is composed of:

- Large coefficients bearing the main features of u_o that one wishes to preserve intact
- Aberrant coefficients (outliers) that must be restored using the regularization term

2. J_0 is composed of:

- Noise coefficients that must be kept null.
- Coefficients $y[i]$ corresponding to edges and other details in u_o – these need to be restored in accordance with the prior incorporated in the regularization term.

In order to reach the goals formulated in 1 and 2 above, denoised coefficients \hat{x} are defined as a minimizer of the hybrid energy $F(., y)$ given below:

$$F(x, y) = \lambda_1 \sum_{i \in J_1} |x[i] - y[i]| + \lambda_0 \sum_{i \in J_0} |x[i]| + \sum_{i \in I} \phi(\|\mathbf{D}_i \tilde{W} x\|_2), \quad \lambda_{0,1} > 0, \quad (37)$$

where ϕ is convex and edge preserving. Then the sought-after denoised image or signal is

$$\hat{u} = \tilde{W}\hat{x} = \sum_{i \in J} \tilde{w}_i \hat{x}[i].$$

Several properties relevant to the minimizers of F in (37), the parameters $\lambda_i, i \in \{0, 1\}$, and the solution \hat{u} are outlined in [46].

Noisy data v are shown along with the original u_o in Fig. 18a. The restoration in Fig. 18b minimizes $\mathcal{F}(u) = \|Au - v\|_2^2 + \beta TV$ – homogeneous regions remain noisy, edges are smoothed, and spikes are eroded. Figure 18c is obtained using the *sure-shrink* method [41] from the toolbox WaveLab. The other restorations use thresholded Daubechies wavelet coefficients with eight vanishing moments. The optimal value for the hard thresholding obtained using (36) is $T = 35$. The relevant restoration – Fig. 18d – exhibits important Gibbs-like oscillations as well as wavelet-shaped artifacts. For $T = 23$ the coefficients have a richer information content, but $\tilde{W}y_T$, shown in Fig. 18e, manifests Gibbs artifacts and many wavelet-shaped artifacts. Introducing the thresholded coefficients of Fig. 18e in the specialized energy F in (37) leads to Fig. 18f: edges are clean and piecewise polynomial parts are well recovered.

7 Nonsmooth Data Fidelity and Regularization

The L_1 -TV Case

For discrete signals of finite length, energies of the form $\mathcal{F}(u, v) = \|u - v\|_1 + \beta \sum_{i=1}^{p-1} |u[i+1] - u[i]|$ were considered by Alliney in 1992 [1].

Following [1, 78, 79], S. Esedoglu and T. Chan explored in [28] the minimizers of the L_1 -TV functional given below

$$\mathcal{F}(u, v) = \int_{\mathbb{R}^d} |u(x) - v(x)| dx + \beta \int_{\mathbb{R}^d} |\nabla u(x)| dx, \quad (38)$$

where the sought-after minimizer \hat{u} belongs to the space of bounded variation functions on \mathbb{R}^d . The main focus is on images, i.e., $d = 2$. The analysis in [28] is based on a representation of \mathcal{F} in (38) in terms of the level sets of u and v . Most of the results are established for data v given by the characteristic function χ_Σ of a bounded domain $\Sigma \subset \mathbb{R}^d$. Theorem 5.2 in [28] says that if $v = \chi_\Sigma$, where $\Sigma \subset \mathbb{R}^d$ is bounded, then $\mathcal{F}(\cdot, v)$ admits a minimizer of the form $\hat{u} = \chi_{\hat{\Sigma}}$ (with possibly $\hat{\Sigma} \neq \Sigma$). Furthermore, Corollary 5.3. in [28] states that if in addition Σ is convex, then for almost every $\beta \geq 0$, $\mathcal{F}(\cdot, v)$ admits a unique minimizer and $\hat{u} = \chi_{\hat{\Sigma}}$ with $\hat{\Sigma} \subseteq \Sigma$. Moreover, it is shown that small features in the image maintain their contrast intact up to some value of β , while for a larger β they suddenly disappear.

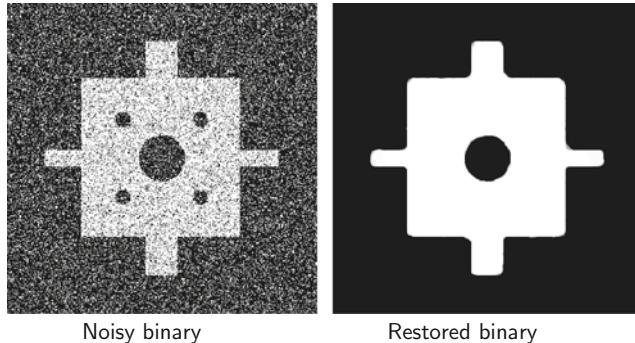

Fig. 19 Restoration of a binary noisy image by minimizing L_1 -TV

Denoising of Binary Images and Convex Relaxation

Many problems such as text denoising and document processing, two-phase image segmentation, shape restoration, and fairing of surfaces in computer graphics are naturally stated as the minimization of an energy over the set of the binary images. These energies are obviously nonconvex since the constraint set is finite. Their global minimizer was shown in [29] to be also the minimizer of the convex L_1 -TV functional which is convex. This result yielded much simpler algorithms for binary image restoration. An illustration is given on Fig. 19.

Since then, L_1 -TV relaxations have became a common tool for convex relaxations; see, e.g., among many others [84] and the references therein.

Also, L_1 -TV energies were revealed very successful in image decomposition; see, e.g., [8, 48].

Multiplicative Noise Removal

In various active imaging systems, such as synthetic aperture radar (SAR), laser, or ultrasound imaging, the data representing the underlying (unknown image) S_0 are corrupted with multiplicative noise. Such a noise is a severe degradation; see Fig. 20. When possible, a few independent measurements for the same scene are realized, $\Sigma_k = S_0 \eta_k$ for $k \in \{1, \dots, K\}$, where the noise η_k is typically modeled by the one-sided exponential distribution. The data Σ used for denoising is the average of the set of all K measurements:

$$\Sigma = \frac{1}{K} \sum_{k=1}^K \Sigma_k = S_0 \eta. \quad (39)$$

The combined multiplicative noise follows a Gamma distribution. Adaptive filtering works only if the noise is weak. For strong noise, variational methods often use TV

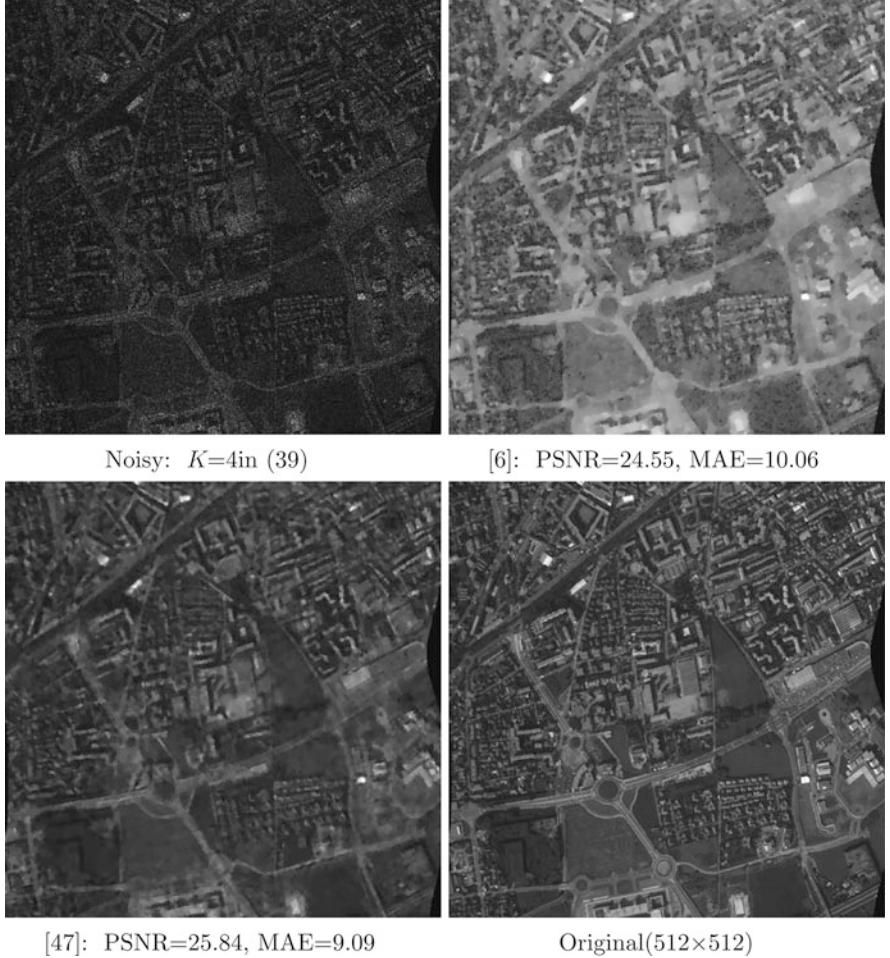

Fig. 20 Aerial image of the town of Nîmes (512×512) for $K = 4$ in (39). Restorations using different methods. Parameters: [6] for $\rho = 120$; [47] $T = 2\sqrt{\psi_1(K)}$, $\lambda_0 = 1.5$, $\lambda_1 = 10$

regularization. In [6] the log-likelihood of the raw data (39) is regularized using TV. Instead, the properties of L_1 -TV are used to design an energy in [47]. First, the log-data $v = \log \Sigma$ is decomposed into a curvelet transform yielding noisy coefficients $y = Wv$. A suboptimal hard thresholding is applied for T adapted to the expectation of the log noise. Let $I_0 = \{i : |y[i]| \leq T\}$ and $I_1 = \{i : |y[i]| > T\}$. Since the threshold is low, I_1 contains outliers. Coefficients \hat{x} are restored by minimizing

$$F(x) = \lambda_1 \sum_{i \in I_1} |(x - y)[i]| + \lambda_0 \sum_{i \in I_0} |x[i]| + \text{TV}(x).$$

The restored image \hat{S} , shown in Fig. 20, is obtained as $\hat{S} = \exp(\tilde{W}(\hat{x})) B$ where \tilde{W} is a left inverse of W and B is a bias correction.

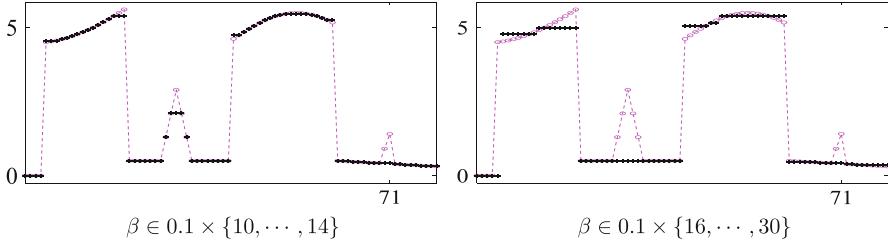

Fig. 21 Minimizers of $\mathcal{F}(\cdot, v)$ as given in (40) for $\phi(t) = \ln(\alpha t + 1)$, $\alpha = 2$ and different values of β . Data samples (○ ○ ○), minimizer samples $\hat{u}[i]$ (+ + +)

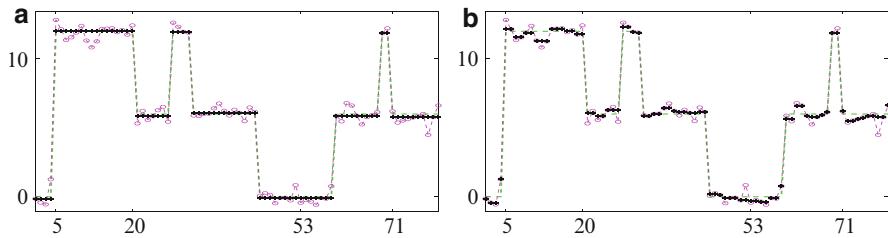

Fig. 22 Minimizers of $\mathcal{F}(\cdot, v)$ as given in (40) for different PFs ϕ . Data are corrupted with Gaussian noise. Data samples $v[i]$ are marked with (○ ○ ○), samples $\hat{u}[i]$ of the minimizer – with (+ + +). The original signal is reminded in (— — —). (a) $\phi(t) = \frac{\alpha t}{\alpha t + 1}$, $\alpha = 4$, $\beta = 3$. (b) $\phi(t) = t$, $\beta = 0.8$

ℓ_1 Data Fidelity with Regularization Concave on \mathbb{R}_+

One could expect that ℓ_1 data fidelity regularized with a PF concave on \mathbb{R}_+ should somehow reinforce the properties of ℓ_1 – TV. The question was recently examined in [83]. Consider the energy

$$\mathcal{F}(u, v) = \sum_{i \in I} |\langle a_i, u \rangle - v[i]| + \beta \sum_{j \in J} \phi(|D_i u|) \quad (40)$$

$$\text{for } I \stackrel{\text{def}}{=} \{1, \dots, q\} \quad \text{and} \quad J \stackrel{\text{def}}{=} \{1, \dots, r\}$$

where $\phi : \mathbb{R}_+ \rightarrow \mathbb{R}_+$ is continuous and concave on \mathbb{R}_+ (e.g., (f10), (f11), and (f12) in Table 1).

Motivation

Figures 21 and 22 depict (the global) minimizers of $\mathcal{F}(u, v)$ in (40) for a one-dimensional signal where $A = \text{Id}$, $\{D_i\}$ are first-order differences, and ϕ is smooth and concave on \mathbb{R}_+ .

The tests in Figs. 21 and 22 show that a PF concave on \mathbb{R}_+ considerably reinforces the properties of ℓ_1 – TV. One observes that the minimizer satisfies *exactly*

part of the data term and part of the prior term (corresponding to constant pieces). In Fig. 22b, the previous $\ell_1 - \text{TV}$ model is considered. Figure 21 shows also that the minimizer remains unchanged for some range of values of β and that after a threshold value, it is simplified.

Example 7 below furnishes a first intuition on the reasons underlying the phenomena observed in Figs. 21 and 22.

Example 7. Given $v \in \mathbb{R}$, consider the function $\mathcal{F}(\cdot, v) : \mathbb{R} \rightarrow \mathbb{R}$ given below

$$\mathcal{F}(u, v) = |u - v| + \beta\phi(|u|) \text{ for } \phi \text{ obeying H .} \quad (41)$$

The necessary conditions for $\mathcal{F}(\cdot, v)$ to have a (local) minimum at $\hat{u} \neq 0$ and $\hat{u} \neq v$ – that its first differential meets $D_1\mathcal{F}(\hat{u}, v) = 0$ and that its second differential obeys $D_1^2\mathcal{F}(\hat{u}, v) \geq 0$ – do not hold:

$$\hat{u} \notin \{0, v\} \Rightarrow \begin{cases} D_1\mathcal{F}(\hat{u}, v) = \text{sign}(\hat{u} - v) + \beta\varphi'(|\hat{u}|)\text{sign}(\hat{u}) = 0 , \\ D_1^2\mathcal{F}(\hat{u}, v) = \beta\varphi''(|\hat{u}|) < 0 , \end{cases}$$

where the last inequality comes from the strict concavity of ϕ on \mathbb{R}_+^* . Hence, $\mathcal{F}(\cdot, v)$ cannot have a minimizer such that $\hat{u} \neq 0$ and $\hat{u} \neq v$, for any $v \in \mathbb{R}$. Being coercive, $\mathcal{F}(\cdot, v)$ does have minimizers. Consequently, any (local) minimizer of \mathcal{F} in (41) satisfies

$$\hat{u} \in \{0, v\} .$$

Main Theoretical Results

The PFs considered here are concave on \mathbb{R}_+ and smooth on \mathbb{R}_+^* . More precisely, they satisfy H1 (Sect. 1), H8, and H10 (section “Assumptions on Potential Functions ϕ ”). One can see Fig. 3, right, for an illustration of the assumptions.

Proposition 3. Let $\mathcal{F}(\cdot, v)$ read as in (40). Assume that H3 (Sect. 3) holds and that ϕ satisfies H1 (Sect. 1), H8, and H10. Then for any v , $\mathcal{F}(\cdot, v)$ has global minimizers.

Given $v \in \mathbb{R}^q$, with each $\hat{u} \in \mathbb{R}^p$ the following subsets are associated:

$$\begin{aligned} \hat{I}_0 &\stackrel{\text{def}}{=} \{i \in I \mid \langle a_i \hat{u} \rangle = v[i]\} \quad \text{and} \quad \hat{I}_0^c \stackrel{\text{def}}{=} I \setminus \hat{I}_0, \\ \hat{J}_0 &\stackrel{\text{def}}{=} \{i \in J \mid D_i \hat{u} = 0\} \quad \text{and} \quad \hat{J}_0^c \stackrel{\text{def}}{=} J \setminus \hat{J}_0 . \end{aligned} \quad (42)$$

Proposition 4. For $\mathcal{F}(\cdot, v)$ as in (40) satisfying H1, H8, and H10, let \hat{u} be a (local) minimizer of $\mathcal{F}(\cdot, v)$. Then

$$(\hat{I}_0 \cup \hat{J}_0) \neq \emptyset .$$

H14 The point $\hat{u} \in \mathbb{R}^p$ is such that $\hat{I}_0 \neq \emptyset$ and that

$$w \in \ker D \setminus \{0\} \Rightarrow \exists i \in \hat{I}_0 \text{ such that } \langle a_i, w \rangle \neq 0. \quad (43)$$

If $\text{rank } D = p$, then (43) is trivial. Anyway, (43) is not a strong requirement.

Theorem 12. Consider $\mathcal{F}(\cdot, v)$, as given in (40), satisfying H3, as well as H1, H8, and H10. Let \hat{u} be a (local) minimizer of $\mathcal{F}(\cdot, v)$ meeting $\hat{J}_0^c \neq \emptyset$ and H14. Then \hat{u} is the unique solution of the full column rank linear system given below

$$\begin{cases} \langle a_i, w \rangle = v[i] & \forall i \in \hat{I}_0, \\ D_j w = 0 & \forall j \in \hat{J}_0. \end{cases} \quad (44)$$

Significance of the Results

An immediate consequence of Theorem 12 is the following:

- Each (local) minimizer of $\mathcal{F}(\cdot, v)$ is strict.

Another consequence is that the matrix H with rows $(a_i^*, \forall i \in \hat{I}_0 \text{ and } D_j, \forall j \in \hat{J}_0)$ has *full column rank*. This provides a strong *necessary condition for a (local) minimizer* of $\mathcal{F}(\cdot, v)$. And since \hat{u} in (44) solves a linear system, it involves the same kind of “contrast invariance” as the $L_1 - \text{TV}$ model. A detailed inspection of the minimizers in Figs. 21 and 22 corroborate Theorem 12. A more practical interpretation of this result reads as follows:

- Each pixel of a (local) minimizer \hat{u} of $\mathcal{F}(\cdot, v)$ is involved in (at least) one data equation that is fitted exactly $\langle a_i, \hat{u} \rangle = v[i]$ or in (at least) one vanishing operator $D_j \hat{u} = 0$ or in both types of equations.

This remarkable property can be used in different ways.

Applications

An energy $\mathcal{F}(\cdot, v)$ of the form in (40) with a PF ϕ strictly concave on \mathbb{R}_+ is a good choice when

- There are some nearly faithful data points $v[i]$;
- The matrix D provides a very reliable prior on the sought-after solution.

A natural way for such a prior is to construct for D an application-dependent dictionary.

MR Image Reconstruction from Highly Undersampled Data

In the experiment in Fig. 23, only **5 % randomly** chosen noisy data samples in the k -space (i.e., individual noisy Fourier coefficients) are available; see (a). Data are

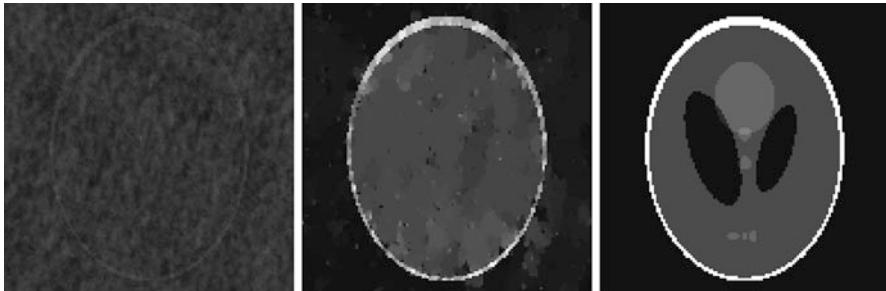

Fig. 23 Reconstructed images from 5 % noisy randomly selected samples in the k -space using different methods. (a) Zero-filling Fourier recovery. (b) $\ell_2 - \text{TV}$. (c) $\mathcal{F}(\cdot, v)$ in (40)

contaminated with $\text{SNR} = 37 \text{ dB}$ white centered *Gaussian noise*. This is a highly underdetermined, ill-posed inverse problem. It can be related to compressed sensing in MRI; see, e.g., [58]. The Shepp-Logan phantom being locally constant with oval shapes, the linear operators $\{D_i\}$ in (40) yield the usual discrete gradient of the image, so that the regularization term provides a correct prior. Indeed, D_{u_o} is the sparsest linear transform for this image. Clearly, A is the undersampled Fourier transform corresponding to the 5 % randomly chosen k -samples. For Gaussian noise, an ℓ_2 quadratic data fitting term is a classical choice. The $\ell_2 - \text{TV}$ cost-function $\|Au - v\|_2^2 + \beta \text{TV}(u)$ is the standard tool to solve this kind of problems. The result is shown in Fig. 23b.

8 Conclusion

This chapter provided some theoretical results relating the shape of the energy \mathcal{F} to minimize and the salient features of its minimizers \hat{u} (see (7), section “The Main Features of the Minimizers as a Function of the Energy”). These results can serve as a kind of *inverse modeling*: given an inverse problem along with our requirements (priors) on its solution, they guide us how to construct an energy functional whose minimizers properly incorporate all this information. The theoretical results are illustrated using numerical examples. Various application fields can take a benefit from these results. The problem of such an inverse modeling remains open because of the diversity of the inverse problems to solve and the possible energy functionals.

Abstract

Compressive sensing is a recent type of sampling theory, which predicts that sparse signals and images can be reconstructed from what was previously believed to be incomplete information. As a main feature, efficient algorithms such as ℓ_1 -minimization can be used for recovery. The theory has many potential applications in signal processing and imaging. This chapter gives an introduction and overview on both theoretical and numerical aspects of compressive sensing.

1 Introduction

The traditional approach of reconstructing signals or images from measured data follows the well-known Shannon sampling theorem [155], which states that the sampling rate must be twice the highest frequency. Similarly, the fundamental theorem of linear algebra suggests that the number of collected samples (measurements) of a discrete finite-dimensional signal should be at least as large as its length (its dimension) in order to ensure reconstruction. This principle underlies most devices of current technology, such as analog to digital conversion, medical imaging, or audio and video electronics. The novel theory of compressive sensing (CS) – also known under the terminology of compressed sensing, compressive sampling, or sparse recovery – provides a fundamentally new approach to data acquisition which overcomes this common wisdom. It predicts that certain signals or images can be recovered from what was previously believed to be highly incomplete measurements (information). This chapter gives an introduction to this new field. Both fundamental theoretical and algorithmic aspects are presented, with the awareness that it is impossible to retrace in a few pages all the current developments of this field, which was growing very rapidly in the past few years and undergoes significant advances on an almost daily basis.

CS relies on the empirical observation that many types of signals or images can be well approximated by a sparse expansion in terms of a suitable basis, that is, by only a small number of nonzero coefficients. This is the key to the efficiency of many lossy compression techniques such as JPEG, MP3, etc. A compression is obtained by simply storing only the largest basis coefficients. When reconstructing the signal, the non-stored coefficients are simply set to zero. This is certainly a reasonable strategy when full information of the signal is available. However, when the signal first has to be acquired by a somewhat costly, lengthy, or otherwise difficult

measurement (sensing) procedure, this seems to be a waste of resources: First, large efforts are spent in order to obtain full information on the signal, and afterwards most of the information is thrown away at the compression stage. One might ask whether there is a clever way of obtaining the compressed version of the signal more directly, by taking only a small number of measurements of the signal. It is not obvious at all whether this is possible since measuring directly the large coefficients requires to know *a priori* their location. Quite surprisingly, compressive sensing provides nevertheless a way of reconstructing a compressed version of the original signal by taking only a small amount of *linear* and *nonadaptive* measurements. The precise number of required measurements is comparable to the compressed size of the signal. Clearly, the measurements have to be suitably designed. It is a remarkable fact that all provably good measurement matrices designed so far are random matrices. It is for this reason that the theory of compressive sensing uses a lot of tools from probability theory.

It is another important feature of compressive sensing that practical reconstruction can be performed by using efficient algorithms. Since the interest is in the vastly undersampled case, the linear system describing the measurements is underdetermined and therefore has infinitely many solutions. The key idea is that the sparsity helps in isolating the original vector. The first naive approach to a reconstruction algorithm consists in searching for the sparsest vector that is consistent with the linear measurements. This leads to the combinatorial ℓ_0 -problem (see (4) below), which unfortunately is NP-hard in general. There are essentially two approaches for tractable alternative algorithms. The first is convex relaxation leading to ℓ_1 -minimization – also known as basis pursuit (see (5)) – while the second constructs greedy algorithms. This overview focuses on ℓ_1 -minimization. By now basic properties of the measurement matrix which ensure sparse recovery by ℓ_1 -minimization are known: the *null space property (NSP)* and the *restricted isometry property (RIP)*. The latter requires that all column submatrices of a certain size of the measurement matrix are well conditioned. This is where probabilistic methods come into play because it is quite hard to analyze these properties for deterministic matrices with minimal amount of measurements. Among the provably good measurement matrices are Gaussian, Bernoulli random matrices, and partial random Fourier matrices.

Figure 1 serves as a first illustration of the power of compressive sensing. It shows an example for recovery of a 10-sparse signal $x \in \mathbb{C}^{300}$ from only 30 samples (indicated by the red dots in Fig. 1b). From a first look at the time-domain signal, one would rather believe that reconstruction should be impossible from only 30 samples. Indeed, the spectrum reconstructed by traditional ℓ_2 -minimization is very different from the true spectrum. Quite surprisingly, ℓ_1 -minimization performs nevertheless an exact reconstruction, that is, with no recovery error at all!

An example from nuclear magnetic resonance imaging serves as a second illustration. Here, the device scans a patient by taking 2D or 3D frequency measurements within a radial geometry. Figure 2a describes such a sampling set of a 2D Fourier transform. Since a lengthy scanning procedure is very uncomfortable for the patient,

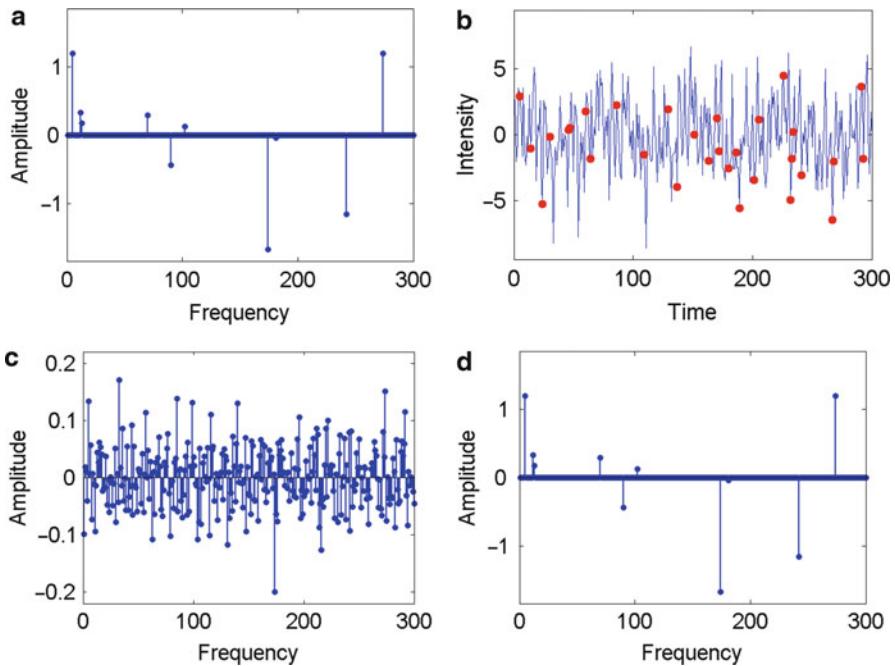

Fig. 1 (a) 10-sparse Fourier spectrum, (b) time-domain signal of length 300 with 30 samples, (c) reconstruction via ℓ_2 -minimization, (d) exact reconstruction via ℓ_1 -minimization

it is desired to take only a minimal amount of measurements. Total variation minimization, which is closely related to ℓ_1 -minimization, is then considered as recovery method. For comparison, Fig. 2b shows the recovery by a traditional back-projection algorithm. Figure 2c, d displays iterations of an algorithm, which was proposed and analyzed in [72] to perform efficient large-scale total variation minimization. The reconstruction in Fig. 2d is again exact!

2 Background

Although the term compressed sensing (compressive sensing) was coined only recently with the paper by Donoho [47], followed by a huge research activity, such a development did not start out of thin air. There were certain roots and predecessors in application areas such as image processing, geophysics, medical imaging, computer science, as well as in pure mathematics. An attempt is made to put such roots and current developments into context below, although only a partial overview can be given due to the numerous and diverse connections and developments.

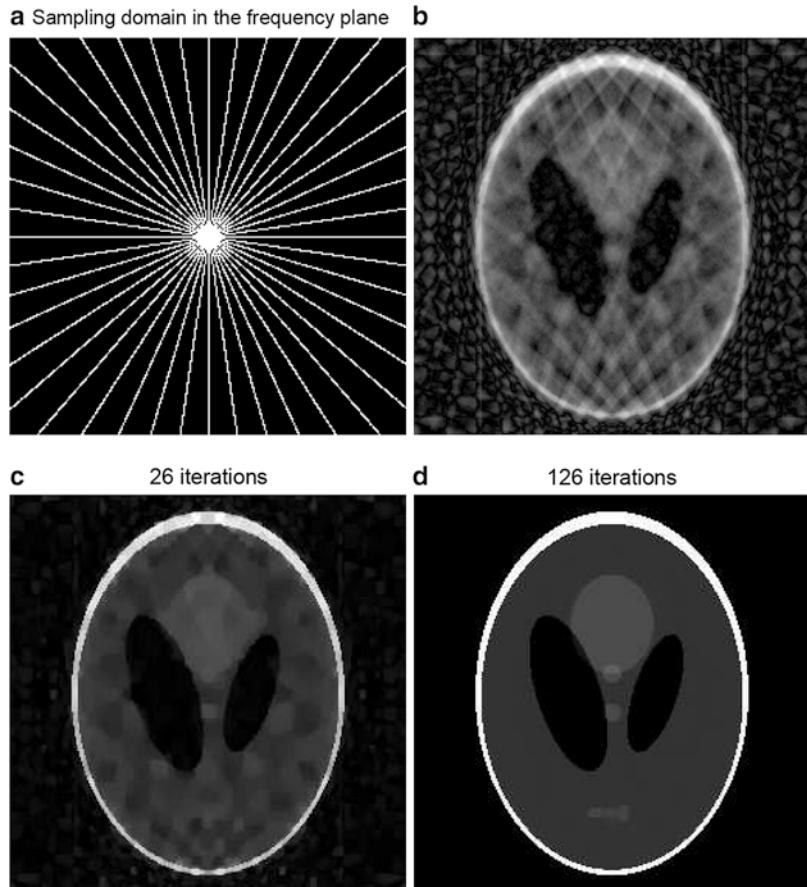

Fig. 2 (a) Sampling data of the NMR image in the Fourier domain which corresponds to only 0.11 % of all samples. (b) Reconstruction by back projection. (c) Intermediate iteration of an efficient algorithm for large-scale total variation minimization. (d) The final reconstruction is exact

Early Developments in Applications

Presumably the first algorithm which can be connected to sparse recovery is due to the French mathematician de Prony [127]. The so-called Prony method, which has found numerous applications [109], estimates nonzero amplitudes and corresponding frequencies of a sparse trigonometric polynomial from a small number of equispaced samples by solving an eigenvalue problem. The use of ℓ_1 -minimization appears already in the Ph.D. thesis of B. Logan [106] in connection with sparse frequency estimation, where he observed that L_1 -minimization may recover exactly a frequency-sparse signal from undersampled data provided the sparsity is small enough. The paper by Donoho and Logan [52] is perhaps the

earliest theoretical work on sparse recovery using L_1 -minimization. Nevertheless, geophysicists observed in the late 1970s and 1980s that ℓ_1 -minimization can be successfully employed in reflection seismology where a sparse reflection function indicating changes between subsurface layers is sought [140, 148]. In NMR spectroscopy the idea to recover sparse Fourier spectra from undersampled non-equispaced samples was first introduced in the 1990s [158] and has seen a significant development since then.

In image processing the use of total variation minimization, which is closely connected to ℓ_1 -minimization and compressive sensing, first appears in the 1990s in the work of Rudin, Osher, and Fatemi [139] and was widely applied later on. In statistics where the corresponding area is usually called *model selection*, the use of ℓ_1 -minimization and related methods was greatly popularized with the work of Tibshirani [149] on the so-called LASSO (Least Absolute Shrinkage and Selection Operator).

Sparse Approximation

Many lossy compression techniques such as JPEG, JPEG-2000, MPEG, or MP3 rely on the empirical observation that audio signals and digital images have a sparse representation in terms of a suitable basis. Roughly speaking one compresses the signal by simply keeping only the largest coefficients. In certain scenarios such as audio signal processing, one considers the generalized situation where sparsity appears in terms of a redundant system – a so-called dictionary or frame [36] – rather than a basis. The problem of finding the sparsest representation/approximation in terms of the given dictionary turns out to be significantly harder than in the case of sparsity with respect to a basis where the expansion coefficients are unique. Indeed, in [108, 114], it was shown that the general ℓ_0 -problem of finding the sparsest solution of an underdetermined system is NP-hard. Greedy strategies such as matching pursuit algorithms [108], FOCUSS [86] and ℓ_1 -minimization [35] were subsequently introduced as tractable alternatives. The theoretical understanding under which conditions greedy methods and ℓ_1 -minimization recover the sparsest solutions began to develop with the work in [50, 51, 62, 78, 81, 87, 151, 152].

Information-Based Complexity and Gelfand Widths

Information-based complexity (IBC) considers the general question of how well a function f belonging to a certain class \mathcal{F} can be recovered from n sample values or, more generally, the evaluation of n linear or nonlinear functionals applied to f [150]. The optimal recovery error which is defined as the maximal reconstruction error for the “best” sampling method and “best” recovery method (within a specified class of methods) over all functions in the class \mathcal{F} is closely related to the so-called *Gelfand width* of \mathcal{F} [38, 47, 117]. Of particular interest for compressive sensing is $\mathcal{F} = B_1^N$, the ℓ_1 -ball in \mathbb{R}^N since its elements can be well

approximated by sparse ones. A famous result due to Kashin [96] and Gluskin and Garnaev [79, 84] sharply bounds the Gelfand widths of B_1^N (as well as their duals, the *Kolmogorov widths*) from above and below; see also [77]. While the original interest of Kashin was in the estimate of n -widths of Sobolev classes, these results give precise performance bounds in compressive sensing on how well any method may recover (approximately) sparse vectors from linear measurements [38, 47]. The upper bounds on Gelfand widths were derived in [96] and [79] using (Bernoulli and Gaussian) random matrices (see also [107]), and in fact such type of matrices have become very useful also in compressive sensing [26, 47].

Compressive Sensing

The numerous developments in compressive sensing began with the seminal work [30, 47]. Although key ingredients were already in the air at that time, as mentioned above, the major contribution of these papers was to realize that one can combine the power of ℓ_1 -minimization and random matrices in order to show *optimal* results on the ability of ℓ_1 -minimization of recovering (approximately) sparse vectors. Moreover, the authors made very clear that such ideas have strong potential for numerous application areas. In their work [26, 30] Candès, Romberg, and Tao introduced the *restricted isometry property* (which they initially called the *uniform uncertainty principle*) which is a key property of compressive sensing matrices. It was shown that Gaussian, Bernoulli, and partial random Fourier matrices [26, 129, 138] possess this important property. These results require many tools from probability theory and finite-dimensional Banach space geometry, which have been developed for a rather long time now; see, e.g., [95, 103].

Donoho [49] developed a different path and approached the problem of characterizing sparse recovery by ℓ_1 -minimization via polytope geometry, more precisely, via the notion of k -neighborliness. In several papers sharp phase transition curves were shown for Gaussian random matrices separating regions where recovery fails or succeeds with high probability [49, 53, 54]. These results build on previous work in pure mathematics by Affentranger and Schneider [2] on randomly projected polytopes.

Developments in Computer Science

In computer science the related area is usually addressed as the *heavy hitters* detection or *sketching*. Here one is interested not only in recovering signals (such as huge data streams on the Internet) from vastly undersampled data, but one requires sublinear runtime in the signal length N of the recovery algorithm. This is no impossibility as one only has to report the locations and values of the nonzero (most significant) coefficients of the sparse vector. Quite remarkably sublinear algorithms are available for sparse Fourier recovery [80]. Such algorithms use ideas from *group testing* which date back to World War II, when Dorfman [56] invented an efficient method for detecting draftees with syphilis.

In sketching algorithms from computer science, one actually designs the matrix and the fast algorithm simultaneously [42, 82]. More recently, *bipartite expander graphs* have been successfully used in order to construct good compressed sensing matrices together with associated fast reconstruction algorithms [11].

3 Mathematical Modelling and Analysis

This section introduces the concept of sparsity and the recovery of sparse vectors from incomplete linear and nonadaptive measurements. In particular, an analysis of ℓ_1 -minimization as a recovery method is provided. The *null space property* and the *restricted isometry property* are introduced, and it is shown that they ensure robust sparse recovery. It is actually difficult to show these properties for deterministic matrices and the optimal number m of measurements, and the major breakthrough in compressive sensing results is obtained for random matrices. Examples of several types of random matrices which ensure sparse recovery are given, such as Gaussian, Bernoulli, and partial random Fourier matrices.

Preliminaries and Notation

This exposition mostly treats complex vectors in \mathbb{C}^N although sometimes the considerations will be restricted to the real case \mathbb{R}^N . The ℓ_p -norm of a vector $x \in \mathbb{C}^N$ is defined as

$$\|x\|_p := \left(\sum_{j=1}^N |x_j|^p \right)^{1/p}, \quad 0 < p < \infty,$$

$$\|x\|_\infty := \max_{j=1,\dots,N} |x_j|. \quad (1)$$

For $1 \leq p \leq \infty$, it is indeed a norm, while for $0 < p < 1$, it is only a quasi-norm. When emphasizing the norm, the term ℓ_p^N is used instead of \mathbb{C}^N or \mathbb{R}^N . The unit ball in ℓ_p^N is $B_p^N = \{x \in \mathbb{C}^N, \|x\|_p \leq 1\}$. The operator norm of a matrix $A \in \mathbb{C}^{m \times N}$ from ℓ_p^N to ℓ_p^m is denoted

$$\|A\|_{p \rightarrow p} = \max_{\|x\|_p=1} \|Ax\|_p. \quad (2)$$

In the important special case $p = 2$, the operator norm is the maximal singular value $\sigma_{\max}(A)$ of A .

For a subset $T \subset \{1, \dots, N\}$, one denotes by $x_T \in \mathbb{C}^N$ the vector which coincides with $x \in \mathbb{C}^N$ on the entries in T and is zero outside T . Similarly, A_T denotes the column submatrix of A corresponding to the columns indexed by T . Further, $T^c = \{1, \dots, N\} \setminus T$ denotes the complement of T and $\#T$ or $|T|$ indicates the cardinality of T . The kernel of a matrix A is denoted by $\ker A = \{x, Ax = 0\}$.

Sparsity and Compression

Compressive sensing is based on the empirical observation that many types of real-world signals and images have a sparse expansion in terms of a suitable basis or frame, for instance, a wavelet expansion. This means that the expansion has only a small number of significant terms, or, in other words, that the coefficient vector can be well approximated with one having only a small number of nonvanishing entries.

The support of a vector x is denoted $\text{supp}(x) = \{j : x_j \neq 0\}$ and

$$\|x\|_0 := |\text{supp}(x)|.$$

It has become common to call $\|\cdot\|_0$ the ℓ_0 -norm, although it is not even a quasi-norm. A vector x is called *k-sparse* if $\|x\|_0 \leq k$. For $k \in \{1, 2, \dots, N\}$,

$$\Sigma_k := \{x \in \mathbb{C}^N : \|x\|_0 \leq k\}$$

denotes the set of *k*-sparse vectors. Furthermore, the *best k-term approximation error* of a vector $x \in \mathbb{C}^N$ in ℓ_p is defined as

$$\sigma_k(x)_p = \inf_{z \in \Sigma_k} \|x - z\|_p.$$

If $\sigma_k(x)$ decays quickly in k , then x is called *compressible*. Indeed, in order to compress x , one may simply store only the k largest entries. When reconstructing x from its compressed version, the non-stored entries are simply set to zero, and the reconstruction error is $\sigma_k(x)_p$. It is emphasized at this point that the procedure of obtaining the compressed version of x is *adaptive* and *nonlinear* since it requires the search of the largest entries of x in absolute value. In particular, the location of the nonzeros is a nonlinear type of information.

The *best k-term approximation* of x can be obtained using the nonincreasing rearrangement $r(x) = (|x_{i_1}|, \dots, |x_{i_N}|)^T$, where i_j denotes a permutation of the indexes such that $|x_{i_j}| \geq |x_{i_{j+1}}|$ for $j = 1, \dots, N - 1$. Then it is straightforward to check that

$$\sigma_k(x)_p := \left(\sum_{j=k+1}^N r_j(x)^p \right)^{1/p}, \quad 0 < p < \infty.$$

And the vector $x_{[k]}$ derived from x by setting to zero all the $N - k$ smallest entries in absolute value is the *best k-term approximation*,

$$x_{[k]} = \arg \min_{z \in \Sigma_k} \|x - z\|_p,$$

for any $0 < p \leq \infty$.

The next lemma states essentially that ℓ_q -balls with small q (ideally $q \leq 1$) are good models for compressible vectors.

Lemma 1. Let $0 < q < p \leq \infty$ and set $r = \frac{1}{q} - \frac{1}{p}$. Then

$$\sigma_k(x)_p \leq k^{-r}, \quad k = 1, 2, \dots, N \quad \text{for all } x \in B_q^N.$$

Proof. Let T be the set of indexes of the k -largest entries of x in absolute value. The nonincreasing rearrangement satisfies $|r_k(x)| \leq |x_j|$ for all $j \in T$, and therefore

$$k r_k(x)^q \leq \sum_{j \in T} |x_j|^q \leq \|x\|_q^q \leq 1.$$

Hence, $r_k(x) \leq k^{-\frac{1}{q}}$. Therefore,

$$\sigma_k(x)_p^p = \sum_{j \notin T} |x_j|^p \leq \sum_{j \notin T} r_k(x)^{p-q} |x_j|^q \leq k^{-\frac{p-q}{q}} \|x\|_q^q \leq k^{-\frac{p-q}{q}},$$

which implies $\sigma_k(x)_p \leq k^{-r}$. ■

Compressive Sensing

The above outlined adaptive strategy of compressing a signal x by only keeping its largest coefficients is certainly valid when full information on x is available. If, however, the signal first has to be acquired or measured by a somewhat costly or lengthy procedure, then this seems to be a waste of resources: At first, large efforts are made to acquire the full signal and then most of the information is thrown away when compressing it. One may ask whether it is possible to obtain more directly a compressed version of the signal by taking only a small amount of *linear and nonadaptive* measurements. Since one does not know a priori the large coefficients, this seems a daunting task at first sight. Quite surprisingly, compressive sensing nevertheless predicts that reconstruction from vastly undersampled nonadaptive measurements is possible – even by using efficient recovery algorithms.

Taking m linear measurements of a signal $x \in \mathbb{C}^N$ corresponds to applying a matrix $A \in \mathbb{C}^{m \times N}$ – the *measurement matrix* –

$$y = Ax. \tag{3}$$

The vector $y \in \mathbb{C}^m$ is called the *measurement vector*. The main interest is in the vastly undersampled case $m \ll N$. Without further information, it is, of course, impossible to recover x from y since the linear system (3) is highly underdetermined and has therefore infinitely many solutions. However, if the additional assumption that the vector x is k -sparse is imposed, then the situation dramatically changes as will be outlined.

The approach for a recovery procedure that probably comes first to mind is to search for the sparsest vector x which is consistent with the measurement vector $y = Ax$. This leads to solving the ℓ_0 -minimization problem

$$\min \|z\|_0 \quad \text{subject to } Az = y. \quad (4)$$

Unfortunately, this combinatorial minimization problem is NP-hard in general [108, 114]. In other words, an algorithm that solves (4) for *any* matrix A and *any* right-hand side y is necessarily computationally intractable. Therefore, essentially two practical and tractable alternatives to (4) have been proposed in the literature: convex relaxation leading to ℓ_1 -minimization – also called basis pursuit [35] – and greedy algorithms, such as various matching pursuits [151, 153]. Quite surprisingly for both types of approaches, various recovery results are available, which provide conditions on the matrix A and on the sparsity $\|x\|_0$ such that the recovered solution coincides with the original x and consequently also with the solution of (4). This is no contradiction to the NP-hardness of (4) since these results apply only to a subclass of matrices A and right-hand sides y .

The ℓ_1 -minimization approach considers the solution of

$$\min \|z\|_1 \quad \text{subject to } Az = y, \quad (5)$$

which is a convex optimization problem and can be seen as a convex relaxation of (4). Various efficient convex optimization techniques apply for its solution [17]. In the real-valued case, (5) is equivalent to a linear program, and in the complex-valued case, it is equivalent to a second-order cone program. Therefore, standard software applies for its solution – although algorithms which are specialized to (5) outperform such standard software; see Sect. 4.

The hope is, of course, that the solution of (5) coincides with the solution of (4) and with the original sparse vector x . Figure 3 provides an intuitive explanation why ℓ_1 -minimization promotes sparse solutions. Here, $N = 2$ and $m = 1$, so one

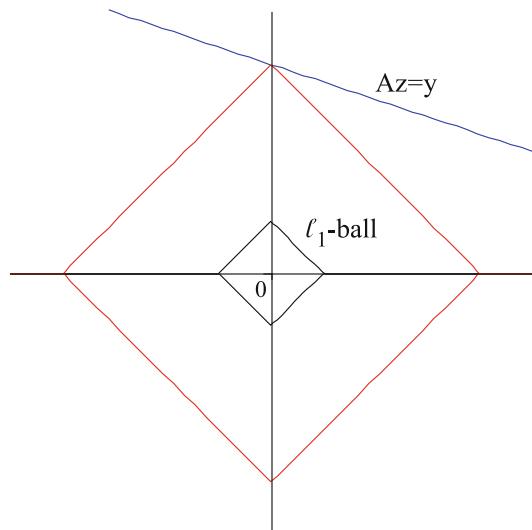

Fig. 3 The ℓ_1 -minimizer within the affine space of solutions of the linear system $Az = y$ coincides with a sparsest solution

deals with a line of solutions $\mathcal{F}(y) = \{z : Az = y\}$ in \mathbb{R}^2 . Except for pathological situations where $\ker A$ is parallel to one of the faces of the polytope B_1^2 , there is a unique solution of the ℓ_1 -minimization problem, which has minimal sparsity, i.e., only one nonzero entry.

Recovery results in the next sections make rigorous the intuition that ℓ_1 -minimization indeed promotes sparsity.

For sparse recovery via greedy algorithms, one refers to the literature [151, 153].

The Null Space Property

The null space property is fundamental in the analysis of ℓ_1 -minimization.

Definition 1. A matrix $A \in \mathbb{C}^{m \times N}$ is said to satisfy the *null space property* (NSP) of order k with constant $\gamma \in (0, 1)$ if

$$\|\eta_T\|_1 \leq \gamma \|\eta_{T^c}\|_1,$$

for all sets $T \subset \{1, \dots, N\}$, $\#T \leq k$ and for all $\eta \in \ker A$.

The following sparse recovery result is based on this notion.

Theorem 1. Let $A \in \mathbb{C}^{m \times N}$ be a matrix that satisfies the NSP of order k with constant $\gamma \in (0, 1)$. Let $x \in \mathbb{C}^N$ and $y = Ax$ and let x^* be a solution of the ℓ_1 -minimization problem (5). Then

$$\|x - x^*\|_1 \leq \frac{2(1 + \gamma)}{1 - \gamma} \sigma_k(x)_1. \quad (6)$$

In particular, if x is k -sparse, then $x^* = x$.

Proof. Let $\eta = x^* - x$. Then $\eta \in \ker A$ and

$$\|x^*\|_1 \leq \|x\|_1$$

because x^* is a solution of the ℓ_1 -minimization problem (5). Let T be the set of the k -largest entries of x in absolute value. One has

$$\|x_T^*\|_1 + \|x_{T^c}^*\|_1 \leq \|x_T\|_1 + \|x_{T^c}\|_1.$$

It follows immediately from the triangle inequality that

$$\|x_T\|_1 - \|\eta_T\|_1 + \|\eta_{T^c}\|_1 - \|x_{T^c}\|_1 \leq \|x_T\|_1 + \|x_{T^c}\|_1.$$

Hence,

$$\|\eta_{T^c}\|_1 \leq \|\eta_T\|_1 + 2\|x_{T^c}\|_1 \leq \gamma \|\eta_{T^c}\|_1 + 2\sigma_k(x)_1,$$

or, equivalently,

$$\|\eta_{T^c}\|_1 \leq \frac{2}{1-\gamma} \sigma_k(x)_1. \quad (7)$$

Finally,

$$\|x - x^*\|_1 = \|\eta_T\|_1 + \|\eta_{T^c}\|_1 \leq (\gamma + 1) \|\eta_{T^c}\|_1 \leq \frac{2(1+\gamma)}{1-\gamma} \sigma_k(x)_1$$

and the proof is completed. \blacksquare

One can also show that if all k -sparse x can be recovered from $y = Ax$ using ℓ_1 -minimization, then necessarily A satisfies the NSP of order k with some constant $\gamma \in (0, 1)$ [38, 87]. Therefore, the NSP is actually equivalent to sparse ℓ_1 -recovery.

The Restricted Isometry Property

The NSP is somewhat difficult to show directly. The *restricted isometry property* (RIP) is easier to handle, and it also implies stability under noise as stated below.

Definition 2. The restricted isometry constant δ_k of a matrix $A \in \mathbb{C}^{m \times N}$ is the smallest number such that

$$(1 - \delta_k) \|z\|_2^2 \leq \|Az\|_2^2 \leq (1 + \delta_k) \|z\|_2^2, \quad (8)$$

for all $z \in \Sigma_k$.

A matrix A is said to satisfy the *restricted isometry property* of order k with constant δ_k if $\delta_k \in (0, 1)$. It is easily seen that δ_k can be equivalently defined as

$$\delta_k = \max_{T \subset \{1, \dots, N\}, \#T \leq k} \|A_T^* A_T - \text{Id}\|_{2 \rightarrow 2},$$

which means that *all* column submatrices of A with at most k columns are required to be well conditioned. The RIP implies the NSP as shown in the following lemma.

Lemma 2. Assume that $A \in \mathbb{C}^{m \times N}$ satisfies the RIP of order $K = k + h$ with constant $\delta_K \in (0, 1)$. Then A has the NSP of order k with constant $\gamma = \sqrt{\frac{k}{h} \frac{1+\delta_K}{1-\delta_K}}$.

Proof. Let $\eta \in \mathcal{N} = \ker A$ and $T \subset \{1, \dots, N\}$, $\#T \leq k$. Define $T_0 = T$ and T_1, T_2, \dots, T_s to be disjoint sets of indexes of size at most h , associated to a nonincreasing rearrangement of the entries of $\eta \in \mathcal{N}$, i.e.,

$$|\eta_j| \leq |\eta_i| \quad \text{for all } j \in T_\ell, i \in T_{\ell'}, \ell \geq \ell' \geq 1. \quad (9)$$

Note that $A\eta = 0$ implies $A\eta_{T_0 \cup T_1} = -\sum_{j=2}^s A\eta_{T_j}$. Then, from the Cauchy–Schwarz inequality, the RIP, and the triangle inequality, the following sequence of inequalities is deduced:

$$\begin{aligned} \|\eta_T\|_1 &\leq \sqrt{k}\|\eta_T\|_2 \leq \sqrt{k}\|\eta_{T_0 \cup T_1}\|_2 \\ &\leq \sqrt{\frac{k}{1-\delta_K}}\|A\eta_{T_0 \cup T_1}\|_2 = \sqrt{\frac{k}{1-\delta_K}}\|A\eta_{T_2 \cup T_3 \cup \dots \cup T_s}\|_2 \\ &\leq \sqrt{\frac{k}{1-\delta_K}} \sum_{j=2}^s \|A\eta_{T_j}\|_2 \leq \sqrt{\frac{1+\delta_K}{1-\delta_K}} \sqrt{k} \sum_{j=2}^s \|\eta_{T_j}\|_2. \end{aligned} \quad (10)$$

It follows from (9) that $|\eta_i| \leq |\eta_\ell|$ for all $i \in T_{j+1}$ and $\ell \in T_j$. Taking the sum over $\ell \in T_j$ first and then the ℓ_2 -norm over $i \in T_{j+1}$ yields

$$|\eta_i| \leq h^{-1}\|\eta_{T_j}\|_1, \quad \text{and} \quad \|\eta_{T_{j+1}}\|_2 \leq h^{-1/2}\|\eta_{T_j}\|_1.$$

Using the latter estimates in (10) gives

$$\|\eta_T\|_1 \leq \sqrt{\frac{1+\delta_K}{1-\delta_K}} \frac{k}{h} \sum_{j=1}^{s-1} \|\eta_{T_j}\|_1 \leq \sqrt{\frac{1+\delta_K}{1-\delta_K}} \frac{k}{h} \|\eta_{T^c}\|_1, \quad (11)$$

and the proof is finished. \blacksquare

Taking $h = 2k$ above shows that $\delta_{3k} < 1/3$ implies $\gamma < 1$. By Theorem 1, recovery of all k -sparse vectors by ℓ_1 -minimization is then guaranteed. Additionally, stability in ℓ_1 is also ensured. The next theorem shows that RIP implies also a bound on the reconstruction error in ℓ_2 .

Theorem 2. Assume $A \in \mathbb{C}^{m \times N}$ satisfies the RIP of order $3k$ with $\delta_{3k} < 1/3$. For $x \in \mathbb{C}^N$, let $y = Ax$ and x^* be the solution of the ℓ_1 -minimization problem (5). Then

$$\|x - x^*\|_2 \leq C \frac{\sigma_k(x)_1}{\sqrt{k}}$$

with $C = \frac{2}{1-\gamma} \left(\frac{\gamma+1}{\sqrt{2}} + \gamma \right)$, $\gamma = \sqrt{\frac{1+\delta_{3k}}{2(1-\delta_{3k})}}$.

Proof. Similarly as in the proof of Lemma 2, denote $\eta = x^* - x \in \mathcal{N} = \ker A$, $T_0 = T$ the set of the $2k$ -largest entries of η in absolute value, and T_j 's of size at most k corresponding to the nonincreasing rearrangement of η . Then, using (10) and (11) with $h = 2k$ of the previous proof,

$$\|\eta_T\|_2 \leq \sqrt{\frac{1 + \delta_{3k}}{2(1 - \delta_{3k})}} k^{-1/2} \|\eta_{T^c}\|_1.$$

From the assumption $\delta_{3k} < 1/3$, it follows that $\gamma := \sqrt{\frac{1 + \delta_{3k}}{2(1 - \delta_{3k})}} < 1$. Lemmas 1 and 2 yield

$$\begin{aligned} \|\eta_{T^c}\|_2 &= \sigma_{2k}(\eta)_2 \leq (2k)^{-\frac{1}{2}} \|\eta\|_1 = (2k)^{-1/2} (\|\eta_T\|_1 + \|\eta_{T^c}\|_1) \\ &\leq (2k)^{-1/2} (\gamma \|\eta_{T^c}\|_1 + \|\eta_{T^c}\|_1) \leq \frac{\gamma + 1}{\sqrt{2}} k^{-1/2} \|\eta_{T^c}\|_1. \end{aligned}$$

Since T is the set of $2k$ -largest entries of η in absolute value, it holds

$$\|\eta_{T^c}\|_1 \leq \|\eta_{(\text{supp } x_{[2k]})^c}\|_1 \leq \|\eta_{(\text{supp } x_{[k]})^c}\|_1, \quad (12)$$

where $x_{[k]}$ is the best k -term approximation to x . The use of this latter estimate, combined with inequality (7), finally gives

$$\begin{aligned} \|x - x^*\|_2 &\leq \|\eta_T\|_2 + \|\eta_{T^c}\|_2 \leq \left(\frac{\gamma + 1}{\sqrt{2}} + \gamma \right) k^{-1/2} \|\eta_{T^c}\|_1 \\ &\leq \frac{2}{1 - \gamma} \left(\frac{\gamma + 1}{\sqrt{2}} + \gamma \right) k^{-1/2} \sigma_k(x)_1. \end{aligned}$$

This concludes the proof. ■

The restricted isometry property implies also robustness under noise on the measurements. This fact was first noted in [26, 30].

Theorem 3. *Assume that the restricted isometry constant δ_{2k} of the matrix $A \in \mathbb{C}^{m \times N}$ satisfies*

$$\delta_{2k} < 1/\sqrt{2} \approx 0.7071 \quad (13)$$

Then the following holds for all $x \in \mathbb{C}^N$. Let noisy measurements $y = Ax + e$ be given with $\|e\|_2 \leq \eta$. Let x^ be the solution of*

$$\min \|z\|_1 \quad \text{subject to } \|Az - y\|_2 \leq \eta. \quad (14)$$

Then

$$\|x - x^*\|_2 \leq C_1 \eta + C_2 \frac{\sigma_k(x)_1}{\sqrt{k}}$$

for some constants $C_1, C_2 > 0$ that depend only on δ_{2k} .

The constant in (13) was improved several times [22, 38, 74–76] until the present statement was reached in [19], which is actually optimal [45].

Coherence

The *coherence* is a by now classical way of analyzing the recovery abilities of a measurement matrix [50, 151]. For a matrix $A = (a_1|a_2|\cdots|a_N) \in \mathbb{C}^{m \times N}$ with normalized columns, $\|a_\ell\|_2 = 1$, it is defined as

$$\mu := \max_{\ell \neq k} |\langle a_\ell, a_k \rangle|.$$

Applying Gershgorin's disc theorem [93] to $A_T^* A_T - I$ with $\#T = k$ shows that

$$\delta_k \leq (k-1)\mu. \quad (15)$$

Several explicit examples of matrices are known which have small coherence $\mu = \mathcal{O}(1/\sqrt{m})$. A simple one is the concatenation $A = (I|F) \in \mathbb{C}^{m \times 2m}$ of the identity matrix and the unitary Fourier matrix $F \in \mathbb{C}^{m \times m}$ with entries $F_{j,k} = m^{-1/2} e^{2\pi i j k / m}$. It is easily seen that $\mu = 1/\sqrt{m}$ in this case. Furthermore, [143] gives several matrices $A \in \mathbb{C}^{m \times m^2}$ with coherence $\mu = 1/\sqrt{m}$. In all these cases, $\delta_k \leq C \frac{k}{\sqrt{m}}$. Combining this estimate with the recovery results for ℓ_1 -minimization above shows that all k -sparse vectors x can be (stably) recovered from $y = Ax$ via ℓ_1 -minimization provided

$$m \geq C' k^2. \quad (16)$$

At first sight, one might be satisfied with this condition since if k is very small compared to N , then still m might be chosen smaller than N and all k -sparse vectors can be recovered from the undersampled measurements $y = Ax$. Although this is great news for a start, one might nevertheless hope that (16) can be improved. In particular, one may expect that actually a linear scaling of m in k should be enough to guarantee sparse recovery by ℓ_1 -minimization. The existence of matrices, which indeed provide recovery conditions of the form $m \geq C k \log^\alpha(N)$ (or similar) with some $\alpha \geq 1$, is shown in the next section. Unfortunately, such results cannot be shown using simply the coherence because of the generally lower bound [143]

$$\mu \geq \sqrt{\frac{N-m}{m(N-1)}} \sim \frac{1}{\sqrt{m}} \quad (N \text{ sufficiently large}).$$

In particular, it is not possible to overcome the “quadratic bottleneck” in (16) by using Gershgorin's theorem or Riesz–Thorin interpolation between $\|\cdot\|_{1 \rightarrow 1}$ and $\|\cdot\|_{\infty \rightarrow \infty}$; see also [131, 141]. In order to improve on (16), one has to take into account also cancellations in the Gramian $A_T^* A_T - I$, and this task seems to be quite difficult using deterministic methods. Therefore, it will not come as a surprise that the major breakthrough in compressive sensing was obtained with random matrices.

It is indeed easier to deal with cancellations in the Gramian using probabilistic techniques.

RIP for Gaussian and Bernoulli Random Matrices

Optimal estimates for the RIP constants in terms of the number m of measurement matrices can be obtained for Gaussian, Bernoulli, or more general subgaussian random matrices.

Let X be a random variable. Then one defines a random matrix $A = A(\omega)$, $\omega \in \Omega$, as the matrix whose entries are independent realizations of X , where $(\Omega, \Sigma, \mathbb{P})$ is their common probability space. One assumes further that for any $x \in \mathbb{R}^N$ one has the identity $\mathbb{E}\|Ax\|_2^2 = \|x\|_2^2$, \mathbb{E} denoting expectation.

The starting point for the simple approach in [7] is a concentration inequality of the form

$$\mathbb{P}(|\|Ax\|_2^2 - \|x\|_2^2| \geq \delta \|x\|_2^2) \leq 2e^{-c_0\delta^2m}, \quad 0 < \delta < 1, \quad (17)$$

where $c_0 > 0$ is some constant.

The two most relevant examples of random matrices which satisfy the above concentration are the following:

1. **Gaussian matrices.** Here the entries of A are chosen as i.i.d. Gaussian random variables with expectation 0 and variance $1/m$. As shown in [1], Gaussian matrices satisfy (17).
2. **Bernoulli matrices** The entries of a Bernoulli matrices are independent realizations of $\pm 1/\sqrt{m}$ Bernoulli random variables, that is, each entry takes the value $+1/\sqrt{m}$ or $-1/\sqrt{m}$ with equal probability. Bernoulli matrices also satisfy the concentration inequality (17) [1].

Based on the concentration inequality (17), the following estimate on RIP constants can be shown [7, 26, 76, 110].

Theorem 4. *Assume $A \in \mathbb{R}^{m \times N}$ to be a random matrix satisfying the concentration property (17). Then there exists a constant C depending only on c_0 such that the restricted isometry constant of A satisfies $\delta_k \leq \delta$ with probability exceeding $1 - \varepsilon$ provided*

$$m \geq C\delta^{-2}(k \log(N/m) + \log(\varepsilon^{-1})).$$

Combining this RIP estimate with the recovery results for ℓ_1 -minimization shows that all k -sparse vectors $x \in \mathbb{C}^N$ can be stably recovered from a random draw of A satisfying (17) with high probability provided

$$m \geq Ck \log(N/m). \quad (18)$$

Up to the logarithmic factor, this provides the desired linear scaling of the number m of measurements with respect to the sparsity k . Furthermore, as shown in Sect. 3 below, condition (18) cannot be further improved; in particular, the log-factor cannot be removed.

It is useful to observe that the concentration inequality is invariant under unitary transforms. Indeed, suppose that z is not sparse with respect to the canonical basis but with respect to a different orthonormal basis. Then $z = Ux$ for a sparse x and a unitary matrix $U \in \mathbb{C}^{N \times N}$. Applying the measurement matrix A yields

$$Az = A(Ux),$$

so that this situation is equivalent to working with the new measurement matrix $A' = AU$ and again sparsity with respect to the canonical basis. The crucial point is that A' satisfies again the concentration inequality (17) once A does. Indeed, choosing $x = U^{-1}x'$ and using unitarity gives

$$\begin{aligned} \mathbb{P}\left(\left|\|AUX\|_2^2 - \|x\|_2^2\right| \geq \delta\|x\|_{\ell_2^N}^2\right) &= \mathbb{P}\left(\left|\|Ax'\|_2^2 - \|U^{-1}x'\|_2^2\right| \geq \delta\|U^{-1}x'\|_{\ell_2^N}^2\right) \\ &= \mathbb{P}\left(\left|\|Ax'\|_2^2 - \|x'\|_2^2\right| \geq \delta\|x'\|_{\ell_2^N}^2\right) \leq 2e^{-c_0\delta^{-2}m}. \end{aligned}$$

Hence, Theorem 4 also applies to $A' = AU$. This fact is sometimes referred to as the *universality* of the Gaussian or Bernoulli random matrices. It does not matter in which basis the signal x is actually sparse. At the coding stage, where one takes random measurements $y = Az$, knowledge of this basis is not even required. Only the decoding procedure needs to know U .

Random Partial Fourier Matrices

While Gaussian and Bernoulli matrices provide optimal conditions for the minimal number of required samples for sparse recovery, they are of somewhat limited use for practical applications for several reasons. Often the application imposes physical or other constraints on the measurement matrix, so that assuming A to be Gaussian may not be justifiable in practice. One usually has only limited freedom to inject randomness in the measurements. Furthermore, Gaussian or Bernoulli matrices are not structured, so there is no fast matrix-vector multiplication available which may speed up recovery algorithms, such as the ones described in Sect. 4. Thus, Gaussian random matrices are not applicable in large-scale problems.

A very important class of structured random matrices that overcomes these drawbacks are random partial Fourier matrices, which were also the object of study in the very first papers on compressive sensing [26, 29, 128, 129]. A random partial Fourier matrix $A \in \mathbb{C}^{m \times N}$ is derived from the discrete Fourier matrix $F \in \mathbb{C}^{N \times N}$ with entries

$$F_{j,k} = \frac{1}{\sqrt{N}} e^{2\pi jk/N},$$

by selecting m rows uniformly at random among all N rows. Taking measurements of a sparse $x \in \mathbb{C}^N$ corresponds then to observing m of the entries of its discrete Fourier transform $\hat{x} = Fx$. It is important to note that the fast Fourier transform may be used to compute matrix-vector multiplications with A and A^* with complexity $\mathcal{O}(N \log(N))$. The following theorem concerning the RIP constant was proven in [131] and improves slightly on the results in [26, 129, 138].

Theorem 5. *Let $A \in \mathbb{C}^{m \times N}$ be the random partial Fourier matrix as just described. Then the restricted isometry constant of the rescaled matrix $\sqrt{\frac{N}{m}}A$ satisfies $\delta_k \leq \delta$ with probability at least $1 - N^{-\gamma \log^3(N)}$ provided*

$$m \geq C \delta^{-2} k \log^4(N). \quad (19)$$

The constants $C, \gamma > 1$ are universal.

Combining this estimate with the ℓ_1 -minimization results above shows that recovery with high probability can be ensured for all k -sparse x provided

$$m \geq C k \log^4(N).$$

The plots in Fig. 1 illustrate an example of successful recovery from partial Fourier measurements.

The proof of the above theorem is not straightforward and involves Dudley's inequality as a main tool [131, 138]. Compared to the recovery condition (18) for Gaussian matrices, one suffers a higher exponent at the log-factor, but the linear scaling of m in k is preserved. Also a nonuniform recovery result for ℓ_1 -minimization is available [29, 128, 131], which states that each k -sparse x can be recovered using a random draw of the random partial Fourier matrix A with probability at least $1 - \varepsilon$ provided $m \geq C k \log(N/\varepsilon)$. The difference to the statement in Theorem 5 is that for each sparse x , recovery is ensured with high probability for a new random draw of A . It does not imply the existence of a matrix which allows recovery of *all* k -sparse x simultaneously. The proof of such recovery results does not make use of the restricted isometry property or the null space property.

One may generalize the above results to a much broader class of structured random matrices which arise from random sampling in bounded orthonormal systems. The interested reader is referred to [128, 129, 131, 132].

Another class of structured random matrices, for which recovery results are known, consist of partial random circulant and Toeplitz matrices. These correspond to subsampling the convolution of x with a random vector b at m fixed (deterministic) entries. The reader is referred to [130, 131, 133] for detailed information. Near-optimal estimates of the RIP constants of such type of random matrices have been established in [101]. Further types of random measurement matrices are discussed in [101, 122, 124, 137, 154]; see also [99] for an overview.

Compressive Sensing and Gelfand Widths

In this section a quite general viewpoint is taken. The question is investigated how well any measurement matrix and any reconstruction method – in this context usually called the *decoder* – may perform. This leads to the study of *Gelfand widths*, already mentioned in Sect. 2. The corresponding analysis allows to draw the conclusion that Gaussian random matrices in connection with ℓ_1 -minimization provide optimal performance guarantees.

Following the tradition of the literature in this context, only the real-valued case will be treated. The complex-valued case is easily deduced from the real-valued case by identifying \mathbb{C}^N with \mathbb{R}^{2N} and by corresponding norm equivalences of ℓ_p -norms.

The measurement matrix $A \in \mathbb{R}^{m \times N}$ is here also referred to as the *encoder*. The set $\mathcal{A}_{m,N}$ denotes all possible encoder/decoder pairs (A, Δ) where $A \in \mathbb{R}^{m \times N}$ and $\Delta : \mathbb{R}^m \rightarrow \mathbb{R}^N$ is any (nonlinear) function. Then, for $1 \leq k \leq N$, the reconstruction errors over subsets $K \subset \mathbb{R}^N$, where \mathbb{R}^N is endowed with a norm $\|\cdot\|_X$, are defined as

$$\begin{aligned}\sigma_k(K)_X &:= \sup_{x \in K} \sigma_k(x)_X, \\ E_m(K, X) &:= \inf_{(A, \Delta) \in \mathcal{A}_{m,N}} \sup_{x \in K} \|x - \Delta(Ax)\|_X.\end{aligned}$$

In words, $E_n(K, X)$ is the worst reconstruction error for the best pair of encoder/decoder. The goal is to find the largest k such that

$$E_m(K, X) \leq C_0 \sigma_k(K)_X.$$

Of particular interest for compressive sensing are the unit balls $K = B_p^N$ for $0 < p \leq 1$ and $X = \ell_2^N$ because the elements of B_p^N are well approximated by sparse vectors due to Lemma 1. The proper estimate of $E_m(K, X)$ turns out to be linked to the geometrical concept of *Gelfand width*.

Definition 3. Let K be a compact set in a normed space X . Then the *Gelfand width* of K of order m is

$$d^m(K, X) := \inf_{\substack{Y \subset X \\ \text{codim}(Y) \leq m}} \sup\{\|x\|_X : x \in K \cap Y\},$$

where the infimum is over all linear subspaces Y of X of codimension less or equal to m .

The following fundamental relationship between $E_m(K, X)$ and the Gelfand widths holds.

Proposition 1. Let $K \subset \mathbb{R}^N$ be a closed compact set such that $K = -K$ and $K + K \subset C_0 K$ for some constant C_0 . Let $X = (\mathbb{R}^N, \|\cdot\|_X)$ be a normed space. Then

$$d^m(K, X) \leq E_m(K, X) \leq C_0 d^m(K, X).$$

Proof. For a matrix $A \in \mathbb{R}^{m \times N}$, the subspace $Y = \ker A$ has codimension less or equal to m . Conversely, to any subspace $Y \subset \mathbb{R}^N$ of codimension less or equal to m , a matrix $A \in \mathbb{R}^{m \times N}$ can be associated, the rows of which form a basis for Y^\perp . This identification yields

$$d^m(K, X) = \inf_{A \in \mathbb{R}^{m \times N}} \sup\{\|\eta\|_X : \eta \in \ker A \cap K\}.$$

Let (A, Δ) be an encoder/decoder pair in $\mathcal{A}_{m,N}$ and $z = \Delta(0)$. Denote $Y = \ker(A)$. Then with $\eta \in Y$ also $-\eta \in Y$, and either $\|\eta - z\|_X \geq \|\eta\|_X$ or $\|-\eta - z\|_X \geq \|\eta\|_X$. Indeed, if both inequalities were false, then

$$\|2\eta\|_X = \|\eta - z + z + \eta\|_X \leq \|\eta - z\|_X + \|-\eta - z\|_X < 2\|\eta\|_X,$$

a contradiction. Since $K = -K$, it follows that

$$\begin{aligned} d^m(K, X) &= \inf_{A \in \mathbb{R}^{m \times N}} \sup\{\|\eta\|_X : \eta \in Y \cap K\} \leq \sup_{\eta \in Y \cap K} \|\eta - z\|_X \\ &= \sup_{\eta \in Y \cap K} \|\eta - \Delta(A\eta)\|_X \leq \sup_{x \in K} \|x - \Delta(Ax)\|_X. \end{aligned}$$

Taking the infimum over all $(A, \Delta) \in \mathcal{A}_{m,N}$ yields

$$d^m(K, X) \leq E_m(K, X).$$

To prove the converse inequality, choose an optimal Y such that

$$d^m(K, X) = \sup\{\|x\|_X : x \in Y \cap K\}.$$

(An optimal subspace Y always exists [107].) Let A be a matrix whose rows form a basis for Y^\perp . Denote the affine solution space $\mathcal{F}(y) := \{x : Ax = y\}$. One defines then a decoder as follows. If $\mathcal{F}(y) \cap K \neq \emptyset$, then choose some $\bar{x}(y) \in \mathcal{F}(y)$ and set $\Delta(y) = \bar{x}(y)$. If $\mathcal{F}(y) \cap K = \emptyset$, then $\Delta(y) \in \mathcal{F}(y)$. The following chain of inequalities is then deduced:

$$\begin{aligned} E_m(K, X) &\leq \sup_y \sup_{x, x' \in \mathcal{F}(y) \cap K} \|x - x'\|_X \\ &\leq \sup_{\eta \in C_0(Y \cap K)} \|\eta\|_X \leq C_0 d^m(K, X), \end{aligned}$$

which concludes the proof. ■

The assumption $K + K \subset C_0 K$ clearly holds for norm balls with $C_0 = 2$ and for quasi-norm balls with some $C_0 \geq 2$. The next theorem provides a two-sided estimate of the Gelfand widths $d^m(B_p^N, \ell_2^N)$ [48, 77, 157]. Note that the case $p = 1$ was considered much earlier in [77, 79, 96].

Theorem 6. *Let $0 < p \leq 1$. There exist universal constants $C_p, D_p > 0$ such that the Gelfand widths $d^m(B_p^N, \ell_2^N)$ satisfy*

$$\begin{aligned} C_p \min \left\{ 1, \frac{\ln(2N/m)}{m} \right\}^{1/p-1/2} &\leq d^m(B_p^N, \ell_2^N) \\ &\leq D_p \min \left\{ 1, \frac{\ln(2N/m)}{m} \right\}^{1/p-1/2} \end{aligned} \quad (20)$$

Combining Proposition 1 and Theorem 6 gives in particular, for large m ,

$$\tilde{C}_1 \sqrt{\frac{\log(2N/m)}{m}} \leq E_m(B_1^N, \ell_2^N) \leq \tilde{D}_1 \sqrt{\frac{\log(2N/m)}{m}}. \quad (21)$$

This estimate implies a lower estimate for the minimal number of required samples which allows for approximate sparse recovery using any measurement matrix and any recovery method whatsoever. The reader should compare the next statement with Theorem 2.

Corollary 1. *Suppose that $A \in \mathbb{R}^{m \times N}$ and $\Delta : \mathbb{R}^m \rightarrow \mathbb{R}^N$ such that*

$$\|x - \Delta(Ax)\|_2 \leq C \frac{\sigma_k(x)_1}{\sqrt{k}}$$

for all $x \in B_1^N$ and some constant $C > 0$. Then necessarily

$$m \geq C' k \log(2N/m). \quad (22)$$

Proof. Since $\sigma_k(x)_1 \leq \|x\|_1 \leq 1$, the assumption implies $E_m(B_1^N, \ell_2^N) \leq C k^{-1/2}$. The lower bound in (21) combined with Proposition 1 yields

$$\tilde{C}_1 \sqrt{\frac{\log(2N/m)}{m}} \leq E_m(B_1^N, \ell_2^N) \leq C k^{-1/2}.$$

Consequently, $m \geq C' k \log(eN/m)$ as claimed. ■

In particular, the above lemma applies to ℓ_1 -minimization and consequently $\delta_k \leq 0.5$ (say) for a matrix $A \in \mathbb{R}^{m \times N}$ implies $m \geq C k \log(N/m)$. Therefore, the recovery results for Gaussian or Bernoulli random matrices with ℓ_1 -minimization stated above are optimal.

It can also be shown that a stability estimate in the ℓ_1 -norm of the form $\|x - \Delta(Ax)\|_1 \leq C\sigma_k(x)_1$ for all $x \in \mathbb{R}^N$ implies (22) as well [46, 77].

Extensions of Compressive Sensing

The problem of recovering nearly sparse vectors from a minimal number of nonadaptive linear measurements can be extended in several forms. In the following two possible, mutually related, extensions are addressed.

The first refers to the object to be recovered: while in the theory of compressive sensing presented so far nearly sparse vectors are the unknowns of the problem at hand, one may consider as well matrices of approximate low rank. This leads to the problem of finding a matrix of minimal rank consistent with a given underdetermined linear system of equations.

The second generalization of compressive sensing considers nonlinear nonadaptive measurements. The simplest nonlinearity consists in *quadratic* measurements, given by the squared magnitude of the scalar products of the vector with respect to a fixed basis or a frame. The associated recovery task – called the *phase retrieval problem* – appears in many physical situations where only intensity values can be observed. More generally, one may consider the recovery from higher-order measurements. Surprisingly enough, polynomial-type, and in particular quadratic, measurements of vectors can be recast into an affine low-rank minimization problem discussed above, creating a connection between these two extensions of compressive sensing.

Affine Low-Rank Minimization

Here one denotes the space of real or complex $n \times p$ matrices by $M_{n \times p}$. Given a linear map $\mathcal{S} : M_{n \times p} \rightarrow \mathbb{C}^m$, with $m \ll pn$, and a vector $y \in \mathbb{C}^m$, one considers the affine rank minimization problem

$$\min_{X \in M_{n \times p}} \text{rank}(X) \quad \text{subject to } \mathcal{S}(X) = y. \quad (23)$$

An important special case of low-rank matrix recovery is matrix completion, where \mathcal{S} samples a few entries,

$$\mathcal{S}(X)_\ell = x_{ij}, \quad (24)$$

for some i, j depending on ℓ .

Like for the ℓ_0 -minimization problem (4), the affine rank minimization problem is NP-hard in general [76, 114, 135]; therefore, it is desirable to have tractable alternatives. In [67], Fazel studied *nuclear norm* minimization for this purpose. Here, the nuclear norm $\|X\|_*$ of a matrix X is the ℓ_1 -norm of its singular values and is the largest convex envelope of the rank function [67]. One solves then

$$\min_{X \in M_{n \times p}} \|X\|_* \quad \text{subject to } \mathcal{S}(X) = y. \quad (25)$$

There are two known regimes where nuclear norm minimization can be guaranteed to return minimal-rank solutions:

RIP measurement maps

The (rank) restricted isometry property is analogous to the classical restricted isometry property from compressive sensing already mentioned in Sect. 3:

Definition 4 (Rank-Restricted Isometry Property [135]). Let $\mathcal{S} : M_{n \times p} \rightarrow \mathbb{C}^m$ be a linear map. For an integer k , with $1 \leq k \leq n$, define the k -restricted isometry constant $\delta_k = \delta_k(\mathcal{S}) > 0$ to be the smallest number such that

$$(1 - \delta_k) \|X\|_F^2 \leq \|\mathcal{S}(X)\|_{\ell_2^m}^2 \leq (1 + \delta_k) \|X\|_F^2$$

holds for all k -rank matrices X .

It is known that nuclear norm minimization (25) recovers all matrices X of rank at most k from the measurements $y = \mathcal{S}(X)$, provided $\delta_{2k} < 1/\sqrt{2}$; see [19, 24, 76, 121, 135].

The restricted isometry property is known to hold for Gaussian (or more generally subgaussian) measurement maps [24, 135], which are of the form

$$\mathcal{S}(X)_\ell = \sum_{k,j} a_{\ell,k,j} X_{k,j}, \quad \ell = 1, \dots, m, \quad (26)$$

where the $a_{\ell,k,j}$ are independent normal distributed random variables with mean zero and variance $1/m$. Such a map satisfies $\delta_k \leq \delta \in (0, 1)$ with high probability provided

$$m \geq C_\delta \max\{p, n\}k; \quad (27)$$

see Theorem 2.3 in [24]. Since the degrees of freedom of a rank k matrix $X \in M_{n \times p}$ are $k(n + p - k)$, the above bound matches this number up to possibly a constant. Therefore, the bound (27) is optimal.

It follows from recent results in [3, 100] that the restricted isometry property also holds for certain *structured* random maps if slightly more measurements are allowed. In particular, let $\mathcal{S} = P_\Omega FD$, where $D : M_{n \times p} \rightarrow M_{n \times p}$ performs independent random sign flips of all entries of a matrix, $F : M_{n \times p} \rightarrow M_{n \times p}$ represents the (suitably normalized) $2D$ Fourier transform, and $P_\Omega : M_{n \times p} \rightarrow \mathbb{C}^m$ is the coordinate projection which extracts the entries of the matrix on a random set $\Omega \subset [n] \times [p]$ which is chosen uniformly at random among all subsets of cardinality m . Then the rank-restricted isometry constants of \mathcal{S} satisfy $\delta_k \leq \delta \in (0, 1)$ with high probability as long as

$$m \geq C_\delta \max\{p, n\}k \log^5(pn). \quad (28)$$

This follows from recent findings in [3, 100] for which such random partial Fourier measurements satisfy a concentration inequality of the form

$$\mathbb{P}\left(\left|\|\mathcal{S}(X)\|^2 - \|X\|_F^2\right| \geq \varepsilon \|X\|_F^2\right) \leq 2 \exp\left(-\frac{m}{2} C_\varepsilon \log^{-4}(pn)\right), \quad (29)$$

for $\varepsilon \in (0, 1)$, together with the same proof strategy employed for subgaussian measurement maps based on covering arguments [24, 76]. This was first noted in the introduction of [73].

Matrix Completion

In the matrix completion setup (24) where measurements are pointwise observations of entries of the matrix, there are obvious rank one matrices in the kernel of the operator \mathcal{S} ; therefore, the RIP fails completely in this setting, and “localized” low-rank matrices in the null space of \mathcal{S} cannot be recovered by any method whatsoever. However, if certain conditions on the left and right singular vectors of the underlying low-rank matrix are imposed, essentially requiring that such vectors are uncorrelated with the canonical basis, then it was shown in [25, 27, 134] that such incoherent matrices of rank at most k can be recovered from m randomly chosen entries with high probability provided

$$m \geq Ck \max\{n, p\} \log^2(\max\{n, p\}).$$

Up to perhaps the exponent 2 at the log-term, this is optimal. One refers to [25, 27, 134] for detailed statements. In [88, 89] extensions to quantum state tomography can be found.

Nonlinear Measurements

Phase Retrieval

In order to understand how one can generalize compressive sensing towards nonlinear measurements, it is instructive to start with the *phase retrieval* problem. Here, the measurements of a signal x are given by $y_i = |\langle a_i, x \rangle|^2$ for some vectors a_i , $i = 1, \dots, m$ and the task is to reconstruct x up to a global phase factor. Practically successful approaches can be found in the physics and optimization literature for well over a decade; see, for instance, [8, 68]. In these investigations, however, neither bounds of the minimal number nor a theoretical discussion on the type of measurements is provided for the phase retrieval problem to ensure reconstruction. Moreover, there are no guarantees for these algorithms to converge to the expected solution. Only recently, uniqueness of feasible solutions was provided by Balan et al. [5] using methods from algebraic geometry. The authors proved injectivity for signals $x \in \mathbb{R}^N$ and $m \geq 2N - 1$ generic measurements or for complex signals $x \in \mathbb{C}^N$ and $m \geq 4N - 2$ generic measurements. Unfortunately, this theoretical work did not provide recovery guarantees for a practical algorithm. The main tool in this work was the observation that quadratic measurements can be written as

$$y_i = |\langle a_i, x \rangle|^2 = \langle a_i a_i^*, x x^* \rangle, \quad i = 1, \dots, m, \quad (30)$$

where the inner product on the right-hand side here denotes the Hilbert-Schmidt inner product $\langle A, B \rangle = \text{Tr}(AB^*)$. Consequently x can be identified as the unique solution of the phase retrieval problem (up to a global phase factor) if $X = xx^*$ is the unique rank one (and thus the minimum rank!) positive semidefinite solution of the linear equations

$$y_i = \mathcal{S}(X)_i = \langle a_i a_i^*, X \rangle, \quad i = 1, \dots, m. \quad (31)$$

This well-known lifting trick is also the basis of the PhaseLift algorithm by Candès et al. [32]. Here, the main ingredient is to pass from the rank minimization problem constrained by (31) to its convex relaxation (25). Using techniques from random matrix theory, the authors showed recovery guarantees for $m = O(N \log(N))$ Gaussian measurements under no structural (sparsity) assumptions on the signal. Although PhaseLift is often not considered a very efficient approach (see Sect. 4 for possible implementations) as one needs to solve a semidefinite program for $N \times N$ matrices – thus squaring the dimension – this work is considered groundbreaking, as for the first time it provided recovery guarantees for a polynomial time algorithm. The number of Gaussian measurements for PhaseLift to recover a generic signal has later been improved to $m = O(N)$ in [23] and for a variant of PhaseLift to $m = O(k^2 \log(N))$ for k -sparse signals in [105]. These recovery guarantees include also stability with respect to measurement noise.

The question of how many measurements are necessary to allow for stable phase retrieval, independently of the algorithm used, has been addressed in a very general setting by Eldar and Mendelson [64]. They showed that the necessary number of phaseless measurements to allow for the recovery of a signal x which is known to lie in a given set S can be estimated in terms of the so-called Gaussian width of the set S . This result is not restricted to Gaussian measurements but extends also to measurement vectors with independent subgaussian entries which in addition satisfy a small ball probability bound. Building upon this work, Ehler et al. [60] showed recovery guarantees for certain greedy algorithms for complex measurements of the same type. Other algorithms, for which recovery guarantees have been provided for Gaussian measurements, include polarization-based approaches [4] and alternating minimization [116].

Rigorous recovery guarantees for phase retrieval have been extended to randomly masked Fourier transforms in [31, 90] and to spherical designs in [91]. These works address more realistic measurement scenarios than Gaussian measurements for practical applications such as X-ray crystallography; see also [99].

Higher-Order Polynomial Measurements

Building upon the successful experience on phase retrieval problems, compressed sensing theory can be further extended to solving nonlinear problems of the type

$$\min \|z\|_0 \quad \text{subject to } y_i = A_i(z), \quad i = 1, \dots, m, \quad (32)$$

where $A_i : \mathbb{C}^N \rightarrow \mathbb{C}$, $i = 1, \dots, m$, are smooth functions. For q being a sufficiently large even integer, one approximates A_i by its q th-order Taylor expansion,

$$A_i(x) \approx \sum_{0 \leq |\alpha| \leq q} \frac{(x - x_0)^\alpha}{\alpha!} \partial^\alpha A_i(x_0) = \bar{x}^* \mathcal{A}_i \bar{x},$$

where \mathcal{A}_i is a $\binom{N + \frac{q}{2}}{\frac{q}{2}} \times \binom{N + \frac{q}{2}}{\frac{q}{2}}$ -symmetric matrix and \bar{x} is the vector whose entries are all the monomials of the elements of x with degree less or equal to $q/2$. Hereby, the standard multi-index notation is used.

Example 1. Let $x = (x_1, x_2)^T$ and $A(x) = 1 + x_1 + x_2^3$. The 4th-order Taylor expansion around $x_0 = 0$ is given by

$$A(x) = \bar{x}^* \mathcal{A} \bar{x}$$

where $\bar{x} = (1, x_1, x_2, x_1 x_2, x_1^2, x_2^2)^T$ and

$$\mathcal{A} = \begin{pmatrix} 1 & 1/2 & 0 & 0 & 0 & 0 \\ 1/2 & 0 & 0 & 0 & 1/12 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1/12 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

One observes again that

$$y_i = \bar{x}^* \mathcal{A}_i \bar{x} = \langle \mathcal{A}_i, \bar{x} \bar{x}^* \rangle, \quad i = 1, \dots, m, \quad (33)$$

where the inner product on the right-hand side denotes the Hilbert-Schmidt inner product. Consequently x can be recognized as the solution of (32) if $X = \bar{x} \bar{x}^*$ is the unique rank one positive definite solution of the linear equations

$$y_i = \mathcal{S}(X)_i = \langle \mathcal{A}_i, X \rangle, \quad i = 1, \dots, m. \quad (34)$$

As for the PhaseLift algorithm for phase retrieval problems, one considers again instead of the rank minimization problem constrained by (34) its convex relaxation (25). One also notices that in case the vector x is sparse, then X is sparse in addition to being of rank one. Hence, one can combine the nuclear norm with the classical ℓ_1 -norm penalization and consider the problem

$$\min_{X \in M_p \times p, 0 \preceq X} \|X\|_* + \gamma \|X\|_{\ell_1}, \text{ subject to } \mathcal{S}(X) = y, \quad (35)$$

where $p = \binom{N + \frac{q}{2}}{\frac{q}{2}}$ and $\gamma > 0$ is a suitable parameter. One refers to (35) as *nonlinear basis pursuit*. This algorithm works surprisingly well in practice to recover sparse vectors from very few measurements [118], but theoretical guarantees for stable and unique recovery are open to date.

Applications

Compressive sensing can be potentially used in all applications where the task is the reconstruction of a signal or an image from linear measurements, while taking many of those measurements – in particular, a complete set of measurements – is a costly, lengthy, difficult, dangerous, impossible, or otherwise undesired procedure. Additionally, there should be reasons to believe that the signal is sparse in a suitable basis (or frame). Empirically, the latter applies to most types of signals.

In computerized tomography, for instance, one would like to obtain an image of the inside of a human body by taking X-ray images from different angles. Taking an almost complete set of images would expose the patient to a large and dangerous dose of radiation, so the amount of measurements should be as small as possible and nevertheless guarantee a good enough image quality. Such images are usually nearly piecewise constant and therefore nearly sparse in the gradient, so there is a good reason to believe that compressive sensing is well applicable. And indeed, it is precisely this application that started the investigations on compressive sensing in the seminal paper [29].

Also radar imaging seems to be a very promising application of compressive sensing techniques [65, 66, 94, 144]. One is usually monitoring only a small number of targets, so that sparsity is a very realistic assumption. Standard methods for radar imaging actually also use the sparsity assumption, but only at the very end of the signal processing procedure in order to clean up the noise in the resulting image. Using sparsity systematically from the very beginning by exploiting compressive sensing methods is therefore a natural approach.

Further potential applications include wireless communication [147], astronomical signal and image processing [14], analog to digital conversion [154], camera design [58], and imaging [136, 159, 160].

Affine low-rank minimization problems (23) arise in many areas of science and technology, including system identification [113], collaborative filtering, quantum state tomography [88, 89], signal, and image processing. An important special case is the matrix completion problem [25, 27, 134], where the task consists in filling in missing entries of a large low-rank data matrix. For applications of low-rank matrix recovery in quantum state tomography, one can refer to [88, 89]. Applications of phase retrieval include diffraction imaging and X-ray crystallography; see, for instance, [111].

4 Numerical Methods

The previous sections showed that ℓ_1 -minimization performs very well in recovering sparse or approximately sparse vectors from undersampled measurements. In applications, it is important to have fast methods for actually solving ℓ_1 -minimization problems. Two such methods – Chambolle and Pock’s primal-dual algorithm [34] and iteratively re-weighted least squares (IRLS) [44] – will be explained in more detail below.

As a first remark, the ℓ_1 -minimization problem

$$\min \|x\|_1 \quad \text{subject to } Ax = y \quad (36)$$

is in the real case equivalent to the linear program

$$\min \sum_{j=1}^{2N} v_j \quad \text{subject to} \quad v \geq 0, \quad (A| - A)v = y. \quad (37)$$

The solution x^* to (36) is obtained from the solution v^* of (37) via $x^* = (\text{Id}| - \text{Id})v^*$. Any linear programming method may therefore be used for solving (36). The simplex method and interior point methods apply in particular [115], and standard software may be used. (In the complex case, (36) is equivalent to a second-order cone program (SOCP) and can also be solved with interior point methods.) However, such methods and software are of general purpose, and one may expect that methods specialized to (36) outperform such existing standard methods. Moreover, standard software often has the drawback that one has to provide the full matrix rather than fast routines for matrix-vector multiplication which are available, for instance, in the case of partial Fourier matrices. In order to obtain the full performance of such methods, one would therefore need to reimplement them, which is a daunting task because interior point methods usually require much fine-tuning. On the contrary, the two specialized methods described below are rather simple to implement and very efficient. Many more methods are available nowadays, including the homotopy and LARS method [55, 59, 119, 120]; greedy methods; such as orthogonal matching pursuit [151], CoSaMP [153]; and iterative hard thresholding [13, 69], which may offer better complexity than standard interior point methods. Due to space limitations, however, only the two methods below are explained in detail.

A Primal-Dual Algorithm

The reconstruction approaches discussed in the previous section can often be solved by optimization problems of the form

$$\min_{x \in \mathbb{C}^N} F(Ax) + G(x) \quad (38)$$

with A being an $m \times N$ matrix and F, G being convex functions with values in $(-\infty, \infty]$. For instance, the ℓ_1 -minimization problem (5) can be recast as (38) with $G(x) = \|x\|_1$ and $F(z) = \chi_{\{y\}}(z)$, where $\chi_{\{y\}}$ is the characteristic function of the singleton set $\{y\}$ that takes the value 0 on y and ∞ elsewhere. Moreover, (14) is equivalent to (38) with $G(x) = \|x\|_1$ and $F = \chi_{\{w: \|y-w\|_2 \leq \eta\}}$. Also the nuclear norm minimization problem (25) takes the form (38) with G being the nuclear norm; see also below.

The so-called dual problem [17, 76] of (38) is given by

$$\max_{\xi \in \mathbb{C}^m} -F^*(\xi) - G^*(-A^*\xi), \quad (39)$$

where

$$F^*(\xi) = \sup_{z \in \mathbb{C}^m} \{\operatorname{Re}\langle z, \xi \rangle - F(z)\}$$

is the convex (Fenchel) conjugate of F and likewise G^* is the convex conjugate of G . The joint primal-dual optimization is equivalent to solving the saddle point problem

$$\min_{x \in \mathbb{C}^N} \max_{\xi \in \mathbb{C}^m} \operatorname{Re}\langle Ax, \xi \rangle + G(x) - F^*(\xi). \quad (40)$$

The primal-dual algorithm introduced by Chambolle and Pock in [34], generalizing [126], and described below solves this problem iteratively. In order to formulate it, one needs to introduce the so-called proximal mapping (proximity operator). For the convex function G , it is defined as

$$P_G(\tau, z) := \operatorname{argmin}_{x \in \mathbb{C}^N} \left\{ \tau G(x) + \frac{1}{2} \|x - z\|_2^2 \right\}.$$

For $G(x) = \|x\|_1$, the proximal mapping reduces to the well-known soft-thresholding operator, which is defined componentwise as

$$S_\tau(z)_\ell = \begin{cases} \operatorname{sgn}(z_\ell)(|z_\ell| - \tau) & \text{if } |z_\ell| \geq \tau, \\ 0 & \text{otherwise.} \end{cases}$$

One also requires below the proximal mapping associated to the convex conjugate F^* .

The primal-dual algorithm performs an iteration on the dual variable, the primal variable, and an auxiliary primal variable. Starting from initial points $x^0, \bar{x}^0 = x \in \mathbb{C}^N, \xi^0 \in \mathbb{C}^m$ and parameters $\tau, \sigma > 0, \theta \in [0, 1]$, one iteratively computes

$$\xi^{n+1} := P_{F^*}(\sigma; \xi^n + \sigma A \bar{x}^n), \quad (41)$$

$$x^{n+1} := P_G(\tau; x^n - \tau A^* \xi^{n+1}), \quad (42)$$

$$\bar{x}^{n+1} := x^{n+1} + \theta(x^{n+1} - x^n). \quad (43)$$

It can be shown that (x, ξ) is a fixed point of these iterations if and only if (x, ξ) is a saddle point of (40) which is equivalent to x being a solution of (38) and ξ of (39); see [76, Proposition 15.6]. For this reason, the algorithm can be interpreted as a fixed point iteration.

For the case that $\theta = 1$, the convergence of the primal-dual algorithm has been established in [34].

Theorem 7. *Consider the primal-dual algorithm (41)–(43) with $\theta = 1$ and $\tau, \sigma > 0$ such that $\tau\sigma \|A\|_{2 \rightarrow 2}^2 < 1$. If the problem (40) has a saddle point, then the sequence (x^n, ξ^n) converges to a saddle point of (40) and in particular (x^n) converges to a minimizer of (38).*

One observes that for the ℓ_1 and nuclear norm minimization problems of this chapter, the assumption of the theorem that (40) has a saddle point will always be satisfied. An estimate of the convergence rate can be shown as well. One refers to [34] for details. Preconditioning was considered in [125], where also parameter choices are discussed. Convergence results for values of θ different from 1 have been obtained in [92] for slight modifications of the algorithm.

One considers again some special cases. For ℓ_1 -minimization (36), where $G(x) = \|x\|_1$ and $F = \chi_{\{y\}}$, the proximal mapping P_G reduces to soft-thresholding (41) while the proximal mapping associated to $F^*(\xi) = \text{Re}\langle y, \xi \rangle$ is given by

$$P_{F^*}(\sigma, \xi) = \xi - \sigma y.$$

Therefore, all operations required in the algorithm (41)–(43) are simple and easy to implement. Also, note that if fast matrix-vector multiplication algorithms are available for A and A^* , these can be easily exploited.

In the case of the nuclear norm minimization problem (25), where $G(X) = \|X\|_*$ and $F = \chi_{\{y\}}$, the proximal mapping of G is given by singular-value soft thresholding: If $Z = U \Sigma V^*$ is the singular value decomposition of a matrix Z with unitary matrices U and V and a diagonal matrix $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_n)$ with $\sigma_1 \geq \sigma_2 \geq \dots \geq 0$, then

$$P_{\|\cdot\|_*}(\tau, Z) = U \text{diag}(S_\tau(\sigma_1), \dots, S_\tau(\sigma_n)) V^*,$$

i.e., the soft-thresholding operator is applied to the singular values. With this information together with the proximal mapping of F^* given above, the iterations (41)–(43) can be implemented for nuclear norm minimization.

Of course, the described algorithm applies to many more optimization problems and turns out to be very efficient when the proximal mappings are simple to evaluate. Notice that the iterations (41)–(43) are strongly influenced by backward–forward splitting methods [41] for the primal problem (38) with differentiable F , which are of the form

$$x^n = P_G(\tau; x^n - \tau \nabla F(x^n)). \quad (44)$$

In fact, (41) can be considered a backward–forward step for the dual variable, while (42) is a backward–forward step for the primal variable. A particular instance of (44) is the soft-thresholding algorithm for minimizing functionals of the form $\|Ax - y\|_2^2 + \lambda \|x\|_1$; see [41, 43] and [9, 10] for an accelerated version. Related optimization algorithms include Douglas–Rachford splittings [39, 40, 57] and the alternating direction method of multipliers [40, 83]. One refers to [142, Chapter 7], [40], [76, Chapter 15], and [156] for overviews on these and further approaches.

Iteratively Re-weighted Least Squares

This section is concerned with an iterative algorithm which, under the condition that A satisfies the NSP (see Definition 1), is guaranteed to reconstruct vectors with the same error estimate (6) as ℓ_1 -minimization. The following discussion is restricted to the real-valued case. This algorithm has a guaranteed linear rate of convergence which can even be improved to a superlinear rate with a small modification. First, a brief introduction aims at shedding light on the basic principles of this algorithm and their interplay with sparse recovery and ℓ_1 -minimization.

Denote $\mathcal{F}(y) = \{x : Ax = y\}$ and $\mathcal{N} = \ker A$. The starting point is the trivial observation that $|t| = \frac{t^2}{|t|}$ for $t \neq 0$. Hence, an ℓ_1 -minimization can be recasted into a weighted ℓ_2 -minimization, with the hope that

$$\arg \min_{x \in \mathcal{F}(y)} \sum_{j=1}^N |x_j| \approx \arg \min_{x \in \mathcal{F}(y)} \sum_{j=1}^N x_j^2 |x_j^*|^{-1},$$

as soon as x^* is the desired ℓ_1 -norm minimizer. The advantage of the reformulation consists in the fact that minimizing the smooth quadratic function t^2 is an easier task than the minimization of the nonsmooth function $|t|$. However, the obvious drawbacks are that neither one disposes of x^* a priori (this is the vector one is interested to compute!) nor one can expect that $x_j^* \neq 0$ for all $j = 1, \dots, N$, since one hopes for k -sparse solutions.

Suppose one has a good approximation w_j^n of $|(x_j^*)^2 + \epsilon_n^2|^{-1/2} \approx |x_j^*|^{-1}$, for some $\epsilon_n > 0$. One computes

$$x^{n+1} = \arg \min_{x \in \mathcal{F}(y)} \sum_{j=1}^N x_j^2 w_j^n \quad (45)$$

and then updates $\epsilon_{n+1} \leq \epsilon_n$ by some rule to be specified later. Further, one sets

$$w_j^{n+1} = |(x_j^n)^2 + \epsilon_{n+1}^2|^{-1/2} \quad (46)$$

and iterates the process. The hope is that a proper choice of $\epsilon_n \rightarrow 0$ allows the iterative computation of an ℓ_1 -minimizer. The next sections investigate convergence of this algorithm and properties of the limit.

Weighted ℓ_2 -Minimization

Suppose that the weight w is *strictly positive* which means that $w_j > 0$ for all $j \in \{1, \dots, N\}$. Then $\ell_2(w)$ is a Hilbert space with the inner product

$$\langle u, v \rangle_w := \sum_{j=1}^N w_j u_j v_j. \quad (47)$$

Define

$$x^w := \arg \min_{z \in \mathcal{F}(y)} \|z\|_{2,w}, \quad (48)$$

where $\|z\|_{2,w} = \langle z, z \rangle_w^{1/2}$. Because the $\|\cdot\|_{2,w}$ -norm is strictly convex, the minimizer x^w is necessarily unique; it is characterized by the orthogonality conditions

$$\langle x^w, \eta \rangle_w = 0, \quad \text{for all } \eta \in \mathcal{N}. \quad (49)$$

An Iteratively Re-weighted Least Squares Algorithm (IRLS)

An IRLS algorithm appears for the first time in the Ph.D. thesis of Lawson in 1961 [102], in the form of an algorithm for solving uniform approximation problems. This iterative algorithm is now well known in classical approximation theory as Lawson's algorithm. In [37] it is proved that it obeys a linear convergence rate. In the 1970s, extensions of Lawson's algorithm for ℓ_p -minimization, and in particular ℓ_1 -minimization, were introduced. In signal analysis, IRLS was proposed as a technique to build algorithms for sparse signal reconstruction in [86]. The interplay of the NSP, ℓ_1 -minimization, and a re-weighted least square algorithm has been clarified only recently in the work [44].

The analysis of the algorithm (45) and (46) starts from the observation that

$$|t| = \min_{w>0} \frac{1}{2} (wt^2 + w^{-1}),$$

the minimum being attained for $w = \frac{1}{|t|}$. Inspired by this simple relationship, given a real number $\epsilon > 0$ and a weight vector $w \in \mathbb{R}^N$, with $w_j > 0$, $j = 1, \dots, N$, one introduces the functional

$$\mathcal{J}(z, w, \epsilon) := \frac{1}{2} \sum_{j=1}^N \left(z_j^2 w_j + \epsilon^2 w_j + w_j^{-1} \right), \quad z \in \mathbb{R}^N. \quad (50)$$

The algorithm roughly described in (45) and (46) can be recast as an alternating method for choosing minimizers and weights based on the functional \mathcal{J} . To describe this more rigorously, recall that $r(z)$ denotes the nonincreasing rearrangement of a vector $z \in \mathbb{R}^N$.

Algorithm IRLS. Initialize by taking $w^0 := (1, \dots, 1)$. Set $\epsilon_0 := 1$. Then recursively define, for $n = 0, 1, \dots$,

$$x^{n+1} := \arg \min_{z \in \mathcal{F}(y)} \mathcal{J}(z, w^n, \epsilon_n) = \arg \min_{z \in \mathcal{F}(y)} \|z\|_{2, w^n} \quad (51)$$

and

$$\epsilon_{n+1} := \min \left\{ \epsilon_n, \frac{r_{K+1}(x^{n+1})}{N} \right\}, \quad (52)$$

where K is a fixed integer that will be specified later. Set

$$w^{n+1} := \arg \min_{w > 0} \mathcal{J}(x^{n+1}, w, \epsilon_{n+1}). \quad (53)$$

The algorithm stops if $\epsilon_n = 0$; in this case, define $x^j := x^n$ for $j > n$. In general, the algorithm generates an infinite sequence $(x^n)_{n \in \mathbb{N}}$ of vectors.

Each step of the algorithm requires the solution of a weighted least squares problem. In matrix form

$$x^{n+1} = D_n^{-1} A^* (A D_n^{-1} A^*)^{-1} y, \quad (54)$$

where D_n is the $N \times N$ diagonal matrix the j th diagonal entry of which is w_j^n . Once x^{n+1} is found, the weight w^{n+1} is given by

$$w_j^{n+1} = [(x_j^{n+1})^2 + \epsilon_{n+1}^2]^{-1/2}, \quad j = 1, \dots, N. \quad (55)$$

Convergence Properties

Lemma 3. Set $L := \mathcal{J}(x^1, w^0, \epsilon_0)$. Then

$$\|x^n - x^{n+1}\|_2^2 \leq 2L [\mathcal{J}(x^n, w^n, \epsilon_n) - \mathcal{J}(x^{n+1}, w^{n+1}, \epsilon_{n+1})].$$

Hence $(\mathcal{J}(x^n, w^n, \epsilon_n))_{n \in \mathbb{N}}$ is a monotonically decreasing sequence and

$$\lim_{n \rightarrow \infty} \|x^n - x^{n+1}\|_2^2 = 0.$$

Proof. Note that $\mathcal{J}(x^n, w^n, \epsilon_n) \geq \mathcal{J}(x^{n+1}, w^{n+1}, \epsilon_{n+1})$ for each $n = 1, 2, \dots$, and

$$L = \mathcal{J}(x^1, w^0, \epsilon_0) \geq \mathcal{J}(x^n, w^n, \epsilon_n) \geq (w_j^n)^{-1}, \quad j = 1, \dots, N.$$

Hence, for each $n = 1, 2, \dots$, the following estimates hold:

$$\begin{aligned} & 2[\mathcal{J}(x^n, w^n, \epsilon_n) - \mathcal{J}(x^{n+1}, w^{n+1}, \epsilon_{n+1})] \\ & \geq 2[\mathcal{J}(x^n, w^n, \epsilon_n) - \mathcal{J}(x^{n+1}, w^n, \epsilon_n)] = \langle x^n, x^n \rangle_{w^n} - \langle x^{n+1}, x^{n+1} \rangle_{w^n} \\ & = \langle x^n + x^{n+1}, x^n - x^{n+1} \rangle_{w^n} = \langle x^n - x^{n+1}, x^n - x^{n+1} \rangle_{w^n} \\ & = \sum_{j=1}^N w_j^n (x_j^n - x_j^{n+1})^2 \geq L^{-1} \|x^n - x^{n+1}\|_2^2. \end{aligned}$$

In the third line, it is used that $\langle x^{n+1}, x^n - x^{n+1} \rangle_{w^n} = 0$ due to (49) since $x^n - x^{n+1}$ is contained in \mathcal{N} . \blacksquare

Moreover, if one assumes that $x^n \rightarrow \bar{x}$ and $\epsilon_n \rightarrow 0$, then, formally,

$$\mathcal{J}(x^n, w^n, \epsilon_n) \rightarrow \|\bar{x}\|_1.$$

Hence, one expects that this algorithm performs similar to ℓ_1 -minimization. Indeed, the following convergence result holds.

Theorem 8. Suppose $A \in \mathbb{R}^{m \times N}$ satisfies the NSP of order K with constant $\gamma < 1$. Use K in the update rule (52). Then, for each $y \in \mathbb{R}^m$, the sequence x^n produced by the algorithm converges to a vector \bar{x} , with $r_{K+1}(\bar{x}) = N \lim_{n \rightarrow \infty} \epsilon_n$, and the following holds:

- (i) If $\epsilon = \lim_{n \rightarrow \infty} \epsilon_n = 0$, then \bar{x} is K -sparse; in this case, there is therefore a unique ℓ_1 -minimizer x^* , and $\bar{x} = x^*$; moreover, one has, for $k \leq K$ and any $z \in \mathcal{F}(y)$,

$$\|z - \bar{x}\|_1 \leq \frac{2(1 + \gamma)}{1 - \gamma} \sigma_k(z)_1 \quad (56)$$

- (ii) If $\epsilon = \lim_{n \rightarrow \infty} \epsilon_n > 0$, then $\bar{x} = x^\epsilon := \arg \min_{z \in \mathcal{F}(y)} \sum_{j=1}^N (z_j^2 + \epsilon^2)^{1/2}$.
- (iii) In this last case, if γ satisfies the stricter bound $\gamma < 1 - \frac{2}{K+2}$ (or, equivalently, if $\frac{2\gamma}{1-\gamma} < K$), then one has, for all $z \in \mathcal{F}(y)$ and any $k < K - \frac{2\gamma}{1-\gamma}$, that

$$\|z - \bar{x}\|_1 \leq \tilde{c} \sigma_k(z)_1, \quad \text{with } \tilde{c} := \frac{2(1 + \gamma)}{1 - \gamma} \left[\frac{K - k + \frac{3}{2}}{K - k - \frac{2\gamma}{1-\gamma}} \right] \quad (57)$$

As a consequence, this case is excluded if $\mathcal{F}(y)$ contains a vector of sparsity $k < K - \frac{2\gamma}{1-\gamma}$.

Note that the approximation properties (56) and (57) are exactly of the same order as the one (6) provided by ℓ_1 -minimization. However, in general, \bar{x} is not necessarily an ℓ_1 -minimizer, unless it coincides with a sparse solution. The proof of this result is not included and the interested reader is referred to [44, 69] for the details.

Rate of Convergence

It is instructive to show a further result concerning the local rate of convergence of this algorithm, which again uses the NSP as well as the optimality conditions introduced above. One assumes here that $\mathcal{F}(y)$ contains the k -sparse vector x^* . The algorithm produces a sequence x^n , which converges to x^* , as established above. One denotes the (unknown) support of the k -sparse vector x^* by T .

For now, one introduces an auxiliary sequence of error vectors $\eta^n \in \mathcal{N}$ via $\eta^n := x^n - x^*$ and

$$E_n := \|\eta^n\|_1 = \|x^* - x^n\|_1.$$

Theorem 8 guarantees that $E_n \rightarrow 0$ for $n \rightarrow \infty$. A useful technical result is reported next.

Lemma 4. *For any $z, z' \in \mathbb{R}^N$, and for any j ,*

$$|\sigma_j(z)_1 - \sigma_j(z')_1| \leq \|z - z'\|_1, \quad (58)$$

while for any $J > j$,

$$(J - j)r_J(z) \leq \|z - z'\|_1 + \sigma_j(z')_1. \quad (59)$$

Proof. To prove (58), approximate z by a best j -term approximation $z'_{[j]} \in \Sigma_j$ of z' in ℓ_1 . Then

$$\sigma_j(z)_1 \leq \|z - z'_{[j]}\|_1 \leq \|z - z'\|_1 + \sigma_j(z')_1,$$

and the result follows from symmetry. To prove (59), it suffices to note that $(J - j)r_J(z) \leq \sigma_j(z)_1$. ■

The following theorem gives a bound on the rate of convergence of E_n to zero.

Theorem 9. *Assume A satisfies the NSP of order K with constant γ . Suppose that $k < K - \frac{2\gamma}{1-\gamma}$, $0 < \rho < 1$, and $0 < \gamma < 1 - \frac{2}{K+2}$ are such that*

$$\mu := \frac{\gamma(1+\gamma)}{1-\rho} \left(1 + \frac{1}{K+1-k} \right) < 1.$$

Assume that $\mathcal{F}(y)$ contains a k -sparse vector x^ and let $T = \text{supp}(x^*)$. Let n_0 be such that*

$$E_{n_0} \leq R^* := \rho \min_{i \in T} |x_i^*|. \quad (60)$$

Then, for all $n \geq n_0$, one has

$$E_{n+1} \leq \mu E_n. \quad (61)$$

Consequently, x^n converges to x^* exponentially.

Proof. The relation (49) with $w = w^n$, $x^w = x^{n+1} = x^* + \eta^{n+1}$, and $\eta = x^{n+1} - x^* = \eta^{n+1}$ gives

$$\sum_{i=1}^N (x_i^* + \eta_i^{n+1}) \eta_i^{n+1} w_i^n = 0.$$

Rearranging the terms and using the fact that x^* is supported on T , one obtains

$$\sum_{i=1}^N |\eta_i^{n+1}|^2 w_i^n = - \sum_{i \in T} x_i^* \eta_i^{n+1} w_i^n = - \sum_{i \in T} \frac{x_i^*}{[(x_i^n)^2 + \epsilon_n^2]^{1/2}} \eta_i^{n+1}. \quad (62)$$

The proof of the theorem is by induction. Assume that $E_n \leq R^*$ has already been established. Then, for all $i \in T$,

$$|\eta_i^n| \leq \|\eta^n\|_1 = E_n \leq \rho|x_i^*|,$$

so that

$$\frac{|x_i^*|}{[(x_i^n)^2 + \epsilon_n^2]^{1/2}} \leq \frac{|x_i^*|}{|x_i^n|} = \frac{|x_i^*|}{|x_i^* + \eta_i^n|} \leq \frac{1}{1-\rho} \quad (63)$$

and hence (62) combined with (63) and the NSP gives

$$\sum_{i=1}^N |\eta_i^{n+1}|^2 w_i^n \leq \frac{1}{1-\rho} \|\eta_T^{n+1}\|_1 \leq \frac{\gamma}{1-\rho} \|\eta_{T^c}^{n+1}\|_1$$

The Cauchy–Schwarz inequality combined with the above estimate yields

$$\begin{aligned} \|\eta_{T^c}^{n+1}\|_1^2 &\leq \left(\sum_{i \in T^c} |\eta_i^{n+1}|^2 w_i^n \right) \left(\sum_{i \in T^c} [(x_i^n)^2 + \epsilon_n^2]^{1/2} \right) \\ &= \left(\sum_{i=1}^N |\eta_i^{n+1}|^2 w_i^n \right) \left(\sum_{i \in T^c} [(\eta_i^n)^2 + \epsilon_n^2]^{1/2} \right) \\ &\leq \frac{\gamma}{1-\rho} \|\eta_{T^c}^{n+1}\|_1 (\|\eta^n\|_1 + N\epsilon_n). \end{aligned} \quad (64)$$

If $\eta_{T^c}^{n+1} = 0$, then $x_{T^c}^{n+1} = 0$. In this case x^{n+1} is k -sparse and the algorithm has stopped by definition; since $x^{n+1} - x^*$ is in the null space \mathcal{N} , which contains no k -sparse elements other than 0, one has already obtained the solution $x^{n+1} = x^*$. If $\eta_{T^c}^{n+1} \neq 0$, then canceling the factor $\|\eta_{T^c}^{n+1}\|_1$ in (64) yields

$$\|\eta_{T^c}^{n+1}\|_1 \leq \frac{\gamma}{1-\rho} (\|\eta^n\|_1 + N\epsilon_n),$$

and thus

$$\|\eta^{n+1}\|_1 = \|\eta_T^{n+1}\|_1 + \|\eta_{T^c}^{n+1}\|_1 \leq (1+\gamma)\|\eta_{T^c}^{n+1}\|_1 \leq \frac{\gamma(1+\gamma)}{1-\rho} (\|\eta^n\|_1 + N\epsilon_n). \quad (65)$$

Now, by (52) and (59), it follows

$$N\epsilon_n \leq r_{K+1}(x^n) \leq \frac{1}{K+1-k} (\|x^n - x^*\|_1 + \sigma_k(x^*)_1) = \frac{\|\eta^n\|_1}{K+1-k}, \quad (66)$$

since by assumption $\sigma_k(x^*)_1 = 0$. Together with (65), this yields the desired bound:

$$E_{n+1} = \|\eta^{n+1}\|_1 \leq \frac{\gamma(1+\gamma)}{1-\rho} \left(1 + \frac{1}{K+1-k} \right) \|\eta^n\|_1 = \mu E_n.$$

In particular, since $\mu < 1$, one has $E_{n+1} \leq R^*$, which completes the induction step. It follows that $E_{n+1} \leq \mu E_n$ for all $n \geq n_0$. \blacksquare

The linear rate (61) can be improved significantly, by a very simple modification of the rule of updating the weight:

$$w_j^{n+1} = \left((x_j^{n+1})^2 + \epsilon_{n+1}^2 \right)^{-\frac{2-\tau}{2}}, \quad j = 1, \dots, N, \text{ for any } 0 < \tau < 1.$$

This corresponds to the substitution of the function \mathcal{J} with

$$\mathcal{J}_\tau(z, w, \epsilon) := \frac{\tau}{2} \sum_{j=1}^N \left(z_j^2 w_j + \epsilon^2 w_j + \frac{2-\tau}{\tau} \frac{1}{w_j^{\frac{\tau}{2-\tau}}} \right),$$

where $z \in \mathbb{R}^N$, $w \in \mathbb{R}_+^N$, $\epsilon \in \mathbb{R}_+$. With this new up-to-date rule for the weight, which depends on $0 < \tau < 1$, one has formally, for $x^n \rightarrow \bar{x}$ and $\epsilon_n \rightarrow 0$,

$$\mathcal{J}_\tau(x^n, w^n, \epsilon_n) \rightarrow \|\bar{x}\|_\tau^\tau.$$

Hence such an iterative optimization tends to promote the ℓ_τ -quasi-norm minimization.

Surprisingly the rate of local convergence of this modified algorithm is superlinear; the rate is larger for smaller τ and approaches a quadratic rate as $\tau \rightarrow 0$. More precisely, the local error $E_n := \|x^n - x^*\|_\tau^\tau$ satisfies

$$E_{n+1} \leq \mu(\gamma, \tau) E_n^{2-\tau}, \quad (67)$$

where $\mu(\gamma, \tau) < 1$ for $\gamma > 0$ sufficiently small. The validity of (67) is restricted to x^n in a (small) ball centered at x^* . In particular, if x^0 is close enough to x^* , then (67) ensures the convergence of the algorithm to the k -sparse solution x^* ; see Fig. 4.

Numerical Experiments

Figure 5 shows a typical *phase transition* diagram related to the (experimentally determined) probability of successful recovery of sparse vectors by means of the iteratively re-weighted least squares algorithm. For each point of this diagram with coordinates $(m/N, k/m) \in [0, 1]^2$, one shows the empirical success probability of recovery of a k -sparse vector $x \in \mathbb{R}^N$ from m measurements $y = Ax$. The brightness level corresponds to the probability. As measurement matrix a real random Fourier type matrix A was used, with entries given by

$$A_{k,j} = \cos(2\pi j \xi_k), \quad j = 1, \dots, N,$$

and the ξ_k , $k = 1, \dots, m$, are sampled independently and uniformly at random from $[0, 1]$. (Theorem 5 does not apply directly to real random Fourier matrices, but an analogous result concerning the RIP for such matrices can be found in [131].)

Figure 6 shows a section of a phase transition diagram related to the (experimentally determined) probability of successful recovery of sparse vectors from linear measurements $y = Ax$, where the matrix A has i.i.d. Gaussian entries. Here both m and N are fixed and only k is variable. This diagram establishes the transition from a situation of exact reconstruction for sparse vectors with high probability to very unlikely recovery for vectors with many nonzero entries. These numerical experiments used the iteratively re-weighted least squares algorithm with different parameters $0 < \tau \leq 1$. It is of interest to emphasize the enhanced success rate when using the algorithm for $\tau < 1$. Similarly, many other algorithms are tested by showing the corresponding phase transition diagrams and comparing them; see [12] for a detailed account of phase transitions for greedy algorithms and [49, 54] for ℓ_1 -minimization.

This section is concluded by showing applications of ℓ_1 -minimization methods to a real-life image recolorization problem [70, 71] in Fig. 7. The image is known completely only on very few colored portions, while on the remaining areas, only gray levels are provided. With this partial information, the use of ℓ_1 -minimization with respect to wavelet or curvelet coefficients allows for high fidelity recolorization of the whole images.

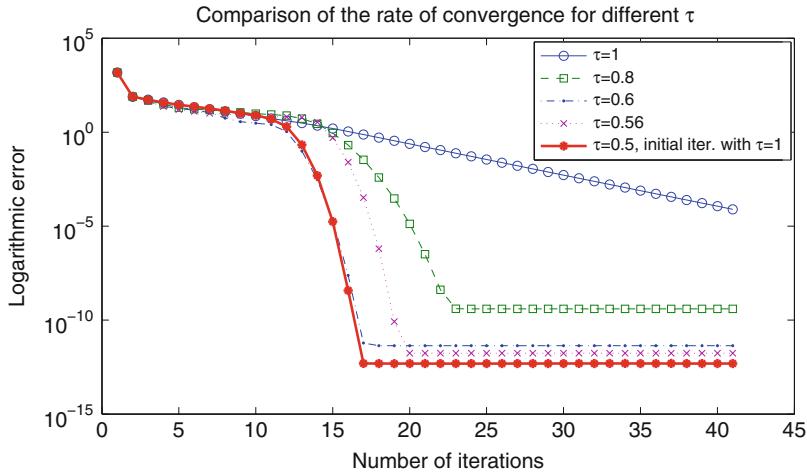

Fig. 4 The decay of logarithmic error is shown, as a function of the number of iterations of IRLS for different values of τ (1, 0.8, 0.6, 0.56). The results of an experiment are also shown, in which the initial 10 iterations are performed with $\tau = 1$ and the remaining iterations with $\tau = 0.5$

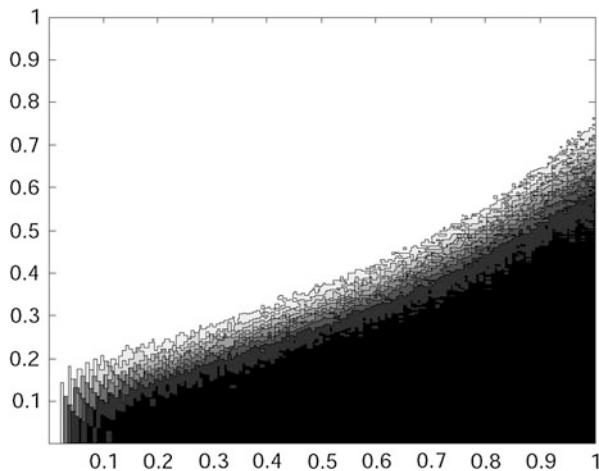

Fig. 5 Empirical success probability of recovery of k -sparse vectors $x \in \mathbb{R}^N$ from measurements $y = Ax$, where $A \in \mathbb{R}^{m \times N}$ is a real random Fourier matrix. The dimension $N = 300$ of the vectors is fixed. Each point of this diagram with coordinates $(m/N, k/m) \in [0, 1]^2$ indicates the empirical success probability of recovery, which is computed by running 100 experiments with randomly generated k -sparse vectors x and randomly generated matrix. The algorithm used for the recovery is the iteratively re-weighted least squares method tuned to promote ℓ_1 -minimization

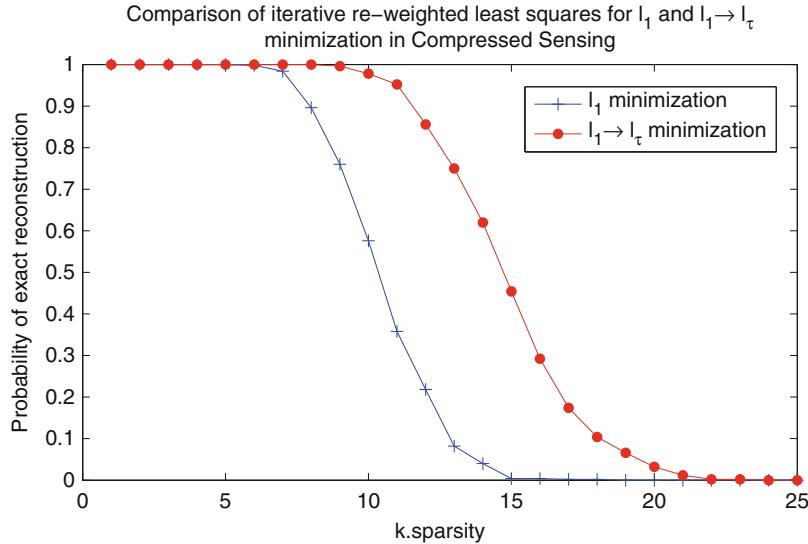

Fig. 6 Empirical success probability of recovery of a k -sparse vector $x \in \mathbb{R}^{250}$ from measurements $y = Ax$, where $A \in \mathbb{R}^{50 \times 250}$ is Gaussian. The matrix is generated once; then, for each sparsity value k shown in the plot, 500 attempts were made, for randomly generated k -sparse vectors x . Two different IRLS algorithms were compared: one with weights inspired by ℓ_1 -minimization and the IRLS with weights that gradually moved during the iterations from an ℓ_1 -to an ℓ_τ -minimization goal, with final $\tau = 0.5$

Fig. 7 Iterations of the recolorization methods proposed in [70, 71] via ℓ_1 and total variation minimization, for the virtual restoration of the frescoes of A. Mantegna (1452), which were destroyed by a bombing during World War II. Only a few colored fragments of the images were saved from the disaster, together with good quality gray-level pictures dated to 1920

Extensions to Affine Low-Rank Minimization

Reformulated as a semidefinite program, the nuclear norm minimization (25) can be solved also by general methods from convex optimization [17]. Unfortunately, standard semidefinite programming tools work efficiently for solving nuclear norm minimization problems only for matrices up to size approximately 100×100 .

Therefore, it is crucial to develop fast algorithms that are specialized to nuclear norm minimization (or other heuristics for rank minimization). Beside the already mentioned primal-dual algorithm of Sect. 4, several alternative approaches have been suggested so far; see, for instance, [20, 85, 97, 98, 104].

Borrowing a leaf from iteratively re-weighted least squares for ℓ_1 -minimization, this section discusses an algorithm inspired by (25). Assume $X \in M_{n \times p}$, $0 \prec W = W^* \in M_{n \times n}$, and consider the functional,

$$\mathcal{J}(X, W) := \frac{1}{2} (\|W^{1/2} X\|_F^2 + \|W^{-1/2}\|_F^2), \quad (68)$$

where $\|\cdot\|_F$ is the Frobenius norm. In order to define the iteration below, one recalls that $\sigma_k(X)$ denotes the k th singular value of a matrix X .

IRLS-M algorithm for low-rank matrix recovery: Initialize by taking $W^0 := I \in M_{n \times n}$. Set $\varepsilon_0 := 1$, $K \geq k$, and $\gamma > 0$. Then recursively define, for $\ell = 1, 2, \dots$,

$$X^\ell := \arg \min_{\mathcal{S}(X) = \mathcal{M}} \mathcal{J}(X, W^\ell)$$

and

$$\varepsilon_\ell := \min \{\varepsilon_{\ell-1}, \gamma \sigma_{K+1}(X^\ell)\}. \quad (69)$$

The update of the weight matrix W^ℓ follows the variational principle

$$W^\ell := \arg \min_{0 \prec W = W^* \leq \varepsilon_\ell^{-1} I} \mathcal{J}(X^\ell, W) \quad (70)$$

The algorithm stops if $\varepsilon_\ell = 0$; in this case, define $X^j := X^\ell$ for $j > \ell$. In general, the algorithm generates an infinite sequence $(X^\ell)_{\ell \in \mathbb{N}}$ of matrices.

The following convergence result can be shown with an analysis similar to the one done for the IRLS for sparse vector recovery, under the assumption that the measurement map \mathcal{S} satisfies the restricted isometry property in Definition 4. One refers to [73] for details.

Proposition 2. *Consider the IRLS-M algorithm with parameters $\gamma = 1/n$ and $K \in \mathbb{N}$. Let $\mathcal{S} : M_{n \times p} \rightarrow \mathbb{C}^m$ be a surjective map with restricted isometry constants δ_{3K}, δ_{4K} satisfying $\eta = \frac{\sqrt{2}\delta_{4K}}{1-\delta_{3K}} < 1 - \frac{2}{K-2}$. Then, if there exists a k -rank matrix X satisfying $\mathcal{S}(X) = \mathcal{M}$ with $k < K - \frac{2\eta}{1-\eta}$, the sequence $(X^\ell)_{\ell \in \mathbb{N}}$ converges to X .*

Actually, one can prove something stronger: the IRLS-M algorithm is *robust*, in the sense that under the same conditions on the measurement map \mathcal{S} , the accumulation points of the IRLS-M algorithm are guaranteed to approximate an

arbitrary $X \in M_{n \times p}$ from the measurements $\mathcal{M} = \mathcal{S}(X)$ to within a factor of the *best k-rank approximation error* of X in the nuclear norm.

By combining both IRLS and IRLS-M, one can formulate an iteratively re-weighted least squares to solve also mixed problems of the type (35).

5 Open Questions

The field of compressed sensing is rather young, so there remain many directions to be explored, and it is impossible to give an exhaustive list here. Below, we focus on two problems which seem to be rather hard and remained unsolved until the time of writing of this article.

Deterministic Compressed Sensing Matrices

So far, only several types of random matrices $A \in \mathbb{C}^{m \times N}$ are known to satisfy the RIP $\delta_s \leq \delta \leq 0.4$ (say) for

$$m = C_\delta s \log^\alpha(N) \quad (71)$$

for some constant C_δ and some exponent α (with high probability). This is a strong form of existence statement. It is open, however, to provide deterministic and explicit $m \times N$ matrices that satisfy the RIP $\delta_s \leq \delta \leq 0.5$ (say) in the desired range (71).

In order to show RIP estimates in the regime (71), one has to take into account cancellations of positive and negative (or more generally complex) entries in the matrix; see also Sect. 3. This is done “automatically” with probabilistic methods but seems to be much more difficult to exploit when the given matrix is deterministic. It may be conjectured that certain equiangular tight frames or the “Alltop matrix” in [123, 143] do satisfy the RIP under (71). This is supported by numerical experiments in [123]. It is expected, however, that a proof is very hard and requires a good amount of analytic number theory. An involved deterministic construction that achieves the RIP in the regime $m \geq C s^{2-\varepsilon}$ – overcoming the quadratic bottleneck inherent to bounds via the coherence – was provided in [15, 16], but the best available estimates of ε are in the range of 10^{-26} [112]. One refers to [76, Chapter 6] for more background information on deterministic RIP matrices.

Another approach for deterministic constructions of CS matrices uses deterministic expander graphs [11]. Instead of the usual RIP, one shows that the adjacency matrix of such an expander graph has the 1-RIP, where the ℓ_2 -norm is replaced by the ℓ_1 -norm at each occurrence in (8). The 1-RIP also implies recovery by ℓ_1 -minimization. The best known deterministic expanders [33] yield sparse recovery under the condition $m \geq C s (\log N)^{c \log^2(N)}$. Although the scaling in s is linear as desired, the term $(\log N)^{c \log^2(N)}$ grows faster than any polynomial in $\log N$.

Another drawback is that the deterministic expander graph is the output of a polynomial time algorithm, and it is questionable whether the resulting matrix can be regarded as *explicit*.

Removing Log-Factors in the Fourier-RIP Estimate

It is known [26, 76, 129, 131, 138] that a random partial Fourier matrix $A \in \mathbb{C}^{m \times N}$ satisfies the RIP with high probability provided

$$\frac{m}{\log(m)} \geq C_\delta s \log^2(s) \log(N).$$

(The condition stated in (19) implies this one.) It is conjectured that one can remove some of the log-factors. It must be hard, however, to improve this to a better estimate than $m \geq C_{\delta,\epsilon} s \log(N) \log(\log N)$. Indeed, this would imply an open conjecture of Talagrand [146] concerning the equivalence of the ℓ_1 and ℓ_2 norm of a linear combination of a subset of characters (complex exponentials). One refers to [76, Chapter 12.7] for more details.

Compressive Sensing with Nonlinear Measurements

As described in Sect. 3, the extension of compressed sensing towards nonlinear measurements is linked through the solution of problems of the type (35) which lead to semidefinite programming. Although some progress has been achieved, there is still the need to develop highly efficient algorithms for solving such problems in large dimensions. Besides these more practical aspects, also theoretical guarantees for algorithms to stably recover nearly sparse solutions consistent with given nonlinear measurements, for instance, phase retrieval problems beyond the case of Gaussian measurements, are a current field of very active research.

6 Conclusion

Compressive sensing established itself by now as a new sampling theory which exhibits fundamental and intriguing connections with several mathematical fields, such as probability, geometry of Banach spaces, harmonic analysis, theory of computability, and information-based complexity. The link to convex optimization and the development of very efficient and robust numerical methods make compressive sensing a concept useful for a broad spectrum of natural science and engineering applications, in particular, in signal and image processing and acquisition. It can be expected that compressive sensing will enter various branches of science and technology to notable effect.

New challenges are now emerging in numerical analysis and simulation where high-dimensional problems (e.g., stochastic partial differential equations in finance and electron structure calculations in chemistry and biochemistry) became the frontier. In this context, besides other forms of efficient approximation, such as sparse grid and tensor product methods [18], compressive sensing is a promising concept which is likely to cope with the “curse of dimensionality.” In particular, further systematic developments of adaptivity in the presence of different scales, randomized algorithms, and an increasing role for combinatorial aspects of the underlying algorithms are examples of possible future developments, which are inspired by the successful history of compressive sensing [145].

Abstract

This chapter surveys key concepts in convex duality theory and their application to the analysis and numerical solution of problem archetypes in imaging.

Convex analysis, Variational analysis, Duality

1 Introduction

An image is worth a thousand words, the joke goes, but takes up a million times the memory – all the more reason to be efficient when computing with images. Whether one is determining a “best” image according to some criteria or applying a “fast” iterative algorithm for processing images, the theory of optimization and variational analysis lies at the heart of achieving these goals. Success or failure hinges on the abstract structure of the task at hand. For many practitioners, these details are secondary: if the picture looks good, it *is* good. For the specialist in variational analysis and optimization, however, it is what is went into constructing the image that matters: if it is *convex*, it is good.

This chapter surveys more than a half-a-century of work in convex analysis that has played a fundamental role in the development of computational imaging and brings to light as many of the contributors to this field as possible. There is no shortage of good books on convex and variational analysis; interested readers are referred to the modern references [4, 6, 24, 27, 31, 49, 61, 71, 72, 80, 93, 99, 103, 106, 107, 110, 111, 118]. References focused more on imaging and signal processing, but with a decidedly variational flavor, include [3, 39, 109]. For general references on numerical optimization, see [21, 35, 42, 86, 97, 117].

For many years, the dominant distinction in applied mathematics between problem types has rested upon linearity, or lack thereof. This categorization still holds sway today with nonlinear problems largely regarded as “hard,” while linear problems are generally considered “easy.” But since the advent of the *interior point revolution* [96], at least in linear optimization, it is more or less agreed that *nonconvexity*, not nonlinearity, more accurately delineates hard from easy. The goal of this chapter is to make this case more broad. Indeed, for convex sets topological, algebraic, and geometric notions often coincide, and so the tools of convex analysis provide not only for a tremendous synthesis of ideas but also for key insights, whose dividends are efficient algorithms for solving large (*infinite dimensional*) problems, and indeed even large *nonlinear* problems.

This chapter concerns different instances of a single optimization model. This model accounts for the vast majority of variational problems appearing in imaging science:

$$\begin{aligned} & \underset{x \in C \subset X}{\text{minimize}} && I_\varphi(x) \\ & \text{subject to} && Ax \in D. \end{aligned} \tag{1}$$

Here, X and Y are real Banach spaces with continuous duals X^* and Y^* , C and D are closed and convex, $A : X \rightarrow Y$ is a continuous linear operator, and the integral functional $I_\varphi(x) := \int_T \varphi(x(t))\mu(dt)$ is defined on some vector subspace $L_p(T, \mu)$ of X for μ , a complete totally finite measure on some measure space T . The integral operator I_φ is an *entropy* with integrand $\varphi : \mathbb{R} \rightarrow]-\infty, +\infty]$ a closed convex function. This provides an extremely flexible framework that specializes to most of the instances of interest and is general enough to extend results to non-Hilbert space settings. The most common examples are

$$\text{Burg entropy: } \varphi(x) := -\ln(x) \tag{2}$$

$$\text{Shannon–Boltzmann entropy: } \varphi(x) := x \ln(x) \tag{3}$$

$$\text{Fermi–Dirac entropy: } \varphi(x) := x \ln(x) + (1-x) \ln(1-x) \tag{4}$$

$$L_p \text{ norm } \varphi(x) := \frac{\|x\|^p}{p} \tag{5}$$

$$L_p \text{ entropy } \varphi(x) := \begin{cases} \frac{x^p}{p} & x \geq 0 \\ +\infty & \text{else} \end{cases} \tag{6}$$

$$\text{Total variation } \varphi(x) := |\nabla x|. \tag{7}$$

See [18, 25, 26, 34, 37, 43, 44, 56, 64, 112] for these and other entropies.

There is a rich correspondence between the algorithmic approach to applications implicit in the variational formulation (1) and the prevalent *feasibility* approach to problems. Here, one considers the problem of finding the point x that lies in the intersection of the constraint sets:

$$\text{find } x \in C \cap S \quad \text{where} \quad S := \{x \in X \mid Ax \in D\}.$$

In the case where the intersection is quite large, one might wish to find the point in the intersection in some sense closest to a reference point x_0 (frequently the origin). It is the job of the objective in (1) to pick the element of $C \cap S$ that has the desired properties, that is, to pick the *best approximation*. The feasibility formulation suggests very naturally projection algorithms for finding the intersection whereby one applies the constraints one at a time in some fashion, e.g., cyclically, or at random [5, 30, 42, 51, 52, 119]. This is quite a powerful framework as it provides a great deal of flexibility and is amenable to parallelization for large-scale problems. Many of the algorithms for feasibility problems have counterparts for the more general best approximation problems [6, 9, 10, 58, 88]. For studies of these algorithms in nonconvex settings, see [2, 7, 8, 11–14, 29, 38, 53, 68, 78, 79, 87–89]. The projection

algorithms that are central to convex feasibility and best approximation problems play a key role in algorithms for solving the problems considered here.

Before detailing specific applications, it is useful to state a general duality result for problem (1) that motivates the convex analytic approach. One of the more central tools is the *Fenchel conjugate* [62] of a mapping $f : X \rightarrow [-\infty, +\infty]$, denoted $f^* : X^* \rightarrow [-\infty, +\infty]$ and defined by

$$f^*(x^*) = \sup_{x \in X} \{ \langle x^*, x \rangle - f(x) \}.$$

The conjugate is always convex (as a supremum of affine functions), while $f = f^{**}|_X$ exactly if f is convex, proper (not everywhere infinite), and lower semi-continuous (lsc) [24, 61]. Here and below, unless otherwise specified, X is a normed space with dual X^* . The following theorem uses constraint qualifications involving the concept of the *core* of a set, the *effective domain* of a function ($\text{dom } f$), and the points of continuity of a function ($\text{cont } f$).

Definition 1 (Core). The core of a set $F \subset X$ is defined by $x \in \text{core } F$ if for each $h \in \{x \in X \mid \|x\| = 1\}$, there exists $\delta > 0$ so that $x + th \in F$ for all $0 \leq t \leq \delta$.

It is clear from the definition that $\text{int } F \subset \text{core } F$. If F is a convex subset of a Euclidean space, or if F is closed, then the core and the interior are identical [27, Theorem 4.1.4].

Theorem 1 (Fenchel Duality [24, Theorems 2.3.4 and 4.4.18]). Let X and Y be Banach spaces, let $f : X \rightarrow (-\infty, +\infty]$ and $g : Y \rightarrow (-\infty, +\infty]$ and let $A : X \rightarrow Y$ be a bounded linear map. Define the primal and dual values $p, d \in [-\infty, +\infty]$ by the Fenchel problems

$$\begin{aligned} p &= \inf_{x \in X} \{f(x) + g(Ax)\} \\ d &= \sup_{y^* \in Y^*} \{-f^*(A^*y^*) - g^*(-y^*)\}. \end{aligned} \tag{8}$$

Then these values satisfy the weak duality inequality $p \geq d$.

If f, g are convex and satisfy either

$$0 \in \text{core}(\text{dom } g - A \text{dom } f) \quad \text{with } f \text{ and } g \text{ lsc}, \tag{9}$$

or

$$A \text{dom } f \cap \text{cont } g \neq \emptyset, \tag{10}$$

then $p = d$, and the supremum to the dual problem is attained if finite.

Applying Theorem 1 to problem (1) yields $f(x) = I_\varphi(x) + \iota_C(x)$ and $g(y) = \iota_D(y)$ where ι_F is the *indicator function* of the set F :

$$\iota_F(x) := \begin{cases} 0 & \text{if } x \in F \\ +\infty & \text{else.} \end{cases} \quad (11)$$

The tools of convex analysis and the phenomenon of duality are central to formulating, analyzing, and solving application problems. Already apparent from the general application above is the necessity for a calculus of Fenchel conjugation in order to compute the conjugate of sums of functions. In some specific cases, one can arrive at the same conclusion with less theoretical overhead, but this is at the cost of missing out more general structures that are not necessarily automatic in other settings.

Duality has a long-established place in economics where primal and dual problems have direct interpretations in the context of the theory of zero-sum games, or where Lagrange multipliers and dual variables are understood, for instance, as shadow prices. In imaging, there is not as often an easy interplay between the physical interpretation of primal and dual problems. Duality has been used toward a variety of ends in contemporary image and signal processing, the majority of them, however, having to do with algorithms [17, 33, 34, 43–46, 54, 55, 57, 70, 73, 90, 116]. Nevertheless, the dual perspective yields new statistical or information theoretic insight into image processing problems, in addition to faster algorithms. Since the publication of the first edition of this handbook, interest in convex duality theory has only continued to grow. This is, in part, due to the now ubiquitous application of convex duality techniques to nonconvex problems; as heuristics, through appropriate convex relaxations, or otherwise [48, 114, 115]. As a measure of this growing interest, a *Web of Science* search for articles published between 2011 and 2013 having either “convex relaxation” or “primal dual” in the title, abstract, or keywords, returns a combined count of approximately 1,500 articles.

Modern optimization packages heavily exploit duality and convex analysis. A new trend that has matured in recent years is the field of *computational convex analysis* which employs symbolic, numerical, and hybrid computations of objects like the Fenchel conjugate [23, 65, 81–85, 91, 98]. Software suites that rely heavily on a convex duality approach include: CCA (Computational Convex Analysis, <http://atoms.scilab.org/toolboxes/CCA>) for *Scilab*, CVX and its extensions (<http://cvxr.com/cvx/>) for *MATLAB* (including a *C* code generator) [65, 91], and S-CAT (Symbolic Convex Analysis Toolkit, <http://web.cs.dal.ca/~chamilton/research.html>) for *Maple* [23]. For a review of the computational aspects of convex analysis see [84].

In this chapter, five main applications illustrate the variational analytical approach to problem solving: linear inverse problems with convex constraints, compressive imaging, image denoising and deconvolution, nonlinear inverse scattering, and finally Fredholm integral equations. A brief review of these applications is presented below. Subsequent sections develop the tools for their

analysis. At the end of the chapter these applications are revisited in light of the convex analytical tools collected along the way.

The application of compressive sensing, or more generally sparsity optimization leads to a new theme that is emerging out of the theory of convex relaxations for nonconvex problems, namely direct global *nonconvex* methods for structured *nonconvex* optimization problems. Starting with the seminal papers of Candès and Tao [40, 41], the theory of convex relaxation for finding the sparsest vector satisfying an underdetermined affine constraint has concentrated on determining sufficient conditions under which the solution to a relaxation of the problem to ℓ_1 minimization with an affine equality constraint corresponds exactly to the global solution of the original nonconvex sparsity optimization problem. These conditions have been used in recent years to guarantee global convergence of simple projected gradient- and alternating projections-type algorithms for solving simpler nonconvex optimization problems whose global solutions correspond to a solution of the original problem (see [15, 16, 19, 20, 63, 69] and references therein). This is the natural point at which this chapter leaves off, and the frontier of *nonconvex* programming begins.

Linear Inverse Problems with Convex Constraints

Let X be a Hilbert space and $\varphi(x) := \frac{1}{2}\|x\|^2$. The integral functional I_φ is the usual L_2 norm and the solution is the closest feasible point to the origin:

$$\begin{aligned} & \underset{x \in C \subset X}{\text{minimize}} && \frac{1}{2}\|x\|^2 \\ & \text{subject to} && Ax = b. \end{aligned} \tag{12}$$

Levi, for instance, used this variational formulation to determine the minimum energy band-limited signal that matched N measurements $b \in \mathbb{R}^n$ with the model $A : X \rightarrow \mathbb{R}^n$ [77]. Note that the signal space is infinite dimensional while the measurement space is finite dimensional, a common situation in practice. Potter and Arun [100] recognized a much broader applicability of this variational formulation to remote sensing and medical imaging and applied duality theory to characterize solutions to (12) by $\bar{x} = P_C A^*(\bar{y})$, where $\bar{y} \in Y$ satisfies $b = AP_C A^* \bar{y}$ [100, Theorem 1]. Particularly attractive is the feature that when Y is finite dimensional, these formulas yield a finite dimensional approach to an infinite dimensional problem. The numerical algorithm suggested by Potter and Arun is an iterative procedure in the dual variables:

$$y_{j+1} = y_j + \gamma(b - AP_C A^* y_j) \quad j = 0, 1, 2, \dots \tag{13}$$

The optimality condition and numerical algorithms are explored at the end of this chapter.

As satisfying as this theory is, there is a crucial assumption in the theorem of Potter and Arun about the existence of $\bar{y} \in Y$ such that $b = AP_C A^* \bar{y}$; one need only to consider linear least squares, for an example, where the primal problem is well posed, but no such \bar{y} exists [22]. A specialization of Theorem 1 to the case of linear constraints facilitates the argument. The next corollary is a specialization of Theorem 1, where g is the indicator function of the point b in the linear constraint.

Corollary 1 (Fenchel Duality for Linear Constraints). *Given any $f : X \rightarrow (-\infty, \infty]$, any bounded linear map $A : X \rightarrow Y$, and any element $b \in Y$, the following weak duality inequality holds:*

$$\inf_{x \in X} \{f(x) \mid Ax = b\} \geq \sup_{y^* \in Y^*} \{ \langle b, y^* \rangle - f^*(A^* y^*) \}.$$

If f is lsc and convex and $b \in \text{core}(A \text{ dom } f)$, then equality holds and the supremum is attained if finite.

Suppose that $C = X$, a Hilbert space and $A : X \rightarrow X$. The Fenchel dual to (12) is

$$\underset{y \in X}{\text{maximize}} \quad \langle y, b \rangle - \frac{1}{2} \|A^* y\|^2. \quad (14)$$

(The L_2 norm is self-dual.) Suppose that the primal problem (12) is *feasible*, that is, $b \in \text{range}(A)$. The objective in (14) is convex and differentiable, so elementary calculus (Fermat's rule) yields the optimal solution \bar{y} with $AA^*\bar{y} = b$, assuming \bar{y} exists. If the range of A is strictly larger than that of AA^* , however, it is possible to have $b \in \text{range}(A)$ but $b \notin \text{range}(AA^*)$, in which case the optimal solution \bar{x} to (12) is *not* equal to $A^*\bar{y}$, since \bar{y} is not attained. For a concrete example see [22, Example 2.1].

Imaging with Missing Data

Let $X = \mathbb{R}^n$ and $\varphi(x) := \|x\|_p$ for $p = 0$ or $p = 1$. The case $p = 1$ is the ℓ_1 norm, and by $\|x\|_0$ is meant the function

$$\|x\|_0 := \sum_j |\text{sign}(x_j)|,$$

where $\text{sign}(0) := 0$. This yields the optimization problem

$$\begin{array}{ll} \underset{x \in \mathbb{R}^n}{\text{minimize}} & \|x\|_p \\ \text{subject to} & Ax = b. \end{array} \quad (15)$$

This model has received a great deal of attention recently in applications of compressive sensing where the number of measurements is much smaller than the dimension of the signal space, that is, $b \in \mathbb{R}^m$ for $m \ll n$. This problem is well known in statistics as the missing data problem.

For ℓ_1 optimization ($p = 1$), the seminal work of Candès and Tao establishes probabilistic criteria for when the solution to (15) is unique and exactly matches the true signal x_* [41]. Sparsity of the original signal x_* and the algebraic structure of the matrix A are key requirements. Convex analysis easily yields a geometric interpretation of these facts. The dual to this problem is the linear program

$$\begin{aligned} & \underset{y \in \mathbb{R}^m}{\text{maximize}} && b^T y \\ & \text{subject to} && (A^* y)_j \in [-1, 1] \quad j = 1, 2, \dots, n. \end{aligned} \tag{16}$$

Deriving this dual is one of the goals of this chapter. Elementary facts from linear programming guarantee that the solution includes a vertex of the polyhedron described by the constraints, and hence, assuming A is full rank, there can be at most m active constraints. The number of active constraints in the dual problem provides an upper bound on the number of nonzero elements in the primal variable – the signal to be recovered. Unless the number of nonzero elements of x_* is less than the number of measurements m , there is no hope of uniquely recovering x_* . The uniqueness of solutions to the primal problem is easily understood in terms of the geometry of the dual problem, that is, whether or not solutions to the dual problem reside along the edges or faces of the polyhedron. More refined details about *how* sparse x_* needs to be in order to have a reasonable hope of exact recovery require more work, but elementary convex analysis already provides the essential intuition.

For the function $\|x\|_0$ ($p = 0$ in (15)) the equivalence of the primal and dual problems is lost due to the nonconvexity of the objective. The theory of Fenchel duality still yields *weak duality*, but this is of limited use in this instance. The Fenchel dual to (15) is

$$\begin{aligned} & \underset{y \in \mathbb{R}^m}{\text{maximize}} && b^T y \\ & \text{subject to} && (A^* y)_j = 0 \quad j = 1, 2, \dots, n. \end{aligned} \tag{17}$$

Denoting the *values* of the primal (15) and dual problems (17) by p and d , respectively, these values satisfy the *weak duality inequality* $p \geq d$. The primal problem is a combinatorial optimization problem, and hence *NP-hard*; the dual problem, however, is a linear program, which is finitely terminating. Relatively elementary variational analysis provides a lower bound on the sparsity of signals x that satisfy the measurements. In this instance, however, the lower bound only reconfirms what is already known. Indeed, if A is full rank, then the only solution to the dual problem is $y = 0$. In other words, the minimal sparsity of the solution to the primal problem is zero, which is obvious. The loss of information in passing from primal to dual formulations of nonconvex problems is a common phenomenon and underscores the importance of convexity.

The Fenchel conjugates of the ℓ_1 norm and the function $\|\cdot\|_0$ are given respectively by

$$\varphi_1^*(y) := \begin{cases} 0 & \|y\|_\infty \leq 1 \\ +\infty & \text{else} \end{cases} \quad (\varphi_1(x) := \|x\|_1) \quad (18)$$

$$\varphi_0^*(y) := \begin{cases} 0 & y = 0 \\ +\infty & \text{else} \end{cases} \quad (\varphi_0(x) := \|x\|_0) \quad (19)$$

It is not uncommon to consider the function $\|\cdot\|_0$ as the limit of $\left(\sum_j |x_j|^p\right)^{1/p}$ as $p \rightarrow 0$. This suggests an alternative approach based on the regularization of the conjugates. For L and $\epsilon > 0$ define

$$\varphi_{\epsilon,L}(y) := \begin{cases} \epsilon \left(\frac{(L+y)\ln(L+y)+(L-y)\ln(L-y)}{2L\ln(2)} - \frac{\ln(L)}{\ln(2)} \right) & (y \in [-L, L]) \\ +\infty & \text{for } |y| > L. \end{cases} \quad (20)$$

This is a scaled and shifted Fermi–Dirac entropy (4). It is also a smooth convex function on the interior of its domain and so elementary calculus can be used to calculate the Fenchel conjugate,

$$\varphi_{\epsilon,L}^*(x) = \frac{\epsilon}{\ln(2)} \ln(4^{xL/\epsilon} + 1) - xL - \epsilon. \quad (21)$$

For $L > 0$ fixed,

$$\lim_{\epsilon \rightarrow 0} \varphi_{\epsilon,L}(y) = \begin{cases} 0 & y \in [-L, L] \\ +\infty & \text{else} \end{cases} \quad \text{and} \quad \lim_{\epsilon \rightarrow 0} \varphi_{\epsilon,L}^*(x) = L|x|.$$

For $\epsilon > 0$ fixed

$$\lim_{L \rightarrow 0} \varphi_{\epsilon,L}(x) = \begin{cases} 0 & y = 0 \\ +\infty & \text{else} \end{cases} \quad \text{and} \quad \lim_{L \rightarrow 0} \varphi_{\epsilon,L}^*(x) := 0.$$

Note that $\|\cdot\|_0$ and $\varphi_{\epsilon,0}^* := 0$ have the same conjugate, but unlike $\|\cdot\|_0$ the biconjugate of $\varphi_{\epsilon,0}^*$ is itself. Also note that $\varphi_{\epsilon,L}$ and $\varphi_{\epsilon,L}^*$ are convex and smooth on the interior of their domains for all $\epsilon, L > 0$. This is in contrast to metrics of the form $\left(\sum_j |x_j|^p\right)$ which are nonconvex for $p < 1$. This suggests solving

$$\begin{array}{ll} \underset{x \in \mathbb{R}^n}{\text{minimize}} & I_{\varphi_{\epsilon,L}^*}(x) \\ \text{subject to} & Ax = b \end{array} \quad (22)$$

as a smooth convex relaxation of the conventional ℓ_p optimization for $0 \leq p \leq 1$. For further details see [28].

Image Denoising and Deconvolution

Consider next problems of the form

$$\underset{x \in X}{\text{minimize}} \quad I_\varphi(x) + \frac{1}{2\lambda} \|Ax - y\|^2 \quad (23)$$

where X is a Hilbert space, $I_\varphi : X \rightarrow (-\infty, +\infty]$ is a semi-norm on X , and $A : X \rightarrow Y$, is a bounded linear operator. This problem is explored in [17] as a general framework that includes total variation minimization [108], wavelet shrinkage [59], and basis pursuit [47]. When A is the identity, problem (23) amounts to a technique for *denoising*; here y is the received, noisy signal, and the solution \bar{x} is an approximation with the desired statistical properties promoted by the objective I_φ . When the linear mapping A is not the identity (for instance, A models convolution against the point spread function of an optical system) problem (23) is a variational formulation of *deconvolution*, that is, recovering the true signal from the image y . The focus here is on total variation minimization.

Total variation was first introduced by Rudin et al. [108] as a regularization technique for denoising images while preserving edges and, more precisely, the statistics of the noisy image. The *total variation* of an image $x \in X = L_1(T)$ – for T and open subset of \mathbb{R}^2 – is defined by

$$I_{TV}(x) := \sup \left\{ \int_T x(t) \operatorname{div} \xi(t) dt \mid \xi \in C_c^1(T, \mathbb{R}^2), |\xi(t)| \leq 1 \forall t \in T \right\}.$$

The integral functional I_{TV} is finite if and only if the distributional derivative Dx of x is a finite Radon measure in T , in which case $I_{TV}(x) = |Dx|(T)$. If, moreover, x has a gradient $\nabla x \in L_1(T, \mathbb{R}^2)$, then $I_{TV}(x) = \int |\nabla x(t)| dt$, or, in the context of the general framework established at the beginning of this chapter, $I_{TV}(x) = I_\varphi(x)$ where $\varphi(x(t)) := |\nabla x(t)|$. The goal of the original *total variation denoising problem* proposed in [108] is then to

$$\begin{array}{ll} \underset{x \in X}{\text{minimize}} & I_{TV}(x) \\ \text{subject to} & \int_T Ax = \int_T x_0 \quad \text{and} \quad \int_T |Ax - x_0|^2 = \sigma^2. \end{array} \quad (24)$$

The first constraint corresponds to the assumption that the noise has zero mean and the second assumption requires the denoised image to have a predetermined standard deviation σ . Under reasonable assumptions [44], this problem is equivalent to the convex optimization problem

$$\begin{aligned} & \underset{x \in X}{\text{minimize}} && I_{TV}(x) \\ & \text{subject to} && \|Ax - x_0\|^2 \leq \sigma^2. \end{aligned} \tag{25}$$

Several authors have exploited duality in total variation minimization for efficient algorithms to solve the above problem [43, 46, 57, 70]. One can “compute” the Fenchel conjugate of I_{TV} indirectly by using the already mentioned property that the *biconjugate* of a proper, convex lsc function is the function itself: $f^{**}(x) = f(x)$ if (and only if) f is proper, convex, and lsc at x . Rewriting I_{TV} as the Fenchel conjugate of some function yields

$$I_{TV}(x) = \sup_v \langle x, v \rangle - \iota_K(v),$$

where

$$K := \overline{\{\operatorname{div} \xi \mid \xi \in C_c^1(T, \mathbb{R}^2) \quad \text{and} \quad |\xi(t)| \leq 1 \forall t \in T\}}.$$

From this, it is then clear that the Fenchel conjugate of I_{TV} is the indicator function of the convex set K , ι_K .

In [43], duality is used to develop an algorithm, with proof of convergence, for the problem

$$\underset{x \in X}{\text{minimize}} I_{TV}(x) + \frac{1}{2\lambda} \|x - x_0\|^2 \tag{26}$$

with X a Hilbert space. First-order optimality conditions for this unconstrained problem are

$$0 \in x - x_0 + \lambda \partial I_{TV}(x), \tag{27}$$

where $\partial I_{TV}(x)$ is the *subdifferential* of I_{TV} at x defined by

$$v \in \partial I_{TV}(x) \iff I_{TV}(y) \geq I_{TV}(x) + \langle v, y - x \rangle \quad \forall y.$$

The optimality condition (27) is equivalent to [24, Proposition 4.4.5]

$$x \in \partial I_{TV}^*((x_0 - x)/\lambda) \tag{28}$$

or, since $I_{TV}^* = \iota_K$,

$$\frac{x_0}{\lambda} \in \left(I + \frac{1}{\lambda} \partial \iota_K \right)(z)$$

where $z = (x_0 - x)/\lambda$. (For the finite dimensional statement, see [71, Proposition I.6.1.2].) Since K is convex, standard facts from convex analysis determine that $\partial \iota_K(z)$ is the *normal cone mapping* to K at z , denoted $N_K(z)$ and defined by

$$N_K(z) := \begin{cases} \{v \in X \mid \langle v, x - z \rangle \leq 0 \text{ for all } x \in K\} & z \in K \\ \emptyset & z \notin K. \end{cases}$$

Note that this is a set-valued mapping. The *resolvent* $(I + \frac{1}{\lambda} \partial \iota_K)^{-1}$ evaluated at x_0/λ is the orthogonal *projection* of x_0/λ onto K . That is, the solution to (26) is

$$x_* = x_0 - P_K(x_0/\lambda) = x_0 - P_{\lambda K}(x_0).$$

The inclusions disappear from the formulation due to convexity of K : the resolvent of the normal cone mapping of a convex set is single valued. The numerical algorithm for solving (26) then amounts to an algorithm for computing the projection $P_{\lambda K}$. The tools from convex analysis used in this derivation are the subject of this chapter.

Inverse Scattering

An important problem in applications involving scattering is the determination of the shape and location of scatterers from measurements of the scattered field at a distance. Modern techniques for solving this problem use *indicator functions* to detect the inconsistency or insolubility of an Fredholm integral equation of the first kind, parameterized by points in space. The shape and location of the object is determined by those points where the auxiliary problem is solvable. Equivalently, the technique determines the shape and location of the scatterer by determining whether a sampling function, parameterized by points in space, is in the range of a compact linear operator constructed from the scattering data.

These methods have enjoyed great practical success since their introduction in the latter half of the 1990s. Recently Kirsch and Grinberg [74] established a variational interpretation of these ideas. They observe that the range of a linear operator $G : X \rightarrow Y$ (X and Y are reflexive Banach spaces) can be characterized by the infimum of the mapping

$$h(\psi) : Y^* \rightarrow \mathbb{R} \cup \{-\infty, +\infty\} := |\langle \psi, F\psi \rangle|,$$

where $F := GSG^*$ for $S : X^* \rightarrow X$, a coercive bounded linear operator. Specifically, they establish the following.

Theorem 2 ([74, Theorem 1.16]). *Let X, Y be reflexive Banach spaces with duals X^* and Y^* . Let $F : Y^* \rightarrow Y$ and $G : X \rightarrow Y$ be bounded linear operators with $F = GSG^*$ for $S : X^* \rightarrow X$ a bounded linear operator satisfying the coercivity condition*

$$|\langle \varphi, S\varphi \rangle| \geq c \|\varphi\|_{X^*}^2 \quad \text{for some } c > 0 \text{ and all } \varphi \in \text{range}(G^*) \subset X^*.$$

Then for any $\phi \in Y \setminus \{0\}$ $\phi \in \text{range}(G)$ if and only if

$$\inf\{h(\psi) \mid \psi \in Y^*, \langle \phi, \psi \rangle = 1\} > 0.$$

It is shown below that the infimal characterization above is equivalent to the computation of the effective domain of the Fenchel conjugate of h ,

$$h^*(\phi) := \sup_{\psi \in Y^*} \{\langle \phi, \psi \rangle - h(\psi)\}. \quad (29)$$

In the case of scattering, the operator F above is an integral operator whose kernel is made up of the “measured” field on a surface surrounding the scatterer. When the measurement surface is a sphere at infinity, the corresponding operator is known as the *far field operator*. The factor G maps the boundary condition of the governing PDE (the Helmholtz equation) to the *far field pattern*, that is, the kernel of the far field operator. Given the right choice of spaces, the mapping G is compact, one-to-one, and dense. There are two keys to using the above facts for determining the shape and location of scatterers: first, the construction of the test function ϕ and, second, the connection of the range of G to that of some operator easily computed from the far field operator F . The secret behind the success of these methods in inverse scattering is, first, that the construction of ϕ is trivial and, second, that there is (usually) a simpler object to work with than the infimum in Theorem 2 that depends only on the far field operator (usually the only thing that is known). Indeed, the test functions ϕ are simply far field patterns due to point sources: $\phi_z := e^{-ik\hat{x} \cdot z}$, where \hat{x} is a point on the unit sphere (the direction of the incident field), k is a nonnegative integer (the wave number of the incident field), and z is some point in space.

The crucial observation of Kirsch is that ϕ_z is in the range of G if and only if z is a point *inside* the scatterer. If one does not know where the scatter is, let alone its shape, then one does not know G , however, the Fenchel conjugate depends not on G but on the operator F which is constructed from measured data. In general, the Fenchel conjugate, and hence the Kirsch–Grinberg infimal characterization, is difficult to compute, but depending on the physical setting, there is a functional U of F under which the ranges of $U(F)$ and G coincide. In the case where F is a normal operator, $U(F) = (F^*F)^{1/4}$; for non-normal F , the functional U depends more delicately on the physical problem at hand and is only known in a handful of cases. So the algorithm for determining the shape and location of a scatterer amounts to determining those points z , where $e^{-ik\hat{x} \cdot z}$ is in the range of $U(F)$ and where U and F are known and easily computed.

Fredholm Integral Equations

In the scattering application of the previous section, the prevailing numerical technique is not to calculate the Fenchel conjugate of $h(\psi)$ but rather to explore

the range of some functional of F . Ultimately, the computation involves solving a Fredholm integral equation of the first kind, returning to the more general setting with which this chapter began. Let

$$(Ax)(s) = \int_T a(s, t)\mu(dt) = b(s)$$

for reasonable kernels and operators. If A is compact, for instance, as in most deconvolution problems of interest, the problem is *ill posed* in the sense of Hadamard. Some sort of *regularization* technique is therefore required for numerical solutions [60, 66, 67, 76, 113]. Regularization is explored in relation to the constraint qualifications (9) or (10).

Formulating the integral equation as an entropy minimization problem yields

$$\begin{aligned} & \underset{x \in X}{\text{minimize}} && I_\varphi(x) \\ & \text{subject to} && Ax = b. \end{aligned} \tag{30}$$

Following [22, Example 2.2], let T and S be the interval $[0, 1]$ with Lebesgue measures μ and ν , and let $a(s, t)$ be a continuous kernel of the Fredholm operator A mapping $X := C([0, 1])$ to $Y := C([0, 1])$, both equipped with the supremum norm. The adjoint operator is given by $A^*y = \{\int_S a(s, t)\lambda(ds)\} \mu(dt)$, where the dual spaces are the spaces of Borel measures, $X^* = M([0, 1])$ and $Y^* = M([0, 1])$. Every element of the range is therefore μ -absolutely continuous and A^* can be viewed as having its range in $L_1([0, 1], \mu)$. It follows from [105] that the Fenchel dual of (30) for the operator A is therefore

$$\max_{y^* \in Y^*} \langle b, y^* \rangle - I_{\varphi^*}(A^*y^*). \tag{31}$$

Note that the dual problem, unlike the primal, is *unconstrained*. Suppose that A is injective and that $b \in \text{range}(A)$. Assume also that φ^* is everywhere finite and differentiable. Assuming the solution \bar{y} to the dual is attained, the naive application of calculus provides that

$$b = A\left(\frac{\partial \varphi^*}{\partial r}(A^*\bar{y})\right) \quad \text{and} \quad x_\varphi = \left(\frac{\partial \varphi^*}{\partial r}(A^*\bar{y})\right). \tag{32}$$

Similar to the counterexample explored in section ‘‘Linear Inverse Problems with Convex Constraints’’, it is quite likely that $A\left(\frac{\partial \varphi^*}{\partial r}(\text{range}(A^*))\right)$ is smaller than the range of A , hence it is possible to have $b \in \text{range}(A)$ but not in $A\left(\frac{\partial \varphi^*}{\partial r}(\text{range}(A^*))\right)$. Thus the assumption that the solution to the dual problem is attained cannot hold and the primal–dual relationship is broken.

For a specific example, following [22, Example 2.2], consider the Laplace transform restricted to $[0, 1]$: $a(s, t) := e^{-st}$ ($s \in [0, 1]$), and let φ be either the Boltzmann–Shannon entropy, Fermi–Dirac entropy, or an L_p norm with $p \in (1, 2)$,

(3)–(5), respectively. Take $b(s) := \int_{[0,1]} e^{-st} \bar{x}(t) dt$ for $\bar{x} := \alpha |t - \frac{1}{2}| + \beta$, a solution to (30). It can be shown that the restricted Laplace operator defines an injective linear operator from $C([0, 1])$ to $C([0, 1])$. However, x_φ given by (32) is continuously differentiable and thus cannot match the known solution \bar{x} which is not differentiable. Indeed, in the case of the Boltzmann–Shannon entropy, the conjugate function and $A^* \bar{y}$ are entire hence the ostensible solution x_φ must be *infinitely* differentiable on $[0, 1]$. One could guarantee that the solution to the primal problem (30) is attained by replacing $C([0, 1])$ with $L_p([0, 1])$, but this does not resolve the problem of attainment in the dual problem.

To recapture the correspondence between primal and dual problems it is necessary to regularize or, alternatively, relax the problem, or to require the constraint qualification $b \in \text{core}(A \text{ dom } \varphi)$. Such conditions usually require A to be surjective, or at least to have closed range.

2 Background

As this is meant to be a survey of some of the more useful milestones in convex analysis, the focus is more on the connections between ideas than their proofs. The reader will find the proofs in a variety of sources. The presentation is by default in a normed space X with dual X^* , though if statements become too technical, the Euclidean space variants will suffice. E denotes a finite-dimensional real vector space \mathbb{R}^n for some $n \in \mathbb{N}$ endowed with the usual norm. Typically, X will be reserved for a real infinite-dimensional Banach space. A common convention in convex analysis is to include one or both of $-\infty$ and $+\infty$ in the range of functions (typically only $+\infty$). This is denoted by the (semi-) closed interval $(-\infty, +\infty]$ or $[-\infty, +\infty]$.

A set $C \subset X$ is said to be convex if it contains all line segments between any two points in C : $\lambda x + (1 - \lambda)y \in C$ for all $\lambda \in [0, 1]$ and $x, y \in C$. Much of the theory of convexity is centered on the analysis of convex sets, however, sets and functions are treated interchangeably through the use of level sets, epigraphs, and indicator functions. The *lower-level sets* of a function $f : X \rightarrow [-\infty, +\infty]$ are denoted $\text{lev}_{\leq \alpha} f$ and defined by $\text{lev}_{\leq \alpha} f := \{x \in X \mid f(x) \leq \alpha\}$ where $\alpha \in \mathbb{R}$. The *epigraph* of a function $f : X \rightarrow [-\infty, +\infty]$ is defined by

$$\text{epi } f := \{(x, t) \in E \times \mathbb{R} \mid f(x) \leq t\}.$$

This leads to the very natural definition of a *convex function* as one whose epigraph is a convex set. More directly, a convex function is defined as a mapping $f : X \rightarrow [-\infty, +\infty]$ with convex domain and

$$f(\lambda x + (1 - \lambda)y) \leq \lambda f(x) + (1 - \lambda)f(y) \quad \text{for any } x, y \in \text{dom } f \text{ and } \lambda \in [0, 1].$$

A proper convex function $f : X \rightarrow [-\infty, +\infty]$ is *strictly convex* if the above inequality is strict for all distinct x and y in the domain of f and all $0 < \lambda < 1$.

A function is said to be *closed* if its epigraph is closed; whereas a *lower semi-continuous* (lsc) function f satisfies $\liminf_{x \rightarrow \bar{x}} f(x) \geq f(\bar{x})$ for all $\bar{x} \in X$. These properties are in fact equivalent:

Proposition 1. *The following properties of a function $f : X \rightarrow [-\infty, +\infty]$ are equivalent:*

- (i) f is lsc.
- (ii) $\text{epi } f$ is closed in $X \times \mathbb{R}$.
- (iii) The level sets $\text{lev}_{\leq \alpha} f$ are closed on X for each $\alpha \in \mathbb{R}$.

Guide. For Euclidean spaces, this is shown in [107, Theorem 1.6]. In the Banach space setting this is [24, Proposition 4.1.1]. This is left as an exercise for the Hilbert space setting in [50, Exercise 2.1]. ■

A principal focus is on *proper* functions, that is, $f : E \rightarrow [-\infty, +\infty]$ with nonempty domain. The indicator function is often used to pass from sets to functions

$$\iota_C(x) := \begin{cases} 0 & x \in C \\ +\infty & \text{else.} \end{cases}$$

For $C \subset X$ convex, $f : C \rightarrow [-\infty, +\infty]$ will be referred to as a convex function if the extended function

$$\overline{f}(x) := \begin{cases} f(x) & x \in C \\ +\infty & \text{else} \end{cases}$$

is convex.

Lipschitzian Properties

Convex functions have the remarkable, yet elementary, property that local boundedness and local Lipschitz properties are *equivalent* without any additional assumptions on the function. In the following statement of this fact, the unit ball is denoted by $B_X := \{x \in X \mid \|x\| \leq 1\}$.

Lemma 1. *Let $f : X \rightarrow (-\infty, +\infty]$ be a convex function and suppose that $C \subset X$ is a bounded convex set. If f is bounded on $C + \delta B_X$ for some $\delta > 0$, then f is Lipschitz on C .*

Guide. See [24, Lemma 4.1.3]. ■

With this fact, one can easily establish the following.

Proposition 2 (Convexity and Continuity in Normed Spaces). *Let $f : X \rightarrow (-\infty, +\infty]$ be proper and convex, and let $x \in \text{dom } f$. The following are equivalent:*

- (i) f is Lipschitz on some neighborhood of x .
- (ii) f is continuous at x .
- (iii) f is bounded on a neighborhood of x .
- (iv) f is bounded above on a neighborhood of x .

Guide. See [24, Proposition 4.1.4] or [31, Sect. 4.1.2]. ■

In finite dimensions, convexity and continuity are much more tightly connected.

Proposition 3 (Convexity and Continuity in Euclidean Spaces). *Let $f : E \rightarrow (-\infty, +\infty]$ be convex. Then f is locally Lipschitz, and hence continuous, on the interior of its domain.*

Guide. See [24, Theorem 2.1.12] or [72, Theorem 3.1.2]. ■

Unlike finite dimensions, in infinite dimensions a convex function need not be continuous. A Hamel basis, for instance, an algebraic basis for the vector space can be used to define discontinuous linear functionals [24, Exercise 4.1.21]. For lsc convex functions, however, the correspondence follows through. The following statement uses the notion of the *core* of a set given by Definition 1.

Example 1 (A Discontinuous Linear Functional). Let c_{00} denote the normed subspace of all finitely supported sequences in c_0 , the vector space of sequences in X converging to 0; obviously c_{00} is open. Define $\Lambda : c_{00} \rightarrow \mathbb{R}$ by $\Lambda(x) = \sum x_j$ where $x = (x_j) \in c_{00}$. This is clearly a linear functional and discontinuous at 0. Now extend Λ to a functional $\hat{\Lambda}$ on the Banach space c_0 by taking a basis for c_0 considered as a vector space over c_{00} . In particular, $C := \hat{\Lambda}^{-1}([-1, 1])$ is a convex set with empty interior for which 0 is a core point. Moreover, $\overline{C} = c_0$ and $\hat{\Lambda}$ is certainly discontinuous. ■

Proposition 4 (Convexity and Continuity in Banach Spaces). *Suppose X is a Banach space and $f : X \rightarrow (-\infty, +\infty]$ is lsc, proper, and convex. Then the following are equivalent:*

- (i) f is continuous at x .
- (ii) $x \in \text{int dom } f$.
- (iii) $x \in \text{core dom } f$.

Guide. This is [24, Theorem 4.1.5]. See also [31, Theorem 4.1.3]. ■

The above result is helpful since it is often easier to verify that a point is in the core of the domain of a convex function than in the interior.

Subdifferentials

The analog to the linear function in classical analysis is the *sublinear function* in convex analysis. A function $f : X \rightarrow [-\infty, +\infty]$ is said to be *sublinear* if

$$f(\lambda x + \gamma y) \leq \lambda f(x) + \gamma f(y) \quad \text{for all } x, y \in X \text{ and } \lambda, \gamma \geq 0.$$

By convention, $0 \cdot (+\infty) = 0$. Sometimes sublinearity is defined as a function f that is *positively homogeneous (of degree 1)* – i.e., $0 \in \text{dom } f$ and $f(\lambda x) = \lambda f(x)$ for all x and all $\lambda > 0$ – and is *subadditive*

$$f(x + y) \leq f(x) + f(y) \quad \text{for all } x \text{ and } y.$$

Example 2 (Norms). A *norm* on a vector space is a sublinear function. Recall that a nonnegative function $\|\cdot\|$ on a vector space X is a norm if

- (i) $\|x\| \geq 0$ for each $x \in X$.
- (ii) $\|x\| = 0$ if and only if $x = 0$.
- (iii) $\|\lambda x\| = |\lambda| \|x\|$ for every $x \in X$ and scalar λ .
- (iv) $\|x + y\| \leq \|x\| + \|y\|$ for every $x, y \in X$.

A *normed space* is a vector space endowed with such a norm and is called a *Banach space* if it is *complete* which is to say that all Cauchy sequences converge. ■

Another important sublinear function is the *directional derivative* of the function f at x in the direction d defined by

$$f'(x; d) := \lim_{t \searrow 0} \frac{f(x + td) - f(x)}{t}$$

whenever this limit exists.

Proposition 5 (Sublinearity of the Directional Derivative). *Let X be a Banach space and let $f : X \rightarrow (-\infty, +\infty]$ be a convex function. Suppose that $\bar{x} \in \text{core}(\text{dom } f)$. Then the directional derivative $f'(\bar{x}; \cdot)$ is everywhere finite and sublinear.*

Guide. See [31, Proposition 4.2.4]. For the finite dimensional analog, see [72, Proposition D.1.1.2] or [24, Proposition 2.1.17]. ■

Another important instance of sublinear functions are *support functions* of convex sets, which, in turn permit local first-order approximations to convex functions. A *support function* of a nonempty subset S of the dual space X^* , usually denoted $\sigma_S(x) := \sup \{\langle s, x \rangle \mid s \in S\}$. The support function is convex, proper (not everywhere infinite), and $0 \in \text{dom } \sigma_S$.

Example 3 (Support Functions and Fenchel Conjugation). From the definition of the support function it follows immediately that, for a closed convex set C ,

$$\iota_C^* = \sigma_C \quad \text{and} \quad \iota_C^{**} = \iota_C. \quad \blacksquare$$

A powerful observation is that any closed sublinear function can be viewed as a support function. This can be seen by the representation of closed convex functions via affine minorants. This is the content of the *Hahn–Banach* theorem, which is stated in infinite dimensions as this setting will be needed below.

Theorem 3 (Hahn–Banach: Analytic Form). *Let X be a normed space and $\sigma : X \rightarrow \mathbb{R}$ be a continuous sublinear function with $\text{dom } \sigma = X$. Suppose that L is a linear subspace of X and that the linear function $h : L \rightarrow \mathbb{R}$ is dominated by σ on L , that is $\sigma \geq h$ on L . Then there is a linear function minorizing σ on X , that is, there exists a $x^* \in X^*$ dominated by σ such that $h(x) = \langle x^*, x \rangle \leq \sigma(x)$ for all $x \in L$.*

Guide. The proof can be carried out in finite dimensions with elementary tools, constructing x^* from h sequentially by one-dimensional extensions from L . See [72, Theorem C.3.1.1] and [24, Proposition 2.1.18]. The technique can be extended to Banach spaces using Zorn’s lemma and a verification that the linear functionals so constructed are continuous (guaranteed by the domination property) [24, Theorem 4.1.7]. See also [110, Theorem 1.11]. \blacksquare

An important point in the Hahn–Banach extension theorem is the *existence* of a minorizing linear function, and hence the existence of the *set* of linear minorants. In fact, σ is the supremum of the linear functions minorizing it. In other words, σ is the support function of the nonempty set

$$S_\sigma := \{s \in X^* \mid \langle s, x \rangle \leq \sigma(x) \quad \text{for all } x \in X\}.$$

A number of facts follow from Theorem 3, in particular the nonemptiness of the subdifferential, a sandwich theorem and, thence, Fenchel Duality (respectively, Theorems 5, 7, and 12). It turns out that the converse also holds, and thus these facts are actually *equivalent* to nonemptiness of the subdifferential. This is the so-called *Hahn–Banach/Fenchel duality circle*.

As stated in Proposition 5, the directional derivative is everywhere finite and sublinear for a convex function f at points in the core of its domain. In light of the Hahn–Banach theorem, then $f'(\bar{x}, \cdot)$ can be expressed for all $d \in X$ in terms of its minorizing function:

$$f'(\bar{x}, d) = \sigma_S(d) = \max_{v \in S} \{\langle v, d \rangle\}.$$

The set S for which $f'(\bar{x}, d)$ is the support function has a special name: the *subdifferential* of f at \bar{x} . It is tempting to *define* the subdifferential this way, however,

there is a more elemental definition that does not rely on directional derivatives or support functions, or indeed even the convexity of f . The correspondence between directional derivatives of convex functions and the subdifferential below is a consequence of the Hahn–Banach theorem.

Definition 2 (Subdifferential). For a function $f : X \rightarrow (-\infty, +\infty]$ and a point $\bar{x} \in \text{dom } f$, the *subdifferential* of f at \bar{x} , denoted $\partial f(\bar{x})$ is defined by

$$\partial f(\bar{x}) := \{v \in X^* \mid v(x) - v(\bar{x}) \leq f(x) - f(\bar{x}) \text{ for all } x \in X\}.$$

When $\bar{x} \notin \text{dom } f$, define $\partial f(\bar{x}) = \emptyset$.

In Euclidean space the subdifferential is just

$$\partial f(\bar{x}) = \{v \in E \mid \langle v, x \rangle - \langle v, \bar{x} \rangle \leq f(x) - f(\bar{x}) \text{ for all } x \in E\}.$$

An element of $\partial f(x)$ is called a *subgradient* of f at x . See [31, 93, 107] for more in-depth discussion of the regular, or limiting subdifferential defined here, in addition to other useful varieties. This is a generalization of the classical gradient. Just as the gradient need not exist, the subdifferential of a lsc convex function may be empty at some points in its domain. Take, for example, $f(x) = -\sqrt{1-x^2}$ for $-1 \leq x \leq 1$. Then $\partial f(x) = \emptyset$ for $x = \pm 1$.

Example 4 (Common Subdifferentials).

(i) Gradients. A function $f : X \rightarrow \mathbb{R}$ is said to be *strictly differentiable* at \bar{x} if

$$\lim_{x \rightarrow \bar{x}, u \rightarrow \bar{x}} \frac{f(x) - f(u) - \nabla f(\bar{x})(x - u)}{\|x - u\|} = 0.$$

This is a stronger differentiability property than Fréchet differentiability since it requires uniformity in pairs of points converging to \bar{x} . Luckily for convex functions the two notions agree. If f is convex and strictly differentiable at \bar{x} , then the subdifferential is exactly the gradient. (This follows from the equivalence of the subdifferential in Definition 2 and the basic limiting subdifferential defined in [93, Definition 1.77] for convex functions and [93, Corollary 1.82].) In finite dimensions, at a point $\bar{x} \in \text{dom } f$ for f convex, Fréchet and Gâteaux differentiability coincide, and the subdifferential is a singleton [24, Theorem 2.2.1]. In infinite dimensions, a convex function f that is continuous at \bar{x} is Gâteaux differentiable at \bar{x} if and only if the $\partial f(\bar{x})$ is a singleton [24, Corollary 4.2.11].

(ii) The subdifferential of the indicator function.

$$\partial \iota_C(\bar{x}) = N_C(\bar{x}),$$

where $C \subset X$ is closed and convex, X is a Banach, and $N_C(\bar{x}) \subset X^*$ is the *normal cone mapping* to C at \bar{x} defined by

$$N_C(\bar{x}) := \begin{cases} \{v \in X^* \mid \langle v, x - \bar{x} \rangle \leq 0 \text{ for all } x \in C\} & \bar{x} \in C \\ \emptyset & \bar{x} \notin C. \end{cases} \quad (33)$$

See (41) for alternative definitions and further discussion of this important mapping.

(iii) Absolute value. For $x \in \mathbb{R}$,

$$\partial|\cdot|(x) = \begin{cases} -1 & x < 0 \\ [-1, 1] & x = 0 \\ 1 & x > 0. \end{cases}$$

■

The following elementary observation suggests the fundamental significance of subdifferential in optimization.

Theorem 4 (Subdifferential at Optimality: Fermat's Rule). *Let X be a normed space, and let $f : X \rightarrow (-\infty, +\infty]$ be proper and convex. Then f has a (global) minimum at \bar{x} if and only if $0 \in \partial f(\bar{x})$.*

Guide. The first implication of the global result follows from a more general local result [93, Proposition 1.114] by convexity; the converse statement follows from the definition of the subdifferential and convexity. ■

Returning now to the correspondence between the subdifferential and the directional derivative of a convex function $f'(x; d)$ has the following fundamental result.

Theorem 5 (Max Formula – Existence of ∂f). *Let X be a normed space, $d \in X$ and let $f : X \rightarrow (-\infty, +\infty]$ be convex. Suppose that $\bar{x} \in \text{cont } f$. Then $\partial f(\bar{x}) \neq \emptyset$ and*

$$f'(\bar{x}, d) = \max \{\langle x^*, d \rangle \mid x^* \in \partial f(\bar{x})\}.$$

Proof. The tools are in place for a simple proof that synthesizes many of the facts tabulated so far. By Proposition 5 $f'(\bar{x}; \cdot)$ is finite; so, for fixed $d \in \{x \in X \mid \|x\| = 1\}$, let $\alpha = f'(\bar{x}; d) < \infty$. The stronger assumption that $\bar{x} \in \text{cont } f$ and the convexity of $f'(\bar{x}; \cdot)$ yield that the directional derivative is Lipschitz continuous with constant K . Let $S := \{td \mid t \in \mathbb{R}\}$ and define the linear function $\Lambda : S \rightarrow \mathbb{R}$ by $\Lambda(td) := t\alpha$ for $t \in \mathbb{R}$. Then $\Lambda(\cdot) \leq f'(\bar{x}; \cdot)$ on S . The Hahn–Banach theorem 3 then guarantees the existence of $\phi \in X^*$ such that

$$\phi = \Lambda \text{ on } S, \quad \phi(\cdot) \leq f'(\bar{x}; \cdot) \text{ on } X.$$

Then $\phi \in \partial f(\bar{x})$ and $\phi(sd) = f'(\bar{x}; sd)$ for all $s \geq 0$. ■

A simple example on \mathbb{R} illustrates the importance of the qualification $\bar{x} \in \text{cont } f$. Let

$$f(x) : \mathbb{R} \rightarrow (-\infty, +\infty] := \begin{cases} -\sqrt{x}, & x \geq 0 \\ +\infty & \text{otherwise.} \end{cases}$$

For this example, $\partial f(0) = \emptyset$.

An important application of the Max formula in finite dimensions is the mean value theorem for convex functions.

Theorem 6 (Convex Mean Value Theorem). *Let $f : E \rightarrow (-\infty, +\infty]$ be convex and continuous. For $u, v \in E$ there exists a point $z \in E$ interior to the line segment $[u, v]$ with*

$$f(u) - f(v) \leq \langle w, u - v \rangle \quad \text{for all } w \in \partial f(z).$$

Guide. See [93, 107] for extensions of this result and detailed historical background. ■

The next theorem is a key tool in developing a subdifferential calculus. It relies on assumptions that are used frequently enough that it is worthwhile to present them separately.

Assumption 6. *Let X and Y be Banach spaces and let $T : X \rightarrow Y$ be a bounded linear mapping. Let $f : X \rightarrow (-\infty, +\infty]$ and $g : Y \rightarrow (-\infty, +\infty]$ satisfy one of*

$$0 \in \text{core}(\text{dom } g - T \text{ dom } f) \text{ and both } f \text{ and } g \text{ are lsc,} \quad (34)$$

or

$$T \text{ dom } f \cap \text{cont } g \neq \emptyset. \quad (35)$$

The later assumption can be used in incomplete normed spaces as well.

Theorem 7 (Sandwich Theorem). *Let X and Y be Banach spaces and let $T : X \rightarrow Y$ be a bounded linear mapping. Suppose that $f : X \rightarrow (-\infty, +\infty]$ and $g : Y \rightarrow (-\infty, +\infty]$ are proper convex functions with $f \geq -g \circ T$ and which satisfy Assumption 6. Then there is an affine function $A : X \rightarrow \mathbb{R}$ defined by $Ax := \langle T^*y^*, x \rangle + r$ satisfying $f \geq A \geq -g \circ T$. Moreover, for any \bar{x} satisfying $f(\bar{x}) = (-g \circ T)(\bar{x})$, it holds that $-y^* \in \partial g(T\bar{x})$.*

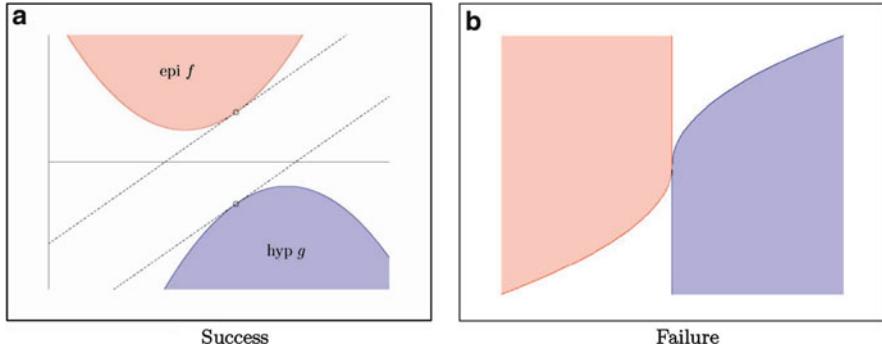

Fig. 1 Hahn–Banach sandwich theorem and its failure. (a) Success; (b) failure

Guide. By the development to this point, the Max formula [24, Theorem 4.1.18] would apply to prove the result. For a vector space version see [110, Corollary 2.1]. Another route is via Fenchel duality which is explored in the next section. A third approach closely related to the Fenchel duality approach [31, Theorem 4.3.2] is based on a *decoupling* lemma which is also presented in the next section (Lemma 3). ■

Corollary 2 (Basic Separation). Let $C \subset X$ be a nonempty convex set with nonempty interior in a normed space, and suppose $x_0 \notin \text{int } C$. Then there exists $\phi \in X^* \setminus \{0\}$ such that

$$\sup_C \phi \leq \phi(x_0) \quad \text{and} \quad \phi(x) < \phi(x_0) \text{ for all } x \in \text{int } C.$$

If $x_0 \notin \overline{C}$ then it can be assumed that $\sup_C \phi < \phi(x_0)$.

Proof. Assume without loss of generality that $0 \in \text{int } C$ and apply the sandwich theorem with $f = \iota_{\{x_0\}}$, T the identity mapping on X and $g(x) = \inf\{r > 0 \mid x \in rC\} - 1$. See [31, Theorem 4.3.8] and [24, Corollary 4.1.15]. ■

The Hahn–Banach theorem 3 can be seen as an easy consequence of the sandwich theorem 7, which completes part of the circle. Figure 1 illustrates these ideas.

In the next section Fenchel duality is added to this cycle. A calculus of subdifferentials and a few fundamental results connecting the subdifferential to classical derivatives and *monotone operators* conclude the present section.

Theorem 8 (Subdifferential Sum Rule). Let X and Y be Banach spaces, $T : X \rightarrow Y$ a bounded linear mapping and let $f : X \rightarrow (-\infty, +\infty]$ and $g : Y \rightarrow (-\infty, +\infty]$ be convex functions. Then at any point $x \in X$

$$\partial(f + g \circ T)(x) \supset \partial f(x) + T^*(\partial g(Tx)),$$

with equality if Assumption 6 holds.

Proof sketch. The inclusion is clear. Proving equality permits an elegant proof using the sandwich theorem [24, Theorem 4.1.19], which we sketch here. Take $\phi \in \partial(f + g \circ T)(\bar{x})$ and assume without loss of generality that

$$x \mapsto f(x) + g(Tx) - \phi(x)$$

attains a minimum of 0 at \bar{x} . By Theorem 7 there is an affine function $A := \langle T^*y^*, \cdot \rangle + r$ with $-y^* \in \partial g(T\bar{x})$ such that

$$f(x) - \phi(x) \geq Ax \geq -g(Ax).$$

Equality is attained at $x = \bar{x}$. It remains to check that $\phi + T^*y^* \in \partial f(\bar{x})$. ■

The next result is a useful extension to Proposition 2.

Theorem 9 (Convexity and Regularity in Normed Spaces). *Let $f : X \rightarrow (-\infty, +\infty]$ be proper and convex, and let $x \in \text{dom } f$. The following are equivalent:*

- (i) f is Lipschitz on some neighborhood of x .
- (ii) f is continuous at x .
- (iii) f is bounded on a neighborhood of x .
- (iv) f is bounded above on a neighborhood of x .
- (v) ∂f maps bounded subsets of X into bounded nonempty subsets of X^* .

Guide. See [24, Theorem 4.1.25]. ■

The next results relate to Example 4 and provide additional tools for verifying differentiability of convex functions. The notation \rightarrow_{w^*} denotes weak* convergence.

Theorem 10 (Šmulian). *Let the convex function f be continuous at \bar{x} .*

- (i) *The following are equivalent:*
 - (a) f is Fréchet differentiable at \bar{x} .
 - (b) For each sequence $x_n \rightarrow \bar{x}$ and $\phi \in \partial f(\bar{x})$, there exist $\bar{n} \in \mathbb{N}$ and $\phi_n \in \partial f(x_n)$ for $n \geq \bar{n}$ such that $\phi_n \rightarrow \phi$.
 - (c) $\phi_n \rightarrow \phi$ whenever $\phi_n \in \partial f(x_n)$, $\phi \in \partial f(\bar{x})$.
- (ii) *The following are equivalent:*
 - (a) f is Gâteaux differentiable at \bar{x} .
 - (b) For each sequence $x_n \rightarrow \bar{x}$ and $\phi \in \partial f(\bar{x})$, there exist $\bar{n} \in \mathbb{N}$ and $\phi_n \in \partial f(x_n)$ for $n \geq \bar{n}$ such that $\phi_n \rightarrow_{w^*} \phi$.
 - (c) $\phi_n \rightarrow_{w^*} \phi$ whenever $\phi_n \in \partial f(x_n)$, $\phi \in \partial f(\bar{x})$.

A more complete statement of these facts and their provenance can be found in [24, Theorems 4.2.8 and 4.2.9]. In particular, in every infinite dimensional normed space,

there is a continuous convex function which is Gâteaux but not Fréchet differentiable at the origin.

An elementary but powerful observation about the subdifferential viewed as a multi-valued mapping will conclude this section. A multi-valued mapping T from X to X^* is denoted with double arrows, $T : X \rightrightarrows X^*$. Then T is *monotone* if

$$\langle v_2 - v_1, x_2 - x_1 \rangle \geq 0 \quad \text{whenever } v_1 \in T(x_1), v_2 \in T(x_2).$$

Proposition 6 (Monotonicity and Convexity). *Let $f : X \rightarrow (-\infty, +\infty]$ be proper and convex on a normed space. Then the subdifferential mapping $\partial f : X \rightrightarrows X^*$ is monotone.*

Proof. Add the subdifferential inequalities in the Definition 2 applied to $f(x_1)$ and $f(x_0)$ for $v_1 \in \partial f(x_1)$ and $v_0 \in \partial f(x_0)$. ■

3 Duality and Convex Analysis

The Fenchel conjugate is to convex analysis what the Fourier transform is to harmonic analysis. To begin, some basic facts about this fundamental tool are collected.

Fenchel Conjugation

The Fenchel conjugate, introduced in [62], of a mapping $f : X \rightarrow [-\infty, +\infty]$, as mentioned above is denoted $f^* : X^* \rightarrow [-\infty, +\infty]$ and defined by

$$f^*(x^*) = \sup_{x \in X} \{\langle x^*, x \rangle - f(x)\}.$$

The conjugate is always convex (as a supremum of affine functions). If the domain of f is nonempty, then f^* never takes the value $-\infty$.

Example 5 (Important Fenchel Conjugates).

(i) Absolute value.

$$f(x) = |x| \quad (x \in \mathbb{R}), \quad f^*(y) = \begin{cases} 0 & y \in [-1, 1] \\ +\infty & \text{else.} \end{cases}$$

(ii) L_p norms ($p > 1$).

$$f(x) = \frac{1}{p} \|x\|^p \quad (p > 1), \quad f^*(y) = \frac{1}{q} \|y\|^q \quad \left(\frac{1}{p} + \frac{1}{q} = 1 \right).$$

In particular, note that the two-norm conjugate is “self-conjugate.”

(iii) Indicator functions.

$$f = \iota_C, \quad f^* = \sigma_C,$$

where σ_C is the *support function* of the set C . Note that if C is not closed and convex, then the conjugate of σ_C , that is the *biconjugate* of ι_C , is the *closed convex hull* of C . (See Proposition 8(ii).)

(iv) Boltzmann–Shannon entropy.

$$f(x) = \begin{cases} x \ln x - x & (x > 0) \\ 0 & (x = 0) \end{cases}, \quad f^*(y) = e^y \quad (y \in \mathbb{R}).$$

(v) Fermi–Dirac entropy.

$$f(x) = \begin{cases} x \ln x + (1-x) \ln(1-x) & (x \in (0, 1)) \\ 0 & (x = 0, 1) \end{cases},$$

$$f^*(y) = \ln(1 + e^y) \quad (y \in \mathbb{R}).$$

■

Some useful properties of conjugate functions are tabulated below.

Proposition 7 (Fenchel–Young Inequality). *Let X be a normed space and let $f : X \rightarrow [-\infty, +\infty]$. Suppose that $x^* \in X^*$ and $x \in \text{dom } f$. Then*

$$f(x) + f^*(x^*) \geq \langle x^*, x \rangle. \quad (36)$$

Equality holds if and only if $x^ \in \partial f(x)$.*

Proof sketch. The proof follows by an elementary application of the definitions of the Fenchel conjugate and the subdifferential. See [103] for the finite dimensional case. The same proof works in the normed space setting. ■

The conjugate, as the supremum of affine functions, is convex. In the following, the closure of a function f is denoted by \overline{f} , and $\overline{\text{conv}} f$ is the function whose epigraph is the closed convex hull of the epigraph of f .

Proposition 8. *Let X be a normed space and let $f : X \rightarrow [-\infty, +\infty]$.*

- (i) *If $f \geq g$ then $g^* \geq f^*$.*
- (ii) *$f^* = (\overline{f})^* = (\overline{\text{conv}} f)^*$.*

Proof. The definition of the conjugate immediately implies (i). This immediately yields $f^* \leq (\overline{f})^* \leq (\overline{\text{conv}} f)^*$. To show (ii) it remains to show that $f^* \geq$

$(\overline{\text{conv}} f)^*$. Choose any $\phi \in X^*$. If $f^*(\phi) = +\infty$ the conclusion is clear, so assume $f^*(\phi) = \alpha$ for some $\alpha \in \mathbb{R}$. Then $\phi(x) - f(x) \leq \alpha$ for all $x \in X$. Define $g := \phi - f$. Then $g \leq \overline{\text{conv}} f$ and, by (i) $(\overline{\text{conv}} f)^* \leq g^*$. But $g^* = \alpha$, so $(\overline{\text{conv}} f)^* \leq \alpha = f^*(\phi)$. ■

Application of Fenchel conjugation twice, or *biconjugation* denoted by f^{**} , is a function on X^{**} . In certain instances, biconjugation is the identity – in this way, the Fenchel conjugate resembles the Fourier transform. Indeed, Fenchel conjugation plays a role in the convex analysis similar to the Fourier transform in harmonic analysis and has a contemporaneous provenance dating back to Legendre.

Proposition 9 (Biconjugation). *Let $f : X \rightarrow (-\infty, +\infty]$, $x \in X$ and $x^* \in X^*$.*

- (i) $f^{**}|_X \leq f$.
- (ii) *If f is convex and proper, then $f^{**}(x) = f(x)$ at x if and only if f is lsc at x . In particular, f is lsc if and only if $f_X^{**} = f$.*
- (iii) $f^{**}|_X = \overline{\text{conv}} f$ if $\overline{\text{conv}} f$ is proper.

Guide. (i) follows from Fenchel–Young, Proposition 7, and the definition of the conjugate. (ii) follows from (i) and an epi-separation property [24, Proposition 4.4.2]. (iii) follows from (ii) of this proposition and 8(ii). ■

The next results highlight the relationship between the Fenchel conjugate and the subdifferential already used in (28).

Proposition 10. *Let $f : X \rightarrow (-\infty, +\infty]$ be a function and $\bar{x} \in \text{dom } f$. If $\phi \in \partial f(\bar{x})$ then $\bar{x} \in \partial f^*(\phi)$. If, additionally, f is convex and lsc at \bar{x} , then the converse holds, namely $\bar{x} \in \partial f^*(\phi)$ implies $\phi \in \partial f(\bar{x})$.*

Guide. See [72, Corollary 1.4.4] for the finite dimensional version of this fact that, with some modification, can be extended to normed spaces. ■

Infimal convolutions conclude this subsection. Among them many applications are smoothing and approximation – just as is the case for integral convolutions.

Definition 3 (Infimal Convolution). Let f and g be proper extended real-valued functions on a normed space X . The *infimal convolution* of f and g is defined by

$$(f \square g)(x) := \inf_{y \in X} f(y) + g(x - y).$$

The infimal convolution of f and g is the largest extended real-valued function whose epigraph contains the sum of epigraphs of f and g ; consequently, it is a convex function when f and g are convex.

The next lemma follows directly from the definitions and careful application of the properties of suprema and infima.

Lemma 2. *Let X be a normed space and let f and g be proper functions on X , then $(f \square g)^* = f^* + g^*$.*

An important example of infimal convolution is *Yosida approximation*.

Theorem 11 (Yosida Approximation). *Let $f : X \rightarrow \mathbb{R}$ be convex and bounded on bounded sets. Then both $f \square n\|\cdot\|^2$ and $f \square n\|\cdot\|$ converge uniformly to f on bounded sets.*

Guide. This follows from the above lemma and basic approximation facts. ■

In the inverse problems literature $(f \square n\|\cdot\|^2)(0)$ is often referred to as *Tikhonov regularization*; elsewhere, $f \square n\|\cdot\|^2$ is referred to as *Moreau–Yosida regularization* because $f \square \frac{1}{2}\|\cdot\|^2$, the *Moreau envelope*, was studied in depth by Moreau [94, 95]. The argmin mapping corresponding to the Moreau envelope – that is the mapping of $x \in X$ to the point $\bar{y} \in X$ at which the value of $f \square \frac{1}{2}\|\cdot\|^2$ is attained – is called the *proximal mapping* [94, 95, 107]

$$\text{prox}_{\lambda, f}(x) := \operatorname{argmin}_{y \in X} f(y) + \frac{1}{2\lambda} \|x - y\|^2. \quad (37)$$

When f is the indicator function of a closed convex set C , the proximal mapping is just the *metric projection* onto C , denoted by $P_C(x)$: $\text{prox}_{\lambda, \iota_C}(x) = P_C(x)$.

Fenchel Duality

Fenchel duality can be proved by Theorem 5 and the sandwich theorem 7 [24, Theorem 4.4.18]. As the syllogism to this point deduces Fenchel duality as a consequence of the Hahn–Banach theorem. In order to close the Fenchel duality/Hahn–Banach circle of ideas, however, following [31] the main duality result of this section follows from the Fenchel–Young inequality and the next important lemma.

Lemma 3 (Decoupling). *Let X and Y be Banach spaces and let $T : X \rightarrow Y$ be a bounded linear mapping. Suppose that $f : X \rightarrow (-\infty, +\infty]$ and $g : Y \rightarrow (-\infty, +\infty]$ are proper convex functions which satisfy Assumption 6. Then there is a $y^* \in Y^*$ such that for any $x \in X$ and $y \in Y$,*

$$p \leq (f(x) - \langle y^*, Tx \rangle) + (g(y) + \langle y^*, y \rangle),$$

where $p := \inf_X \{f(x) + g(Tx)\}$.

Guide. Define the perturbed function $h : Y \rightarrow [-\infty, +\infty]$ by

$$h(u) := \inf_{x \in X} \{f(x) + g(Tx + u)\},$$

which has the property that h is convex, $\text{dom } h = \text{dom } g - T \text{dom } f$ and (the most technical part of the proof) $0 \in \text{int}(\text{dom } h)$. This can be proved by assuming the first of the constraint qualifications (34). The second condition (35) implies (34). Then Theorem 5 yields $\partial h(0) \neq \emptyset$, which guarantees the attainment of a minimum of the perturbed function. The decoupling is achieved through a particular choice of the perturbation u . See [31, Lemma 4.3.1]. ■

One can now provide an elegant proof of Theorem 1, which is restated here for convenience.

Theorem 12 (Fenchel Duality). *Let X and Y be normed spaces, consider the functions $f : X \rightarrow (-\infty, +\infty]$ and $g : Y \rightarrow (-\infty, +\infty]$ and let $T : X \rightarrow Y$ be a bounded linear map. Define the primal and dual values $p, d \in [-\infty, +\infty]$ by the Fenchel problems*

$$p = \inf_{x \in X} \{f(x) + g(Tx)\} \quad (38)$$

$$d = \sup_{y^* \in Y^*} \{-f^*(T^*y^*) - g^*(-y^*)\}. \quad (39)$$

These values satisfy the weak duality inequality $p \geq d$.

If X, Y are Banach, f, g are convex and satisfy Assumption 6 then $p = d$, and the supremum to the dual problem is attained if finite.

Proof. Weak duality follows directly from the Fenchel–Young inequality.

For equality assume that $p \neq -\infty$ (this case is clear). Then Assumption 6 guarantees that $p < +\infty$, and by the decoupling lemma (Lemma 3), there is a $\phi \in Y^*$ such that for all $x \in X$ and $y \in Y$

$$p \leq (f(x) - \langle \phi, Tx \rangle) + (g(y) - \langle -\phi, y \rangle).$$

Taking the infimum over all x and then over all y yields

$$p \leq -f^*(T^*, \phi) - g^*(-\phi) \leq d \leq p.$$

Hence, ϕ attains the supremum in (39), and $p = d$. ■

Fenchel duality for *linear constraints*, Corollary 1, follows immediately by taking $g := \iota_{\{b\}}$.

Applications

Calculus Fenchel duality is, in some sense, the dual space representation of the sandwich theorem. It is a straightforward exercise to derive Fenchel duality from Theorem 7. Conversely, the existence of a point of attainment in Theorem 12 yields an explicit construction of the linear mapping in Theorem 7: $A := \langle T^*\phi, \cdot \rangle + r$, where ϕ is the point of attainment in (39) and $r \in [a, b]$ where $a := \inf_{x \in X} f(x) - \langle T^*\phi, x \rangle$ and $b := \sup_{z \in X} -g(Tz) - \langle T^*\phi, z \rangle$. One could then derive all the theorems using the sandwich theorem, in particular the Hahn–Banach theorem 3 and the subdifferential sum rule, Theorem 8, as consequences of Fenchel duality instead. This establishes the *Hahn–Banach/Fenchel duality* circle: Each of these facts is equivalent and easily interderivable with the nonemptiness of the subgradient of a function at a point of continuity.

An immediate consequence of Fenchel duality is a calculus of polar cones. Define the negative polar cone of a set K in a Banach space X by

$$K^- = \{x^* \in X^* \mid \langle x^*, x \rangle \leq 0 \forall x \in K\}. \quad (40)$$

An important example of a polar cone that has appeared in the applications discussed in this chapter is the *normal cone* of a convex set K at a point $x \in K$, defined by (33). Note that

$$N_K(\bar{x}) := (K - \bar{x})^-.$$
 (41)

Corollary 3 (Polar Cone Calculus). *Let X and Y be Banach spaces and $K \subset X$ and $H \subset Y$ be cones, and let $A : X \rightarrow Y$ be a bounded linear map. Then*

$$K^- + A^*H^- \subset (K + A^{-1}H)^-$$

where equality holds if K and H are closed convex cones which satisfy $H - AK = Y$.

This can be used to easily establish the normal cone calculus for closed convex sets C_1 and C_2 at a point $x \in C_1 \cap C_2$

$$N_{C_1 \cap C_2}(x) \supset N_{C_1}(x) + N_{C_2}(x)$$

with equality holding if, in addition, $0 \in \text{core}(C_1 - C_2)$ or $C_1 \cap \text{int } C_2 \neq \emptyset$.

Optimality Conditions Another important consequence of these ideas is the Pshenichnyi–Rockafellar [101, 103] condition for optimality for nonsmooth constrained optimization.

Theorem 13 (Pshenichnyi–Rockafellar Conditions). Let X be a Banach space, let $C \subset X$ be closed and convex, and let $f : X \rightarrow (-\infty, +\infty]$ be a convex function. Suppose that either $\text{int } C \cap \text{dom } f \neq \emptyset$ and f is bounded below on C , or $C \cap \text{cont } f \neq \emptyset$. Then there is an affine function $\alpha \leq f$ with $\inf_C f = \inf_C \alpha$. Moreover, \bar{x} is a solution to

$$(\mathcal{P}_0) \quad \begin{array}{ll} \underset{x \in X}{\text{minimize}} & f(x) \\ \text{subject to} & x \in C \end{array}$$

if and only if

$$0 \in \partial f(\bar{x}) + N_C(\bar{x}).$$

Guide. Apply the subdifferential sum rule to $f + \iota_C$ at \bar{x} . ■

A slight generalization extends this to linear constraints

$$(\mathcal{P}_{\text{lin}}) \quad \begin{array}{ll} \underset{x \in X}{\text{minimize}} & f(x) \\ \text{subject to} & Tx \in D \end{array}$$

Theorem 14 (First-Order Necessary and Sufficient). Let X and Y be Banach spaces with $D \subset Y$ convex, and let $f : X \rightarrow (-\infty, +\infty]$ be convex and $T : X \rightarrow Y$ a bounded linear mapping. Suppose further that one of the following holds:

$$0 \in \text{core}(D - T \text{dom } f), \quad D \text{ is closed and } f \text{ is lsc}, \quad (42)$$

or

$$T \text{dom } f \cap \text{int}(D) \neq \emptyset. \quad (43)$$

Then the feasible set $C := \{x \in X \mid Tx \in D\}$ satisfies

$$\partial(f + \iota_C)(x) = \partial f(x) + T^*(N_D(Tx)) \quad (44)$$

and \bar{x} is a solution to $(\mathcal{P}_{\text{lin}})$ if and only if

$$0 \in \partial f(\bar{x}) + T^*(N_D(T\bar{x})). \quad (45)$$

A point $y^* \in Y^*$ satisfying $T^*y^* \in -\partial f(\bar{x})$ in Theorem 14 is a *Lagrange multiplier*.

Lagrangian Duality The setting is limited to Euclidean space and the general convex program

$$(\mathcal{P}_{\text{cvx}}) \begin{array}{ll} \underset{x \in E}{\text{minimize}} & f_0(x) \\ \text{subject to} & f_j(x) \leq 0 \quad (j = 1, 2, \dots, m) \end{array}$$

where the functions f_j for $j = 0, 1, 2, \dots, m$ are convex and satisfy

$$\bigcap_{j=0}^m \text{dom } f_j \neq \emptyset. \quad (46)$$

Define the *Lagrangian* $L : E \times \mathbb{R}^m_+ \rightarrow (-\infty, +\infty]$ by

$$L(x, \lambda) := f_0(x) + \lambda^T F(x),$$

where $F := (f_1, f_2, \dots, f_m)^T$. A *Lagrange multiplier* in this context is a vector $\bar{\lambda} \in \mathbb{R}^m_+$ for a feasible solution \bar{x} if \bar{x} minimizes the function $L(\cdot, \bar{\lambda})$ over E and $\bar{\lambda}$ satisfies the so-called *complimentary slackness conditions*: $\bar{\lambda}_j = 0$ whenever $f_j(\bar{x}) < 0$. On the other hand, if \bar{x} is feasible for the convex program $(\mathcal{P}_{\text{cvx}})$ and there is a Lagrange multiplier, then \bar{x} is optimal. Existence of the Lagrange multiplier is guaranteed by the following *Slater constraint qualification* first introduced in the 1950s.

Assumption 7 (Slater Constraint Qualification). *There exists an $\hat{x} \in \text{dom } f_0$ with $f_j(\hat{x}) < 0$ for $j = 1, 2, \dots, m$.*

Theorem 15 (Lagrangian Necessary Conditions). *Suppose that $\bar{x} \in \text{dom } f_0$ is optimal for the convex program $(\mathcal{P}_{\text{cvx}})$ and that Assumption 7 holds. Then there is a Lagrange multiplier vector for \bar{x} .*

Guide. See [27, Theorem 3.2.8]. ■

Denote the optimal value of $(\mathcal{P}_{\text{cvx}})$ by p . Note that, since

$$\sup_{\lambda \in \mathbb{R}^m_+} L(x, \lambda) = \begin{cases} f(x) & \text{if } x \in \text{dom } f \\ +\infty & \text{otherwise,} \end{cases}$$

then

$$p = \inf_{x \in E} \sup_{\lambda \in \mathbb{R}^m_+} L(x, \lambda). \quad (47)$$

It is natural, then to consider the problem

$$d = \sup_{\lambda \in \mathbb{R}^m_+} \inf_{x \in E} L(x, \lambda) \quad (48)$$

where d is the *dual value*. It follows immediately that $p \geq d$. The difference between d and p is called the *duality gap*. The interesting problem is to determine when the gap is zero, that is, when $d = p$.

Theorem 16 (Dual Attainment). *If Assumption 7 holds for the convex programming problem (\mathcal{P}_{cvx}) , then the primal and dual values are equal and the dual value is attained if finite.*

Guide. For a more detailed treatment of the theory of Lagrangian duality see [27, Sect. 4.3]. ■

Optimality and Lagrange Multipliers

In the previous sections, duality theory was presented as a byproduct of the Hahn–Banach/Fenchel duality circle of ideas. This provides many entry points to the theory of convex and variational analysis. For present purposes, however, the real significance of duality lies with its power to illuminate duality in convex optimization, not only as a theoretical phenomenon but also as an algorithmic strategy.

In order to get to optimality criteria and the existence of solutions to convex optimization problems, turn to the approximation of minima, or more generally the *regularity* and *well-posedness* of convex optimization problems. Due to its reliance on the Slater constraint qualification (49), Theorem 16 is not adequate for problems with equality constraints:

$$(\mathcal{P}_{eq}) \quad \begin{array}{ll} \underset{x \in S}{\text{minimize}} & f_0(x) \\ \text{subject to} & F(x) = 0 \end{array}$$

for $S \subset E$ closed and $F : E \rightarrow Y$ a Fréchet differentiable mapping between the Euclidean spaces E and Y .

More generally, one has problems of the form

$$(\mathcal{P}_E) \quad \begin{array}{ll} \underset{x \in S}{\text{minimize}} & f_0(x) \\ \text{subject to} & F(x) \in D \end{array} \tag{49}$$

for E and Y Euclidean spaces, and $S \subset E$ and $D \subset Y$ are convex but not necessarily with nonempty interior.

Example 6 (Simple Karush–Kuhn–Tucker). For linear optimization problems, relatively elementary linear algebra is all that is needed to assure the existence of Lagrange multipliers. Consider

$$(\mathcal{P}_E) \begin{array}{ll} \underset{x \in S}{\text{minimize}} & f_0(x) \\ \text{subject to} & f_j(x) \in D_j, \quad j = 1, 2, \dots, m \end{array}$$

for $f_j : \mathbb{R}^n \rightarrow \mathbb{R}$ ($j = 0, 1, 2, \dots, s$) continuously differentiable, $f_j : \mathbb{R}^n \rightarrow \mathbb{R}$ ($j = s+1, \dots, m$) linear. Suppose $S \subset E$ is closed and convex, while $D_i := (-\infty, 0]$ for $j = 1, 2, \dots, s$ and $D_j := \{0\}$ for $j = s+1, \dots, m$.

Theorem 17. Denote by $f'_J(x)$ the submatrix of the Jacobian of $(f_1, \dots, f_s)^T$ (assuming this is defined at x) consisting only of those f'_j for which $f_j(x) = 0$. In other words, $f'_J(x)$ is the Jacobian of the active inequality constraints at x . Let \bar{x} be a local minimizer for (\mathcal{P}_E) at which f_j are continuously differentiable ($j = 0, 1, \dots, s$) and the matrix

$$\begin{pmatrix} f'_J(\bar{x}) \\ A \end{pmatrix} \tag{50}$$

is full-rank where $A := (\nabla f_{s+1}, \dots, \nabla f_m)^T$. Then there are $\bar{\lambda} \in \mathbb{R}^s$ and $\bar{\mu} \in \mathbb{R}^m$ satisfying

$$\bar{\lambda} \geq 0. \tag{51a}$$

$$(f_1(\bar{x}), \dots, f_s(\bar{x}))\bar{\lambda} = 0. \tag{51b}$$

$$f'_0(\bar{x}) + \sum_{j=1}^s \bar{\lambda}_j f'_j(\bar{x}) + \bar{\mu}^T A = 0. \tag{51c}$$

Guide. An elegant and elementary proof is given in [36]. ■

For more general constraint structure, *regularity* of the feasible region is essential for the normal cone calculus which plays a key role in the requisite optimality criteria. More specifically, one has the following constraint qualification.

Assumption 8 (Basic Constraint Qualification).

$y = (0, \dots, 0)$ is the only solution in $N_D(F(\bar{x}))$ to $0 \in \nabla F^T(\bar{x})y + N_S(\bar{x})$.

Theorem 18 (Optimality on Sets with Constraint Structure). Let

$$C = \{x \in S \mid F(x) \in D\}$$

for $F = (f_1, f_2, \dots, f_m) : E \rightarrow \mathbb{R}^m$ with f_j continuously differentiable ($j = 1, 2, \dots, m$), $S \subset E$ closed, and for $D = D_1 \times D_2 \times \dots \times D_m \subset \mathbb{R}^m$ with D_j closed intervals ($j = 1, 2, \dots, m$). Then for any $\bar{x} \in C$ at which Assumption 8 is satisfied one has

$$N_C(\bar{x}) = \nabla F^T(\bar{x})N_D(F(\bar{x})) + N_S(\bar{x}). \quad (52)$$

If, in addition, f_0 is continuously differentiable and \bar{x} is a locally optimal solution to (\mathcal{P}_E) then there is a vector $\bar{y} \in N_D(F(\bar{x}))$, called a Lagrange multiplier such that $0 \in \nabla f_0(\bar{x}) + \nabla F^T(\bar{x})\bar{y} + N_S(\bar{x})$.

Guide. See [107, Theorems 6.14 and 6.15]. ■

Variational Principles

The Slater condition (49) is an *interiority* condition on the solutions to optimization problems. Interiority is just one type of *regularity* required of the solutions, wherein one is concerned with the behavior of solutions under perturbations. The next classical result lays the foundation for many modern notions of regularity of solutions.

Theorem 19 (Ekeland's Variational Principle). *Let (X, d) be a complete metric space and let $f : X \rightarrow (-\infty, +\infty]$ be a lsc function bounded from below. Suppose that $\epsilon > 0$ and $z \in X$ satisfy*

$$f(z) < \inf_X f + \epsilon.$$

For a given fixed $\lambda > 0$, there exists $y \in X$ such that

- (i) $d(z, y) \leq \lambda$.
- (ii) $f(y) + \frac{\epsilon}{\lambda}d(z, y) \leq f(z)$.
- (iii) $f(x) + \frac{\epsilon}{\lambda}d(x, y) > f(y)$, for all $x \in X \setminus \{y\}$.

Guide. For a proof see [61]. For a version of the principle useful in the presence of symmetry see [32]. ■

An important application of Ekeland's variational principle is to the theory of subdifferentials. Given a function $f : X \rightarrow (-\infty, +\infty]$, a point $x_0 \in \text{dom } f$ and $\epsilon \geq 0$, the ϵ -subdifferential of f at x_0 is defined by

$$\partial_\epsilon f(x_0) = \{\phi \in X^* \mid \langle \phi, x - x_0 \rangle \leq f(x) - f(x_0) + \epsilon, \forall x \in X\}.$$

If $x_0 \notin \text{dom } f$ then by convention $\partial_\epsilon f(x_0) := \emptyset$. When $\epsilon = 0$ one has $\partial_\epsilon f(x) = \partial f(x)$. For $\epsilon > 0$ the domain of the ϵ -subdifferential coincides with $\text{dom } f$ when f is a proper convex lsc function.

Theorem 20 (Brønsted–Rockafellar). *Suppose f is a proper lsc convex function on a Banach space X . Then given any $x_0 \in \text{dom } f, \epsilon > 0, \lambda > 0$ and $w_0 \in \partial_\epsilon f(x_0)$*

there exist $x \in \text{dom } f$ and $w \in X^*$ such that

$$w \in \partial f(x), \quad \|x - x_0\| \leq \epsilon/\lambda \quad \text{and} \quad \|w - w_0\| \leq \lambda.$$

In particular, the domain of ∂f is dense in $\text{dom } f$.

Guide. Define $g(x) := f(x) - \langle w_0, x \rangle$ on X , a proper lsc convex function with the same domain as f . Then $g(x_0) \leq \inf_X g(x) + \epsilon$. Apply Theorem 19 to yield a nearby point y that is the minimum of a slightly perturbed function, $g(x) + \lambda \|x - y\|$. Define the new function $h(x) := \lambda \|x - y\| - g(y)$, so that $h(x) \leq g(x)$ for all x . The sandwich theorem (Theorem 7) establishes the existence of an affine separator $\alpha + \phi$ which is used to construct the desired element of $\partial f(x)$. ■

A nice application of Ekeland's variational principle provides an elegant proof of Klee's problem in Euclidean spaces [75]: Is every Čebyčev set C convex? Here, a Čebyčev set is one with the property that every point in the space has a unique best approximation in C . A famous result is as follows.

Theorem 21. Every Čebyčev set in a Euclidean space is closed and convex.

Guide. Since, for every finite dimensional Banach space with smooth norm, approximately convex sets are convex, it suffices to show that C is approximately convex, that is, for every closed ball disjoint from C there is another closed ball disjoint from C of arbitrarily large radius containing the first. This follows from the mean value Theorem 6 and Theorem 19. See [24, Theorem 3.5.2]. It is not known whether the same holds for Hilbert space. ■

Fixed Point Theory and Monotone Operators

Another application of Theorem 19 is Banach's fixed point theorem.

Theorem 22. Let (X, d) be a complete metric space and let $\phi : X \rightarrow X$. Suppose there is a $\gamma \in (0, 1)$ such that $d(\phi(x), \phi(y)) \leq \gamma d(x, y)$ for all $x, y \in X$. Then there is a unique fixed point $\bar{x} \in X$ such that $\phi(\bar{x}) = \bar{x}$.

Guide. Define $f(x) := d(x, \phi(x))$. Apply Theorem 19 to f with $\lambda = 1$ and $\epsilon = 1 - \gamma$. The fixed point \bar{x} satisfies $f(x) + \epsilon d(x, \bar{x}) \geq f(\bar{x})$ for all $x \in X$. ■

The next theorem is a celebrated result in convex analysis concerning the *maximality* of lsc proper convex functions. A monotone operator T on X is *maximal* if $\text{gph } T$ cannot be enlarged in $X \times X$ without destroying the monotonicity of T .

Theorem 23 (Maximal Monotonicity of Subdifferentials). Let $f : X \rightarrow (-\infty, +\infty]$ be a lsc proper convex function on a Banach space. Then ∂f is maximal monotone.

Guide. The result was first shown by Moreau for Hilbert spaces [95, Proposition 12.b], and shortly thereafter extended to Banach spaces by Rockafellar [102, 104]. For a modern infinite dimensional proof see [1, 24]. This result fails badly in incomplete normed spaces [24]. ■

Maximal monotonicity of subdifferentials of convex functions lies at the heart of the success of algorithms as this is equivalent to *firm nonexpansiveness* of the *resolvent* of the subdifferential $(I + \partial f)^{-1}$ [92]. An operator T is *firmly nonexpansive* on a closed convex subset $C \subset X$ when

$$\|Tx - Ty\|^2 \leq \langle x - y, Tx - Ty \rangle \quad \text{for all } x, y \in X. \quad (53)$$

T is just *nonexpansive* on the closed convex subset $C \subset X$ if

$$\|Tx - Ty\| \leq \|x - y\| \quad \text{for all } x, y \in C. \quad (54)$$

Clearly, all firmly nonexpansive operators are nonexpansive. One of the most longstanding questions in geometric fixed point theory is whether a nonexpansive self-map T of a closed bounded convex subset C of a reflexive space X must have a fixed point. This is known to hold in Hilbert space.

4 Case Studies

One can now collect the dividends from the analysis outlined above for problems of the form

$$\begin{array}{ll} \underset{x \in C \subset X}{\text{minimize}} & I_\varphi(x) \\ \text{subject to} & Ax \in D \end{array} \quad (55)$$

where X and Y are real Banach spaces with continuous duals X^* and Y^* , C and D are closed and convex, $A : X \rightarrow Y$ is a continuous linear operator, and the integral functional $I_\varphi(x) := \int_T \varphi(x(t))\mu(dt)$ is defined on some vector subspace $L_p(T, \mu)$ of X .

Linear Inverse Problems with Convex Constraints

Suppose X is a Hilbert space, $D = \{b\} \in \mathbb{R}^m$ and $\varphi(x) := \frac{1}{2}\|x\|^2$. To apply Fenchel duality, rewrite (12) using the indicator function

$$\begin{array}{ll} \text{minimize}_{x \in X} & \frac{1}{2} \|x\|^2 + \iota_C(x) \\ \text{subject to} & Ax = b. \end{array} \quad (56)$$

Note that the problem is posed on an infinite dimensional space, while the constraints (the measurements) are finite dimensional. Here Fenchel duality is used to transform an infinite dimensional problem into a finite dimensional problem. Let $F := \{x \in C \subset E \mid Ax = b\}$ and let G denote the extensible set in E consisting of all measurement vectors b for which F is nonempty. Potter and Arun show that the existence of $\bar{y} \in \mathbb{R}^m$ such that $b = AP_C A^* \bar{y}$ is guaranteed by the constraint qualification $b \in \text{ri } G$, where ri denotes the *relative interior* [100, Corollary 2]. This is a special case of Assumption 6, which here reduces to $b \in \text{int } A(C)$. Though at first glance the latter condition is more restrictive, it is no real loss of generality since, if it fails, one can restrict the problem to $\text{range}(A)$ which is closed. Then it turns out that $b \in A\text{ri } C$, the image of the *quasi-relative interior* of C [27, Exercise 4.1.20]. Assuming this holds Fenchel duality, Theorem 12, yields the dual problem

$$\sup_{y \in \mathbb{R}^m} \langle b, y \rangle - \left(\frac{1}{2} \|\cdot\|^2 + \iota_C \right)^*(A^* y), \quad (57)$$

whose value is equivalent to the value of the primal problem. This is a finite dimensional unconstrained convex optimization problem whose solution is characterized by the inclusion (Theorem 4)

$$0 \in \partial \left(\frac{1}{2} \|\cdot\|^2 + \iota_C \right)^*(A^* y) - b. \quad (58)$$

Now from Lemma 2, Examples 5(ii) and (iii), and (37),

$$\left(\frac{1}{2} \|\cdot\|^2 + \iota_C \right)^*(x) = (\sigma_C \square \frac{1}{2} \|\cdot\|)(x) = \inf_{z \in X} \sigma_C(z) + \frac{1}{2} \|x - z\|^2.$$

The argmin of the Yosida approximation above (see Theorem 11) is the proximal operator (37). Applying the sum rule for differentials, Theorem 8 and Proposition 10 yield

$$\text{prox}_{1,\sigma_C}(x) = \arg\min_{z \in X} \{\sigma_C(z) + \frac{1}{2} \|z - x\|^2\} = x - P_C(x), \quad (59)$$

where P_C is the orthogonal projection onto the set C . This together with (58) yields the optimal solution \bar{y} to (57):

$$b = AP_C(A^* \bar{y}). \quad (60)$$

Note that the existence of a solution to (60) is guaranteed by Assumption 6. This yields the solution to the primal problem as $\bar{x} = P_C(A^* \bar{y})$.

With the help of (59), the iteration proposed in [100] can be seen as a subgradient descent algorithm for solving

$$\inf_{y \in \mathbb{R}^m} h(y) := \sigma_C(A^*y - P_C(A^*y)) + \frac{1}{2}\|P_C(A^*y)\|^2 - \langle b, y \rangle.$$

The proposed algorithm is, given $y_0 \in \mathbb{R}^m$ generates the sequence $\{y_n\}_{n=0}^\infty$ by

$$y_{n+1} = y_n - \lambda \partial h(y_n) = y_n + \lambda (b - AP_C A^* y_n).$$

For convergence results of this algorithm in a much larger context see [55].

Imaging with Missing Data

This application is formally simpler than the previous example since there is no abstract constraint set. As discussed in section “Imaging with Missing Data” in Sect. 1 relaxations to the conventional problem take the form

$$\begin{array}{ll} \underset{x \in \mathbb{R}^n}{\text{minimize}} & I_{\varphi_{\epsilon,L}^*}(x) \\ \text{subject to} & Ax = b, \end{array} \quad (61)$$

where

$$\varphi_{\epsilon,L}^*(x) = \frac{\epsilon}{\ln(2)} \ln(4^{xL/\epsilon} + 1) - xL - \epsilon. \quad (62)$$

Using Fenchel duality, the dual to this problem is the concave optimization problem

$$\sup_{y \in \mathbb{R}^m} y^T b - I_{\varphi_{\epsilon,L}}(A^*y),$$

where

$$\begin{aligned} \varphi_{\epsilon,L}(x) &:= \epsilon \left(\frac{(L+x)\ln(L+x) + (L-x)\ln(L-x)}{2L\ln(2)} - \frac{\ln(L)}{\ln(2)} \right) \\ L, \epsilon > 0, x &\in [-L, L]. \end{aligned}$$

If there exists a point \bar{y} satisfying $b = AA^*\bar{y}$, then the optimal value in the dual problem is attained and the primal solution is given by $A^*\bar{y}$. The objective in the dual problem is smooth and convex, so we could apply any number of efficient unconstrained optimization algorithms. Also, for this relaxation, the same numerical techniques can be used for all $L \rightarrow 0$. For further details see [28].

Inverse Scattering

Theorem 24. Let X, Y be reflexive Banach spaces with duals X^* and Y^* . Let $F : Y^* \rightarrow Y$ and $G : X \rightarrow Y$ be bounded linear operators with $F = GSG^*$ for $S : X^* \rightarrow X$ a bounded linear operator satisfying the coercivity condition

$$|\langle \varphi, S\varphi \rangle| \geq c \|\varphi\|_{X^*}^2 \quad \text{for some } c > 0 \text{ and all } \varphi \in \text{range}(G^*) \subset X^*.$$

Define $h(\psi) : Y^* \rightarrow (-\infty, +\infty] := |\langle \psi, F\psi \rangle|$, and let h^* denote the Fenchel conjugate of h . Then $\text{range}(G) = \text{dom } h^*$.

Proof. Following [74, Theorem 1.16], one shows that $h^*(\phi) = \infty$ for $\phi \notin \text{range}(G)$. To do this it is helpful to work with a dense subset of $\text{range } G$: $G^*(C)$ for $C := \{\psi \in Y^* \mid \langle \psi, \phi \rangle = 0\}$. It was shown in [74, Theorem 1.16] that $G^*(C)$ is dense in $\text{range}(G)$.

Now by the Hahn–Banach theorem 3 there is a $\hat{\phi} \in Y^*$ such that $\langle \hat{\phi}, \phi \rangle = 1$. Since $G^*(C)$ is dense in $\text{range}(G^*)$, there is a sequence $\{\psi_n\}_{n=1}^\infty \subset C$ with

$$G^*\psi_n \rightarrow -G^*\hat{\phi}, \quad n \rightarrow \infty.$$

Now set $\psi_n := \hat{\psi}_n + \hat{\phi}$. Then $\langle \phi, \alpha\psi_n \rangle = \alpha$ and $G^*(\alpha\psi_n) = \alpha G^*\psi_n \rightarrow 0$ for any $\alpha \in \mathbb{R}$. Using the factorization of F one has

$$|\langle \psi_n, F\psi_n \rangle| = |\langle G^*\psi_n, SG^*\psi_n \rangle| \leq \|S\| \|G^*\psi_n\|_{X^*}^2$$

hence $\alpha^2 \langle \psi_n, F\psi_n \rangle \rightarrow 0$ as $n \rightarrow \infty$ for all α , but $\langle \phi, \alpha\psi_n \rangle = \alpha$, that is, $\langle \phi, \alpha\psi_n \rangle - h(\alpha\psi_n) \rightarrow \alpha$ and $h^*(\phi) = \infty$. ■

In the scattering application, one has a scatterer supported on a domain $D \subset \mathbb{R}^m$ ($m = 2$ or 3) that is illuminated by an incident field. The Helmholtz equation models the behavior of the fields on the exterior of the domain and the boundary data belongs to $X = H^{1/2}(\Gamma)$. On the sphere at infinity the leading-order behavior of the fields, the so-called far field pattern, lies in $Y = L^2(\mathbb{S})$. The operator mapping the boundary condition to the far field pattern – the *data-to-pattern operator* – is $G : H^{1/2}(\Gamma) \rightarrow L^2(\mathbb{S})$. Assume that the *far field operator* $F : L^2(\mathbb{S}) \rightarrow L^2(\mathbb{S})$ has the factorization $F = GS^*G^*$, where $S : H^{-1/2}(\Gamma) \rightarrow H^{1/2}(\Gamma)$ is a *single layer boundary operator* defined by

$$(S\varphi)(x) := \int_\Gamma \Phi(x, y)\varphi(y)ds(y), \quad x \in \Gamma,$$

for $\Phi(x, y)$ the fundamental solution to the Helmholtz equation. With a few results about the denseness of G and the coercivity of S , which, though standard, will be glossed over, one has the following application to inverse scattering.

Corollary 4 (Application to Inverse Scattering). Let $D \subset \mathbb{R}^m$ ($m = 2$ or 3) be an open bounded domain with connected exterior and boundary Γ . Let $G : H^{1/2}(\Gamma) \rightarrow L^2(\mathbb{S})$, be the data-to-pattern operator; $S : H^{-1/2}(\Gamma) \rightarrow H^{1/2}(\Gamma)$, the single layer boundary operator and let the far field pattern $F : L^2(\mathbb{S}) \rightarrow L^2(\mathbb{S})$ have the factorization $F = GS^*G^*$. Assume k^2 is not a Dirichlet eigenvalue of $-\Delta$ on D . Then $\text{range } G = \text{dom } h^*$ where $h(\psi) : L^2(\mathbb{S}) \rightarrow (-\infty, +\infty] := |\langle \psi, F\psi \rangle|$.

Fredholm Integral Equations

The introduction featured the failure of Fenchel duality for Fredholm integral equations. The following sketch of a result on regularizations, or relaxations, recovers duality relationships. The result will show that by introducing a relaxation, one can recover the solution to ill-posed integral equations as the norm limit of solutions computable from a dual problem of maximum entropy type.

Theorem 25 ([22], Theorem 3.1). Let $X = L_1(T, \mu)$ on a complete measure finite measure space and let $(Y, \|\cdot\|)$ be a normed space. The infimum $\inf_{x \in X} \{I_\varphi(x) \mid Ax = b\}$ is attained when finite. In the case where it is finite, consider the relaxed problem for $\epsilon > 0$

$$(\mathcal{P}_{MEP}^\epsilon) \quad \begin{aligned} &\underset{x \in X}{\text{minimize}} && I_\varphi(x) \\ &\text{subject to} && \|Ax - b\| \leq \epsilon. \end{aligned}$$

Let p_ϵ denote the value of $(\mathcal{P}_{MEP}^\epsilon)$. The value of p_ϵ equals d_ϵ , the value of the dual problem

$$(\mathcal{P}_{DEP}^\epsilon) \quad \underset{y^* \in Y^*}{\text{maximize}} \quad \langle b, y^* \rangle - \epsilon \|y^*\|_* - I_{\varphi^*}(A^*y^*),$$

and the unique optimal solution of $(\mathcal{P}_{MEP}^\epsilon)$ is given by

$$\bar{x}_{\varphi, \epsilon} := \frac{\partial \varphi^*}{\partial r} (A^*y_\epsilon^*),$$

where y_ϵ^* is any solution to $(\mathcal{P}_{DEP}^\epsilon)$. Moreover, as $\epsilon \rightarrow 0^+$, $\bar{x}_{\varphi, \epsilon}$ converges in mean to the unique solution of (\mathcal{P}_{MEP}^0) and $p_\epsilon \rightarrow p_0$.

Guide. Attainment of the infimum in $\inf_{x \in X} \{I_\varphi(x) \mid Ax = b\}$ follows from *strong convexity* of I_φ [26, 112]: strictly convex with weakly compact lower-level sets and with the *Kadec property*, i.e., that weak convergence together with convergence of the function values implies norm convergence. Let $g(y) := \iota_S(y)$ for $S = \{y \in Y \mid b \in y + \epsilon B_Y\}$ and rewrite $(\mathcal{P}_{MEP}^\epsilon)$ as $\inf \{I_\varphi(x) + g(Ax) \mid x \in X\}$. An elementary calculation shows that the Fenchel dual to $(\mathcal{P}_{MEP}^\epsilon)$ is $(\mathcal{P}_{DEP}^\epsilon)$. The

relaxed problem $(\mathcal{P}_{MEP}^\epsilon)$ has a constraint for which a Slater-type constraint qualification holds at any feasible point for the unrelaxed problem. The value d_ϵ is thus attained and equal to p_ϵ . Subgradient arguments following [25] show that $\bar{x}_{\varphi,\epsilon}$ is feasible for $(\mathcal{P}_{MEP}^\epsilon)$ and is the unique solution to $(\mathcal{P}_{MEP}^\epsilon)$. Convergence follows from weak compactness of the lower-level set $L(p_0) := \{x \mid I_\varphi(x) \leq p_0\}$, which contains the sequence $(\bar{x}_{\varphi,\epsilon})_{\epsilon>0}$. Weak convergence of $\bar{x}_{\varphi,\epsilon}$ to the unique solution to the unrelaxed problem follows from strict convexity of I_φ . Convergence of the function values and strong convexity of I_φ then yields norm convergence. ■

Notice that the dual in Theorem 25 is unconstrained and easier to compute with, especially when there are finitely many constraints. This theorem remains valid for objectives of the form $I_\varphi(x) + \langle x^*, x \rangle$ for x^* in $L_\infty(T)$. This enables one to apply them to many *Bregman distances*, that is, integrands of the form $\phi(x) - \phi(x_0) - \langle \phi'(x_0), x - x_0 \rangle$, where ϕ is closed and convex on \mathbb{R} .

5 Open Questions

Regrettably, due to space constraints, fixed point theory and many facts about monotone operators that are useful in proving convergence of algorithms have been omitted. However, it is worthwhile noting two long-standing problems that impinge on fixed point and monotone operator theory.

1. Klee's problem: is every Čebyčev set C in a Hilbert space convex?
2. Must a nonexpansive self-map T of a closed bounded convex subset C of a reflexive space X have a fixed point?

6 Conclusion

Duality and convex programming provides powerful techniques for solving a wide range of imaging problems. While frequently a means toward computational ends, the dual perspective can also yield new insight into image processing problems and the information content of data implicit in certain models. Five main applications illustrate the convex analytical approach to problem solving and the use of duality: linear inverse problems with convex constraints, compressive imaging, image denoising and deconvolution, nonlinear inverse scattering, and finally Fredholm integral equations. These are certainly not exhaustive, but serve as good templates. The Hahn–Banach/Fenchel duality cycle of ideas developed here not only provides a variety of entry points into convex and variational analysis, but also underscores duality in convex optimization as both a theoretical phenomenon and an algorithmic strategy.

As readers of this volume will recognize, not all problems of interest are convex. But just as nonlinear problems are approached numerically by sequences of linear

approximations, nonconvex problems can be approached by sequences of convex approximations. Convexity is the central organizing principle and has tremendous algorithmic implications, including not only computable guarantees about solutions, but efficient means toward that end. In particular, convexity implies the existence of implementable, polynomial-time, algorithms. This chapter is meant to be a foundation for more sophisticated methodologies applied to more complicated problems.

1 Maximum Likelihood Estimation

Expectation-maximization algorithms, or EM algorithms for short, are iterative algorithms designed to solve maximum likelihood estimation problems. The general setting is that one observes a random sample Y_1, Y_2, \dots, Y_n of a random variable Y whose probability density function (pdf) $f(\cdot | x_o)$ with respect to some (known) dominating measure is known up to an unknown “parameter” x_o . The goal is to estimate x_o and, one might add, to do it well. In this chapter, that means to solve the maximum likelihood problem

$$\text{maximize} \quad \prod_{i=1}^n f(Y_i | x) \quad \text{over} \quad x, \quad (1)$$

and to solve it by means of EM algorithms. The solution, assuming it exists and is unique, is called the *maximum likelihood estimator* of x_o . Here, the estimator is typically denoted by \hat{x} .

The notion of EM algorithms was coined by [27], who unified various earlier instances of EM algorithms and in particular emphasized the notion of “missing” data in maximum likelihood estimation problems, following Hartley [53]. Here, the missing data refers to data that were not observed. Although this seems to imply that these data could have or should have been observed, it is usually the case that these missing data are inherently inaccessible. Typical examples of this are deconvolution problems, but it may be instructive to describe a simplified version in the form of finite mixtures of probability densities.

Let the random variable Y be a mixture of some other continuous random variables Z_1, Z_2, \dots, Z_m for some known integer m . For each j , $1 \leq j \leq m$, denote the pdf of Z_j by $f(\cdot | j)$. The pdf of Y is then

$$f_Y(y) = \sum_{j=1}^m w_j^* f(y | j), \quad (2)$$

where $w^* = (w_1^*, w_2^*, \dots, w_m^*)$ is a probability vector. In other words, the w_j^* are nonnegative and add up to 1. The interpretation is that for each j ,

$$Y = Z_j \quad \text{with probability } w_j^*. \quad (3)$$

As before, given a random sample Y_1, Y_2, \dots, Y_n of the random variable Y , the goal is to estimate the “parameter” w^* . The maximum likelihood problem for doing this is

$$\text{maximize} \quad \prod_{i=1}^n \left\{ \sum_{j=1}^m w_j f(Y_i | j) \right\} \quad (4)$$

subject to $w = (w_1, w_2, \dots, w_m)$ is a probability vector.

Now, what are the “missing” data for this finite mixture problem? In view of the interpretation (3), it would clearly be useful if for each Y_i , it was known which random variable Z_j it was supposed to be a random sample of. Thus, let $J_i \in \{1, 2, \dots, m\}$ such that

$$Y_i | J_i = Z_{J_i}. \quad (5)$$

Then, J_1, J_2, \dots, J_n would be a random sample of the random variable J , whose distribution would then be easy to estimate: for each j ,

$$\hat{w}_j = \frac{\#\{J_i = j\}}{n}, \quad (6)$$

the fraction of the J_i that were equal to j . Note that the distribution of J is given by

$$\mathbb{P}[J = j] = w_j^*, \quad j = 1, 2, \dots, m. \quad (7)$$

Of course, unfortunately, the J_i are not known. It is not even apparent that it would be advantageous to think about the J_i , but in fact it is, as this chapter tries to make clear.

From the image processing point of view, the above problem becomes more interesting if the finite sum in (2) is interpreted as a discretization of the integral transform

$$f_Y(y) = \int f(y | x) w(x) dx \quad (8)$$

and the goal is to recover the function or image w from the random sample Y_1, Y_2, \dots, Y_n . The maximum likelihood problem of estimating w ,

$$\text{maximize } \prod_{i=1}^n \left\{ \int f(Y_i | x) w(x) dx \right\} \quad \text{over } w, \quad (9)$$

is (formally) a straightforward extension of the mixture problem. Such (one- and two-dimensional) deconvolution problems abound in practice, e.g., in astronomy and tomography. See the suggested reading list.

In the next two sections, the bare essentials of a more-or-less general version of the EM algorithm are presented and it is shown that it increases the likelihood. Without special conditions, that is, all one can say about the convergence of the EM algorithm, one cannot even claim that in the limit, it achieves the maximum value of the likelihood. See [98]. For the convex case, where the negative log-likelihood is convex and the constraint set is convex as well, one can say much more, as will become clear.

Before discussing the two “big” applications of positron emission tomography (PET) and three-dimensional electron microscopy (3D-EM. Yes, another instance of EM!), it is prudent to discuss some simple examples of maximum likelihood estimation and to derive the associated EM algorithms. It turns that the prototypical example is that of estimating the weights in a mixture of known distributions; see (2). By analogy, this example shows how one should derive the EM algorithm for deconvolution problems with binned data, which is similar to the situation in positron emission tomography. The general parametric maximum likelihood estimation is also discussed, as well as the related case of empirical Bayes estimation. The latter has some similarity with 3D-EM.

All of this naturally leads to the discussion of the maximum likelihood approach to positron emission tomography (which originated with Rockmore and Macovski [82], but who mistakenly took the road of a least-squares treatment) and the EM algorithm of Shepp and Vardi [88]. This is one of the classic examples of Poisson data. However, even Poisson data may be interpreted as a random sample of some random variable; see section “The Emission Tomography Experiment.” For the ubiquitous nature of Poisson data, see [4] and references therein.

The very messy example of the reconstruction of the shapes of macromolecules of biological interest by way of 3D-EM also passes review.

For the example of mixtures of known distributions as well as for positron emission tomography, there is a well-rounded theory for the convergence of the EM algorithm to wit the alternating projection approach of Csiszár and Tusnády [23] and the majorizing functional approach of Mülthei and Schorr [75] and De Pierro [29]. This approach extends to EM-like algorithms for some maximum likelihood-like problems. Unfortunately, this ignores the fact that the maximum likelihood problem is ill conditioned when the number of components in the mixture is large (or that the deconvolution problem is ill-posed). So, one needs to regularize the maximum likelihood problems, and then, in this chapter, the issue is whether there are EM algorithms for the regularized problems. For the PET problem, this certainly works for Bayesian approaches, leading to maximum a posteriori (MAP) likelihood problems as well as to arbitrary convex maximum

penalized likelihood problems. In this context, mention should be made of the EMS algorithm of Silverman et al. [90], the EM algorithm with a linear smoothing step added, and the NEMS algorithm of Eggernmont and LaRiccia [36] in which an extra nonlinear smoothing step is added to the EMS algorithm to make it a genuine EM algorithm for a smoothed maximum likelihood problem. However, the convergence of regularization procedures for ill-posed maximum likelihood estimation problems, whether Tikhonov style penalization or “optimally” stopping the EM algorithm, will not be discussed. See, e.g., [80].

The final issue under consideration is that EM algorithms are painfully slow, so methods for accelerating EM algorithms are discussed as well. The accelerated methods take the form of block-iterative methods, including the extreme case of row-action methods.

The selection of topics is driven by applications to image processing. As such, there is very little overlap with the extensive up-to-date survey of EM algorithms of McLachlan and Krishnan [71].

2 The Kullback–Leibler Divergence

Before turning to the issue of EM algorithms, emphatic mention must be made of the pervasiveness of the Kullback–Leibler divergence (also called I -divergence or information divergence; see, e.g., [22] and references therein) in maximum likelihood estimation. For probability density functions f and g on \mathbb{R}^d , say, it is defined as

$$\text{KL}(f, g) = \int_{\mathbb{R}^d} \left(f(y) \log \left\{ \frac{f(y)}{g(y)} \right\} + g(y) - f(y) \right) d\mu(y), \quad (10)$$

with μ denoting Lebesgue measure. Here, $0 \log(0/0)$ is defined as 0. Note that the Kullback–Leibler divergence is not symmetric in its arguments. Also note that the integrand is nonnegative, so that the integral is well defined if the value $+\infty$ is admitted. Moreover, the integrand equals 0 if and only if $f(y) = g(y)$, so that $\text{KL}(f, g) > 0$ unless $f = g$ almost everywhere, in which case $\text{KL}(f, g) = 0$.

Now consider the problem of estimating the unknown parameter x_o in a probability density $f(\cdot | x_o)$. In view of the above, the ideal way would be to

$$\text{minimize } \text{KL}(f(\cdot | x_o), f(\cdot | x)) \quad \text{over } x, \quad (11)$$

but of course, this is not a rational problem because the objective function is unknown. However, note that

$$\begin{aligned} \text{KL}(f(\cdot | x_o), f(\cdot | x)) &= - \int_{\mathbb{R}^d} f(y|x_o) \log f(y|x) d\mu(y) \\ &\quad + \int_{\mathbb{R}^d} f(y|x_o) \log f(y|x_o) d\mu(y), \end{aligned} \quad (12)$$

and that the second term does not depend on x . So, the problem (11) is equivalent to (has the same solutions as)

$$\text{minimize } - \int_{\mathbb{R}^d} f(y|x_o) \log f(y|x) d\mu(y) \quad \text{over } x. \quad (13)$$

Of course, this is still not a rational problem, but the objective function equals $\mathbb{E}[L_n(x)]$, where $L_n(x)$ is the scaled negative log-likelihood

$$L_n(x) = -\frac{1}{n} \sum_{i=1}^n \log f(Y_i|x), \quad (14)$$

if Y_1, Y_2, \dots, Y_n is a random sample of the random variable Y with probability density function $f(\cdot|x_o)$. So, solving the maximum likelihood problem (1) may be viewed as approximately solving the minimum Kullback–Leibler divergence problem (11). This is the basic reason for the pervasiveness of the Kullback–Leibler divergence in the analysis of maximum likelihood estimation and EM algorithms.

The above illustrates two additional points. First, in maximum likelihood estimation, one attempts to solve the minimum Kullback–Leibler problem (11) by first estimating the objective function. So, if the estimator is “optimal” at all, it has to be in a sense related to the Kullback–Leibler divergence. Second, one may well argue that one is not estimating the parameter x_o but rather the density $f(\cdot|x_o)$. This becomes especially clear if $f(\cdot|x)$ is reparametrized as $\varphi(\cdot|z) = f(\cdot|T(z))$ for some transformation T . This would have an effect on the possible unbiasedness of the estimators \hat{x} and \hat{z} of x_o and z_o . However, under reasonable conditions on T , the maximum likelihood density estimators $f(\cdot|\hat{x})$ and $\varphi(\cdot|\hat{z})$ of $f(\cdot|x_o)$ will be the same.

3 The EM Algorithm

The Maximum Likelihood Problem

Let $(\mathcal{Y}, \mathcal{B}_{\mathcal{Y}}, \mathcal{P})$ be a statistical space, i.e., $(\mathcal{Y}, \mathcal{B}_{\mathcal{Y}})$ is a measurable space and \mathcal{P} is a collection of probability measures on $\mathcal{B}_{\mathcal{Y}}$, represented as a family indexed by some index set \mathcal{X} as follows:

$$\mathcal{P} = \{P(\cdot|x) : x \in \mathcal{X}\}. \quad (15)$$

Assume that there is a measure P_∞ that dominates \mathcal{P} in the sense that every $P(\cdot|x)$ is absolutely continuous with respect to P_∞ . Then, the Radon–Nikodym derivative of $P(\cdot|x)$ with respect to P_∞ exists and is $\mathcal{B}_{\mathcal{Y}}$ measurable for all $x \in \mathcal{X}$. It may be written as

$$f_{\mathcal{Y}}(y|x) = \left[\frac{dP(\cdot|x)}{dP_\infty} \right](y) \quad (16)$$

and is referred to as the density of $P(\cdot | x)$ with respect to P_∞ . It should be observed that $f_{\mathcal{Y}}(\cdot | x_o) = f_Y(\cdot)$ is the density of the random variable Y with respect to P_∞ . For arbitrary x , $f_{\mathcal{Y}}(\cdot | x)$ is a density, but since it is not known of what random variable, the subscript \mathcal{Y} is used here.

Let Y be a random variable with values in \mathcal{Y} , and assume that it is distributed as $P(\cdot | x_o)$ for some (unknown) $x_o \in \mathcal{X}$. The objective is to estimate x_o based on a random sample Y_1, Y_2, \dots, Y_n of the random variable Y . Note that estimating x_o amounts to constructing a measurable function of the data, which may then be denoted as $\hat{x} = \hat{x}(Y_1, Y_2, \dots, Y_n)$.

The maximum likelihood problem for estimating x_o is then written in the form of minimizing the scaled negative log-likelihood,

$$\begin{aligned} \text{minimize } & L_n(x) \stackrel{\text{def}}{=} -\frac{1}{n} \sum_{i=1}^n \log f_{\mathcal{Y}}(Y_i | x) \\ \text{subject to } & x \in \mathcal{X}. \end{aligned} \quad (17)$$

In this formulation, the parameter x is deemed important. The alternative formulation in which the densities are deemed important is

$$\begin{aligned} \text{minimize } & \tilde{L}_n(f) \stackrel{\text{def}}{=} -\frac{1}{n} \sum_{i=1}^n \log f(Y_i) \\ \text{subject to } & f \in \mathcal{P}. \end{aligned} \quad (18)$$

In this formulation, there are two ingredients: the likelihood function and the (parametric) family of densities under consideration.

It is not obvious that solutions should exist, especially if the index set \mathcal{X} is large, but in applications of image processing type, this turns out to be of lesser importance than one might think. See Sect. 7. Regardless, closed form solutions are generally not available, and one must employ iterative methods for the solution of the maximum likelihood problem. In this chapter, that means EM algorithms.

The Bare-Bones EM Algorithm

Here, the bare essentials of the EM algorithm are presented. The basic premise in the derivation of the EM algorithm is that there is “missing” data that would make estimating x_o a lot easier had they been observed. So, assume that the missing data refers to data in a space \mathcal{Z} , with $(\mathcal{Z}, \mathcal{B}_{\mathcal{Z}}, \mathcal{Q})$ another statistical space, where the collection of probability measures is again indexed by \mathcal{X} ,

$$\mathcal{Q} = \{\mathcal{Q}(\cdot | x) : x \in \mathcal{X}\}. \quad (19)$$

Assume that \mathcal{Q} is dominated by some measure \mathcal{Q}_∞ , and denote the associated Radon–Nikodym derivatives as

$$f_{\mathcal{Z}}(z|x) = \left[\frac{d\mathcal{Q}(\cdot|x)}{d\mathcal{Q}_\infty} \right](z), \quad z \in \mathcal{Z}. \quad (20)$$

Let Z be a random variable with values in \mathcal{Z} and with distribution $\mathcal{Q}(\cdot|x_o)$, with the same x_o as for the random variable Y . Note that the pair (Y, Z) takes on values in $\mathcal{Y} \times \mathcal{Z}$. The relevant statistical space is then $(\mathcal{Y} \times \mathcal{Z}, \mathcal{B}_{\mathcal{Y} \times \mathcal{Z}}, \mathcal{R})$, where $\mathcal{B}_{\mathcal{Y} \times \mathcal{Z}}$ is the smallest σ -algebra that contains all sets $A \times B$ with $A \in \mathcal{B}_{\mathcal{Y}}$ and $B \in \mathcal{B}_{\mathcal{Z}}$. Again, assume that \mathcal{R} may be indexed by \mathcal{X} as

$$\mathcal{R} = \{R(\cdot|x) : x \in \mathcal{X}\}, \quad (21)$$

and that \mathcal{R} is dominated by some measure R_∞ . Write

$$f_{\mathcal{Y}, \mathcal{Z}}(y, z|x) = \left[\frac{dR(\cdot|x)}{dR_\infty} \right](y, z) \quad (22)$$

for the associated Radon–Nikodym derivatives.

Now, if the “complete” data $(Y_1, Z_1), (Y_2, Z_2), \dots, (Y_n, Z_n)$, a random sample of the random variable (Y, Z) , is available, then the maximum likelihood problem for estimating x_o is

$$\begin{aligned} & \text{minimize} && -\frac{1}{n} \sum_{i=1}^n \log f_{\mathcal{Y}, \mathcal{Z}}(Y_i, Z_i|x) \\ & \text{subject to} && x \in \mathcal{X}. \end{aligned} \quad (23)$$

Of course, this is not a rational problem, since the Z_i went unobserved. In other words, the objective function is not known (and not knowable). However, one may attempt to estimate it by the conditional expectation

$$\mathbb{E} \left[-\frac{1}{n} \sum_{i=1}^n \log f_{\mathcal{Y}, \mathcal{Z}}(Y_i, Z_i|x) \middle| \mathbb{Y}_n \right] = -\frac{1}{n} \sum_{i=1}^n \mathbb{E} \left[\log f_{\mathcal{Y}, \mathcal{Z}}(Y_i, Z_i|x) \middle| Y_i \right],$$

where $\mathbb{Y}_n = (Y_1, Y_2, \dots, Y_n)$. The fly in the ointment is that computing this expectation involves the distribution of Z conditioned on Y , which surely will involve the unknown x_o one wishes to estimate! So, at this point, assume that some initial guess x_1 for x_o is available; then denote the resulting (approximate) conditional expectation by $\mathbb{E}[\dots | \mathbb{Y}_n, x_1]$.

Determining this conditional expectation constitutes the E-step of the first iteration of the EM algorithm. The M-step of the first iteration then amounts to solving the minimization problem

$$\begin{aligned} \text{minimize } \Lambda_n(x|x_1) &\stackrel{\text{def}}{=} -\frac{1}{n} \sum_{i=1}^n \mathbb{E}[\log f_{\mathcal{Y}, \mathcal{Z}}(Y_i, Z_i|x) | x_1, Y_i] \\ \text{subject to } x &\in \mathcal{X}. \end{aligned} \quad (24)$$

Denote the solution by x_2 (assuming it exists). Suppressing the presence of the Y_i in the notation, one may define the iteration operator by $x_2 = R(x_1)$, and then the EM algorithm may be stated as

$$x_{k+1} = R(x_k), \quad k = 1, 2, \dots, \quad (25)$$

provided x_1 has been chosen appropriately. This is the bare-bones version of the EM algorithm. Note that it may not be necessary to solve the problem (24) exactly, e.g., one may consider (over)relaxation ideas or the so-called stochastic EM algorithms. See, e.g., [76] and references therein. This will not be considered further.

- Remark 1.* (a) It may be inappropriate to speak of the EM algorithm, since the introduction of different missing data may lead to a different algorithm. However, usually there is not much choice in the missing data.
(b) There is a different approach to the complete data, by assuming that $Y = T(Z)$ for some many-to-one map $T : \mathcal{Z} \rightarrow \mathcal{Y}$. Then, Z is the complete data and Y is the incomplete data, but one does not identify missing data as such.

The Bare-Bones EM Algorithm Fleshed Out

Here, some of the details of the bare-bones EM algorithm are filled in by using explicit expressions for the conditional expectations. To that end, assume that one may take the dominating measure R_∞ to be $R_\infty = P_\infty \cdot Q_\infty$, in the sense that

$$R_\infty(A \times B) = P_\infty(A) \cdot Q_\infty(B) \quad \text{for all } A \in \mathcal{B}_Y \text{ and } B \in \mathcal{B}_Z. \quad (26)$$

Let (Y, Z) have density $f_{\mathcal{Y}, \mathcal{Z}}(y, z|x_o)$ with respect to the product measure $P_\infty \times Q_\infty$. Then, for all $\mathcal{A} \in \mathcal{B}_{Y \times Z}$ and all measurable functions h on $\mathcal{Y} \times \mathcal{Z}$ with finite expectation $\mathbb{E}[h(Y, Z)]$, one may write

$$\begin{aligned} \mathbb{E}[h(Y, Z)] &= \int_{\mathcal{A}} h(y, z) f_{\mathcal{Y}, \mathcal{Z}}(y, z|x) dP_\infty(y) dQ_\infty(z) \\ &= \int_{\mathcal{Y}} \left\{ \int_{\mathcal{Z}} h(y, z) f_{\mathcal{Y}, \mathcal{Z}}(y, z|x) dQ_\infty(z) \right\} dP_\infty(y) \quad (\text{Fubini}) \\ &= \int_{\mathcal{Y}} \left\{ \int_{\mathcal{Z}} h(y, z) \frac{f_{\mathcal{Y}, \mathcal{Z}}(y, z|x)}{f_{\mathcal{Y}}(y|x)} dQ_\infty(z) \right\} f_{\mathcal{Y}}(y|x) dP_\infty(y). \end{aligned}$$

It is clear that this may be interpreted as the expected value of

$$\int_{\mathcal{Z}} h(Y, z) \frac{f_{Y,Z}(Y, z|x)}{f_Y(Y|x)} dQ_{\infty}(z),$$

and then interpret this in turn as $\mathbb{E}[h(Y, Z) | Y]$, the expected value of $h(Y, Z)$ conditioned on Y .

Now define the density of Z conditional on Y by

$$f_{Z|Y}(z|y, x) = \frac{f_{Y,Z}(y, z|x)}{f_Y(y|x)} \quad (27)$$

for those y for which $f_Y(y|x) > 0$ (and arbitrarily if $f_Y(y|x) = 0$). Similarly, one defines

$$f_{Y|Z}(y|z, x) = \frac{f_{Y,Z}(y, z|x)}{f_Z(z|x)} \quad (28)$$

for those z for which $f_Z(z|x) > 0$ (and arbitrarily if $f_Z(z|x) = 0$). So then Bayes' rule yields

$$f_{Z|Y}(z|y, x) = \frac{f_{Y|Z}(y|z, x) f_Z(z|x)}{f_Y(y|x)}. \quad (29)$$

The conditional expectation of a measurable function $h(Y, Z)$ given Y is then

$$\mathbb{E}[h(Y, Z)|Y, x] = \int_{\mathcal{Z}} h(Y, z) f_{Z|Y}(z|Y, x) dQ_{\infty}(z). \quad (30)$$

Probabilists force us to add ‘‘almost surely’’ here.

Now apply this to the conditional expectation of $\log f_{Y,Z}(Y, Z|x)$, with a guess x_1 of the true x . Then,

$$\begin{aligned} & \mathbb{E}[\log f_{Y,Z}(Y, Z|x)|Y, x_1] \\ &= \mathbb{E}[\log f_Z(Z|x) + \log f_{Y|Z}(Y|Z, x)|Y, x_1] \\ &= \int_{\mathcal{Z}} \frac{f_{Y|Z}(Y|z, x_1) f_Z(z|x_1)}{f_Y(y|x_1)} \log f_Z(z|x) dQ_{\infty}(z) \\ &+ \int_{\mathcal{Z}} \frac{f_{Y|Z}(Y|z, x_1) f_Z(z|x_1)}{f_Y(Y_i|x_1)} \log f_{Y|Z}(Y|z, x) dQ_{\infty}(z). \end{aligned} \quad (31)$$

For $\Lambda_n(x|x_1)$, this gives

$$\begin{aligned}\Lambda_n(x|x_1) &= \int_{\mathcal{Z}} \varphi_{\mathcal{Z}}(z|x_1) \log f_{\mathcal{Z}}(z|x) dQ_{\infty}(z) + \\ &- \frac{1}{n} \sum_{i=1}^n \int_{\mathcal{Z}} \frac{f_{\mathcal{Y}|Z}(Y_i|z, x_1) f_{\mathcal{Z}}(z|x_1)}{f_{\mathcal{Y}}(Y_i|x_1)} \log f_{\mathcal{Y}|Z}(Y_i|z, x) dQ_{\infty}(z),\end{aligned}\quad (32)$$

with

$$\varphi_{\mathcal{Z}}(z) = f_{\mathcal{Z}}(z|x_1) \cdot \frac{1}{n} \sum_{i=1}^n \frac{f_{\mathcal{Y}|Z}(Y_i|z, x_1)}{f_{\mathcal{Y}}(Y_i|x_1)}. \quad (33)$$

For the M-step of the algorithm, one has to minimize this over x , which is in general not trivial. The problem is simplified somewhat in the important case where $f_{\mathcal{Y}|Z}(y|z, x)$ is known and does not depend on x . Then, the problem reduces to solving

$$\begin{aligned}\text{minimize } \mathfrak{L}_n(x|x_1) &\stackrel{\text{def}}{=} - \int_{\mathcal{Z}} \varphi_{\mathcal{Z}}(z|x_1) \log f_{\mathcal{Z}}(z|x) dQ_{\infty}(z) \\ \text{subject to } x &\in \mathcal{X}.\end{aligned}\quad (34)$$

Note that

$$\mathfrak{L}_n(x|x_1) = \text{KL}(\varphi_{\mathcal{Z}}(\cdot|x), f_{\mathcal{Z}}(\cdot, x)) + (\text{terms not depending on } x), \quad (35)$$

where $\text{KL}(f, g)$ is the Kullback–Leibler divergence between the density f and g with respect to the same measure Q_{∞} , defined as

$$\text{KL}(f, g) = \int_{\mathcal{Z}} \left\{ f(z) \log \left\{ \frac{f(z)}{g(z)} \right\} + f(z) - g(z) \right\} dQ_{\infty}(z). \quad (36)$$

Compare with (10).

So, solving (34) amounts to computing what one may call the Kullback–Leibler projection of $\varphi_{\mathcal{Z}}(\cdot|x_1)$ onto the parametric family \mathcal{P} . If \mathcal{P} is such that $\varphi_{\mathcal{Z}}(\cdot|x_1) \in \mathcal{P}$, then the projection is $f_{\mathcal{Z}}(\cdot|x) = \varphi_{\mathcal{Z}}(\cdot|x_1)$.

The EM Algorithm Increases the Likelihood

The expression for $\Lambda_n(x|x_1)$ (see (24)) may be reworked as follows. Using

$$f_{\mathcal{Y}, \mathcal{Z}}(y, z, |x) = f_{\mathcal{Z}|Y}(z|y, x) f_{\mathcal{Y}}(y|x)$$

(see (27)), one gets

$$\mathbb{E} \left[\log f_{\mathcal{Y}, \mathcal{Z}}(Y, Z|x) \mid x_1, Y \right] = \log f_{\mathcal{Y}}(Y|x) + \mathbb{E}[\log f_{\mathcal{Z}|Y}(Z|Y, x) \mid Y, x_1],$$

and so,

$$\Lambda(x|x_1) = L_n(x) + e_n(x_1|x), \quad (37)$$

where $L_n(x)$ is given by (17) and

$$e_n(u|w) \stackrel{\text{def}}{=} - \sum_{i=1}^n \int_{\mathcal{Z}} f_{\mathcal{Z}|Y}(z|Y_i, u) \log f_{\mathcal{Z}|Y}(z|Y_i, w) dQ_{\infty}(z). \quad (38)$$

It is now obvious that the EM algorithm decreases $L_n(x)$: Let x_2 be the minimizer of $\Lambda(x|x_1)$ over $x \in \mathcal{X}$. Then, $\Lambda_n(x_2|x_1) \leq \Lambda_n(x_1|x_1)$, and so $L_n(x_2) + e_n(x_1|x_2) \leq L_n(x_1) + e_n(x_1|x_1)$, or

$$L_n(x_1) - L_n(x_2) \geq e_n(x_1|x_2) - e_n(x_1|x_1) = K_n(x_1|x_2), \quad (39)$$

where

$$K_n(u|w) = \sum_{i=1}^n \text{KL} \left(f_{\mathcal{Z}|Y}(\cdot|Y_i, u), f_{\mathcal{Z}|Y}(\cdot|Y_i, w) \right) \quad (40)$$

is a sum of Kullback–Leibler “distances”; see (36). Then, $K_n(x_1|x_2) \geq 0$ unless $x_1 = x_2$, assuming that the conditional densities $f_{Z|Y}(\cdot|Y, u)$ and $f_{Z|Y}(\cdot|Y, w)$ are equal Q_{∞} almost everywhere only if $u = w$. Then, the conclusion

$$L_n(x_1) > L_n(x_2) \quad \text{unless} \quad x_1 = x_2 \quad (41)$$

is justified. Thus, the EM algorithm decreases the likelihood.

Unfortunately, $x_1 = x_2$ being a fixed point of the EM iteration does not guarantee that then x_1 is a maximum likelihood estimator of x_o . Equally unfortunately, even if one gets an infinite sequence of estimators, this does not imply that the sequence of estimators converges, nor that the likelihood converges to its maximum. Later on, the convergence of EM algorithms for special, convex maximum likelihood problems is discussed in detail.

4 The EM Algorithm in Simple Cases

In this section, some simple cases of the EM algorithm are discussed, capturing some of the essential features of more complicated “real” examples of maximum likelihood estimation to be discussed later on. It turns out that the EM algorithms are the “same” in all but the last example (regarding a finite mixture of unknown

densities), even though the settings appear to be quite different. However, even in the last case, the “same” EM algorithm arises via the empirical Bayes approach.

A word on notation: The scaled negative log-likelihood for each problem is always denoted as L_n ; $L_n(x)$ in the discrete case, $L_n(f)$ in the continuous case. The negative log-likelihood in the M-step of the EM algorithm is denoted by $\Lambda(x|x_1)$ or variations thereof.

Mixtures of Known Densities

Let $d \geq 1$ be an integer and consider the statistical space $(\mathcal{Y}, \mathcal{B}, \mathcal{P})$, with $\mathcal{Y} = \mathbb{R}^d$, \mathcal{B} the σ -algebra of Borel subsets of \mathcal{Y} and \mathcal{P} the collection of probability measures that are absolutely continuous with respect to Lebesgue measure. Consider the random variable Y with values in \mathcal{Y} and with density

$$f_Y(y) = \sum_{j=1}^m x_o(j) a_j(y), \quad y \in \mathcal{Y}, \quad (42)$$

where a_1, a_2, \dots, a_m are known densities and $x_o = (x_{o,1}, x_{o,2}, \dots, x_{o,m})^\top$ is a probability vector, i.e., $x_o \in V_m$,

$$V_m = \left\{ x \in \mathbb{R}^m \mid x \geq 0 \text{ (componentwise)}, \sum_{j=1}^m x(j) = 1 \right\}. \quad (43)$$

Suppose that one has a random sample Y_1, Y_2, \dots, Y_n of the random variable Y . The maximum likelihood problem for estimating f_Y (or estimating the probability vector x_o) is then

$$\text{minimize } L_n(x) \stackrel{\text{def}}{=} -\frac{1}{n} \sum_{i=1}^n \log \left(\sum_{j=1}^m x(j) a_j(Y_i) \right) \quad (44)$$

$$\text{subject to } x \in V_m.$$

To derive an EM algorithm, missing data must be introduced. To see what could be missing, it is helpful to think of how one would simulate the random variable Y . First, draw the random variable J from the distribution

$$f_J(j) = \mathbb{P}[J = j] = x_o(j), \quad j = 1, 2, \dots, m. \quad (45)$$

Then, conditional on $J = j$, draw Y from the distribution with density a_j . So, the missing data is J , a random variable with values in $\mathcal{M} = \{1, 2, \dots, m\}$. The associated statistical space is

$$(\mathcal{M}, 2^{\mathcal{M}}, V_m), \quad (46)$$

the σ -algebra is the collection of all subsets of \mathcal{M} , and the collection of all probability measures on \mathcal{M} may be represented by V_m . Let α denote counting measure on \mathcal{M} , i.e., for any $A \in 2^{\mathcal{M}}$,

$$\alpha(A) = |A| \quad (\text{the number of elements in } A). \quad (47)$$

Then, it is easy to see that the distribution of (Y, J) is absolutely continuous with respect to the product measure $\mu \times \alpha$, with density

$$f_{Y,J}(y, j) = f_J(j) f_{Y|J}(y|j) = x_o(j) a_j(y), \quad y \in \mathcal{Y}, j \in \mathcal{M}. \quad (48)$$

Now, the complete data is $(Y_1, J_1), (Y_2, J_2), \dots, (Y_n, J_n)$ and the complete maximum likelihood problem for estimating x_o is

$$\text{minimize} \quad -\frac{1}{n} \sum_{i=1}^n \log \left\{ x(J_i) a_{J_i}(Y_i) \right\} \quad \text{subject to} \quad x \in V_m. \quad (49)$$

Of course, the J_i went unobserved, so one must compute the conditional expectations $\mathbb{E}[\log \{x(J) a_J(Y)\} | Y]$. Now,

$$f_{J|Y}(j|y) = \frac{f_{Y,J}(y, j)}{f_Y(y)} = \frac{x_o(j) a_j(y)}{\sum_{p=1}^m a_p(y) x_o(p)},$$

but of course, x_o is unknown; approximate it by some initial guess $x^{[1]} \in V_m$, e.g., $x_j^{[1]} = 1/m$ for all j . Then, the conditional expectation in question is approximated by

$$\begin{aligned} \mathbb{E}[\log \{x(J) a_J(Y)\} | Y, x^{[1]}] &= - \int_{\mathcal{M}} \log \{x(j) a_j(Y)\} x^{[2]}(j, Y) d\alpha(j) \\ &= - \sum_{j \in \mathcal{M}} x^{[2]}(j, Y) \log \{x(j) a_j(Y)\}, \end{aligned}$$

$$\text{with} \quad x^{[2]}(j, Y) = \frac{x^{[1]}(j) a_j(Y)}{\sum_{p=1}^m a_p(Y) x^{[1]}(p)}, \quad j \in \mathcal{M}.$$

Then, the E-step of the EM algorithm leads to the problem

$$\text{minimize} \quad - \sum_{j \in \mathcal{M}} x^{[2]}(j) \log \{x(j) a_{ij}\} \quad \text{subject to} \quad x \in V_\ell, \quad (50)$$

where $a_{ij} = a_j(Y_i)$ for all i, j and $x^{[2]}(j) = \frac{1}{n} \sum_{i=1}^n x^{[2]}(j, Y_i)$, or

$$x^{[2]}(j) = x^{[1]}(j) \cdot \frac{1}{n} \sum_{i=1}^n \frac{a_{ij}}{\left(\sum_{p=1}^m a_{ip} x^{[1]}(p) \right)}. \quad (51)$$

Taking into account that

$$\log \{x(j) a_j(Y)\} = \log x(j) + (\text{a term not depending on } x),$$

one then arrives at the problem

$$\begin{aligned} \text{minimize} \quad & \Lambda_n(x|x^{[2]}) \stackrel{\text{def}}{=} -\sum_{j=1}^m x^{[2]}(j) \log x(j) \\ \text{subject to} \quad & x \in V_m. \end{aligned} \quad (52)$$

This is the E-step of the first iteration of the EM algorithm. Now consider the identity

$$\Lambda(x|x^{[2]}) - \Lambda(x^{[2]}|x^{[2]}) = \text{KL}(x^{[2]}, x), \quad (53)$$

where for u, w nonnegative vectors in \mathbb{R}^m ,

$$\text{KL}(u, w) \stackrel{\text{def}}{=} \sum_{j=1}^m \left\{ u(j) \log \frac{u(j)}{w(j)} + w(j) - u(j) \right\}. \quad (54)$$

This is the finite-dimensional Kullback–Leibler divergence between the nonnegative vectors u and w . Note that the summand is nonnegative and so is minimal when $u = w$. So, the solution of (52) is precisely $x = x^{[2]}$. This would be the M-step of the first iteration of the EM algorithm. The EM-step is then (51).

A Deconvolution Problem

The setting is the statistical space $(\mathbb{R}^d, \mathcal{B}, \mathcal{P})$, where \mathcal{B} is the σ -algebra of Borel subsets of \mathbb{R}^d and \mathcal{P} is the collection of all probability density functions on \mathbb{R}^d (with respect to Lebesgue measure). Denote Lebesgue measure by μ . Let Y be a random variable with values in \mathbb{R}^d and with density f_Y (with respect to Lebesgue measure); the interest is in estimating f_Y . Now, assume that one is unable to observe Y directly but that instead one only observes a corrupted version, viz., $W = Y + Z$, where Z is another \mathbb{R}^d -valued random variable. Assume that the distribution of Z is completely known; denote its density by k . The density of W is then $\mathcal{K}f_Y$, where the integral operator $\mathcal{K} : L^1(\mathbb{R}^d, d\mu) \rightarrow L^1(\mathbb{R}^d, d\mu)$ is defined as

$$[\mathcal{K} f](w) = \int_{\mathbb{R}^d} k(w - y) f(y) d\mu(y), \quad w \in \mathbb{R}^d. \quad (55)$$

Note that $k(\cdot - y)$ is the density of W conditioned on $Y = y$, i.e., $f_{W|Y}(w|y) = k(w - y)$ for all w and y , and then

$$f_{W,Y}(w, y) = k(w - y) f_Y(y), \quad w, y \in \mathbb{R}^d. \quad (56)$$

So, assume that one has a random sample W_1, W_2, \dots, W_n of the random variable W . The maximum likelihood problem for estimating f_Y is then

$$\begin{aligned} \text{minimize } L_n(f) &\stackrel{\text{def}}{=} -\frac{1}{n} \sum_{i=1}^n \log [\mathcal{K} f](W_i) \\ \text{subject to } f &\in \mathcal{P}. \end{aligned} \quad (57)$$

Recall that \mathcal{P} is the collection of all pdfs in $L^1(\mathbb{R}^d, d\mu)$. It is impossible to guarantee that this problem has a solution. In fact, regularization is required; see section ‘‘Smoothed EM Algorithms.’’ Nevertheless, one can use EM algorithms to construct useful approximations to the density f_Y by the expedient of stopping the iteration ‘‘early.’’

Note that one could view (57) as a continuous mixture problem, since $\mathcal{K} f$ is a continuous mixture of known densities with the known densities $k_y(w) = k(w - y)$, $y \in \mathbb{R}^d$, and the continuous weights are the unknown $f_Y(y)$, $y \in \mathbb{R}^d$. However, the present approach is somewhat different.

To derive an EM algorithm, one must decide on the missing data. It seems obvious that the missing data is Y itself or Z (or both), but the choice Y seems the most convenient. Thus, assume that one has available the random sample $(W_1, Y_1), (W_2, Y_2), \dots, (W_n, Y_n)$ of the random variable (W, Y) . In view of (56), the maximum likelihood problem for estimating f_Y is then

$$\begin{aligned} \text{minimize } \Lambda_n(f) &\stackrel{\text{def}}{=} -\frac{1}{n} \sum_{i=1}^n \log \{k(W_i - Y_i) f(W_i)\} \\ \text{subject to } f &\in \mathcal{P}. \end{aligned} \quad (58)$$

Since the Y_i are not really observed, one must compute or approximate the conditional expectation $\mathbb{E}[\log \{k(W - Y) f(Y)\} | W]$. Since the density of Y conditioned on W may be written as

$$f_{Y|W}(y|w) = \frac{k(w - y) f_Y(y)}{[\mathcal{K} f_Y](w)},$$

then, approximating f_Y by some initial guess f_1 , the conditional expectation is approximated by

$$\int_{\mathbb{R}^d} \frac{k(W - y) f_1(y)}{[\mathcal{K} f_1](w)} \log f(y) d\mu(y),$$

apart from a term not depending on f . So then, the problem (58) is approximated by

$$\text{minimize } - \int_{\mathbb{R}^d} f_2(y) \log f(y) d\mu(y) \quad \text{subject to } f \in \mathcal{P}, \quad (59)$$

where

$$f_2(y) = f_1(y) \cdot \frac{1}{n} \sum_{i=1}^n \frac{k(W_i - y)}{[\mathcal{K} f_1](W_i)}, \quad y \in \mathbb{R}^d. \quad (60)$$

This is the E-step of the EM algorithm

For the M-step, i.e., actually solving (59), note that

$$\Lambda_n(f|f_1) - \Lambda_n(f_1|f_1) = \text{KL}(f_2, f), \quad (61)$$

which is minimal for f_2 . Thus, the solution of (59) is $f = f_2$ as well. Thus, the EM algorithm takes the form (60) iteratively applied.

The discretized EM algorithm: The EM algorithm (60) cannot be implemented as is, but it certainly may be discretized. However, it is more straightforward to discretize the maximum likelihood problem (57).

A reasonable way to discretize the maximum likelihood problem (57) is to restrict the minimization to step functions on a suitable partition of the space. Suppose that the compact set $C_o \subset \mathbb{R}^d$ contains the support of f_Y , and let $\{C_j\}_{j=1}^m$ be a partition of C_o . Define the (step) functions a_j by

$$a_j(y) = |C_j|^{-1} \mathbf{1}(y \in C_j), \quad i = 1, 2, \dots, m, \quad (62)$$

where for any set A , the indicator function $\mathbf{1}(y \in A)$ is defined as

$$\mathbf{1}(y \in A) = 1 \quad \text{if } y \in A \quad \text{and} \quad = 0 \quad \text{otherwise.} \quad (63)$$

Then, define \mathcal{P}_m to be the set of pdfs in the linear span of the a_j ,

$$\mathcal{P}_m = \left\{ \sum_{j=1}^m x_j a_j(\cdot) \mid x \in V_m \right\}. \quad (64)$$

Note that the a_j are pdfs, and in fact, one could take the a_j , $j = 1, 2, \dots, m$ to be any collection of pdfs.

Now, consider the restricted maximum likelihood problem

$$\text{minimize} \quad -\frac{1}{n} \sum_{i=1}^n \log[\mathcal{K}f](W_i) \quad \text{subject to} \quad f \in \mathcal{P}_m \quad (65)$$

and observe that it may obviously be rewritten as

$$\text{minimize} \quad -\frac{1}{n} \sum_{i=1}^n \log \left(\sum_{j=1}^m a_{ij} x_j \right) \quad \text{subject to} \quad x \in V_m, \quad (66)$$

where for $i = 1, 2, \dots, n$ and $j = 1, 2, \dots, m$,

$$a_{ij} = \int_{\mathbb{R}^d} k(W_i - y) a_j(y) d\mu(y).$$

And this is all there is to it: The problem (66) is just a finite mixture problem with known distributions! Thus, the EM algorithm is as in section ‘‘Mixtures of Known Densities,’’

$$x_j^{[k+1]} = x_j^{[k]} \cdot \frac{1}{n} \sum_{i=1}^n \frac{a_{ij}}{\left(\sum_{p=1}^m a_{ip} x_p^{[k]} \right)}, \quad j = 1, 2, \dots, m, \quad (67)$$

with the estimator for f_Y induced by the representation of (64).

Another EM algorithm? There is of course another way to derive an EM algorithm for the problem (65), viz., by introducing the missing data Y_i as before. As for the unrestricted maximum likelihood problem (57), the E-step of the first iteration of the EM algorithm leads to the problem, analogous to (59),

$$\text{minimize} \quad -\int_{\mathbb{R}^d} f_2(y) \log f(y) d\mu(y) \quad \text{subject to} \quad f \in \mathcal{P}_m, \quad (68)$$

with f_2 given by (60). Now, using the representations

$$f(y) = \sum_{j=1}^m x_j a_j(y), \quad f_k(y) = \sum_{j=1}^m x_j^{[k]} a_j(y)$$

with the step functions a_j , for $k = 1, 2$, the objective function in (65) may be written as

$$-\sum_{j=1}^m (\log x_j) \int_{C_j} f_2(y) d\mu(y),$$

and of course

$$\int_{C_j} f_2(y) d\mu(y) = x_j^{[1]} \cdot \frac{1}{n} \sum_{i=1}^n \frac{a_{ij}}{[\mathcal{K} f_1](W_i)} \stackrel{\text{def}}{=} x_j^{[2]}, \quad (69)$$

where

$$a_{ij} = \int_{\mathbb{R}^d} k(W_i - y) a_j(y) d\mu(y) = |C_j|^{-1} \int_{C_j} k(W_i - y) d\mu(y).$$

Note that

$$[\mathcal{K} f_1](W_i) = \sum_{j=1}^m a_{ij} x_j^{[1]}, \quad i = 1, 2, \dots, n.$$

Thus, the problem (68) is equivalent to

$$\text{minimize } - \sum_{j=1}^m x_j^{[2]} \log x_j \quad \text{subject to } x \geq 0, \quad \sum_{j=1}^m x_j = 1. \quad (70)$$

But it was already shown in section “Mixtures of Known Densities” that the solution is $x = x^{[2]}$. So, the iterative step is *exactly* the same as in (67). As an aside, this is a case where the introduction of “different” missing data leads to the same EM algorithm.

The Deconvolution Problem with Binning

Consider again the deconvolution problem of section “A Deconvolution Problem,” but now with the extra twist that the data is binned.

Recall that the random variable of interest is Y which lives in the statistical space $(\mathcal{Y}, \mathcal{B}_{\mathcal{Y}}, \mathcal{P})$ with $\mathcal{Y} = \mathbb{R}^d$, $\mathcal{B}_{\mathcal{Y}}$ the σ -algebra of Borel subsets of \mathcal{Y} , and \mathcal{P} the collection of probability measures on $\mathcal{B}_{\mathcal{Y}}$ that are absolutely continuous with respect to Lebesgue measure. The density of Y is denoted by f_Y . The random variable Y was not observable. Instead, one can observe the random variable

$$W = Y + Z,$$

where Z is another random variable living in $(\mathcal{Y}, \mathcal{B}_{\mathcal{Y}}, \mathcal{P})$, with known density denoted by k and independent of Y . Actually, with binned data, W is not observed either. Let $\ell \in \mathbb{N}$ and let $\{B_j\}_{j=1}^\ell \subset \mathcal{B}_{\mathcal{Y}}$ be a partition of \mathcal{Y} (or of a set containing the support of W). What one does observe is which “bin” B_j the observation W belongs to. That is, one observes the random variable J , with $J = j$ if

$$\mathbf{1}(W \in B_j) = 1, \quad (71)$$

cf. (63). Then, the statistical space of interest is $(\mathcal{M}, 2^{\mathcal{M}}, V_m)$; see (46). Of course, V_m is dominated by the counting measure, denoted by α ; see (47). The density of J then satisfies

$$f_J(j) = [\mathcal{K}f_Y](B_j) = \int_{B_j} [\mathcal{K}f_Y](w) d\mu(w), \quad j \in \mathcal{M}. \quad (72)$$

So, now one observes the random sample J_1, J_2, \dots, J_n of the random variable J , and the goal is to estimate f_Y . The maximum likelihood problem is then

$$\text{minimize } -\frac{1}{n} \sum_{i=1}^n \log[\mathcal{K}f](B_{J_i}) \quad \text{subject to } f \in \mathcal{P}, \quad (73)$$

which is equivalent to

$$\text{minimize } -\frac{1}{n} \sum_{j=1}^{\ell} N_j \log[\mathcal{K}f](B_j) \quad \text{subject to } f \in \mathcal{P}. \quad (74)$$

Here, the N_j are the bin counts

$$N_j = \sum_{i=1}^n \mathbf{1}(J_i = j), \quad j \in \mathcal{M}. \quad (75)$$

Remark 2. Later, for any function $h : \mathcal{M} \rightarrow \mathbb{R}$, the more general identity

$$\sum_{i=1}^n h(J_i) = \sum_{j=1}^m N_j h(j)$$

will be useful.

So, the real data are the bin counts, but it is advantageous to keep the J_i . It has to be seen whether one can get away it, though. So, the starting point is (73) and not (74).

To derive an EM algorithm, the missing data must be considered. It seems obvious that the W_i are missing, and the treatment in section “A Deconvolution Problem” suggests that the Y_i are missing as well. So, the complete data is the random sample (J_i, W_i, Y_i) of the random variable (J, W, Y) . This random variable lives in the statistical space $(\mathcal{M} \times \mathcal{Y} \times \mathcal{Y}, \mathcal{B}, \mathcal{Q})$, with \mathcal{B} the σ -algebra generated by the sets $A \times B \times C$ with $A \subset \mathcal{M}$ and $B, C \in \mathcal{B}_{\mathcal{Y}}$. Finally, \mathcal{Q} is the collection of probability measures on \mathcal{B} that are absolutely continuous with respect to the product measure $\alpha \times \mu \times \mu$. The density of (J, W, Y) is then

$$f_{J,W,Y}(j, w, y) = k(w - y) f_Y(y) \mathbf{1}(w \in B_j), \quad j \in \mathcal{M}, w, y \in \mathcal{Y}. \quad (76)$$

The complete maximum likelihood problem for estimating f_Y is now

$$\text{minimize} \quad -\frac{1}{n} \sum_{i=1}^n \log \{k(W_i - Y_i) f(Y_i)\} \quad \text{subject to} \quad f \in \mathcal{P}. \quad (77)$$

This is the same as the problem (58). However, here one conditions differently. At issue is the conditional expectation $\mathbb{E}[\log\{k(W - Y) f(Y)\} | J]$. Observe that

$$f_{W,Y|J}(w, y | j) = \frac{f_{J,W,Y}(j, w, y)}{f_J(j)} = \frac{k(w - y) f_Y(y) \mathbf{1}(w \in B_j)}{[\mathcal{K}f_Y](B_j)}, \quad (78)$$

so that, replacing f_Y by some initial guess f_1 , one finds that

$$\begin{aligned} & \mathbb{E}[\log\{k(W - Y) f(Y)\} | J, f_1] \\ &= \int_{\mathcal{Y} \times \mathcal{Y}} \log\{k(w - y) f(y)\} \frac{k(w - y) f_1(y) \mathbf{1}(w \in B_j)}{[\mathcal{K}f_1](B_j)} d\mu(w) d\mu(y). \end{aligned}$$

Now, using

$$\log\{k(w - y) f(y)\} = \log\{f(y)\} + (\text{a term not depending on } f),$$

one arrives at

$$\begin{aligned} & \mathbb{E}[\log\{k(W - Y) f(Y)\} | J, f_1] \\ &= \int_{\mathcal{Y}} \frac{f_1(y) k_j(y)}{[\mathcal{K}f_1](B_j)} \log\{f(y)\} d\mu(y) + \text{rem}, \end{aligned} \quad (79)$$

where “rem” involves terms not depending on f , and

$$k_j(y) = \int_{B_j} k(w - y) d\mu(w), \quad j \in \mathcal{M}. \quad (80)$$

Note that then

$$[\mathcal{K}f_1](B_j) = \int_{\mathcal{Y}} k_j(y) f_1(y) d\mu(y). \quad (81)$$

So, the E-step of the EM algorithm leads to the problem

$$\text{minimize} \quad - \int_{\mathcal{Y}} f_2(y) \log f(y) d\mu(y) \quad \text{subject to} \quad f \in \mathcal{P}, \quad (82)$$

where (one would say: as always)

$$f_2(y) = f_1(y) \cdot \frac{1}{n} \sum_{i=1}^n \frac{k_{J_i}(y)}{[\mathcal{K}f_1](B_{J_i})}, \quad y \in \mathcal{Y}. \quad (83)$$

Since

$$\int_{\mathcal{Y}} f_1(y) d\mu(y) = \frac{1}{n} \sum_{i=1}^n \left\{ \int_{\mathcal{Y}} k_{J_i}(y) f(y) d\mu(y) \Big/ [\mathcal{K}f_1](B_j) \right\} = 1,$$

the solution of (82) is f_2 . So, the iterative step of the EM algorithm is given by (83). Actually, the situation is a little sticky, since (83) involves the J_i . However, one may collect the J_i with equal values, so that then

$$N_j = \sum_{i=1}^n \mathbf{1}(j = J_i),$$

and so an equivalent definition of f_2 is

$$f_2(y) = f_1(y) \cdot \frac{1}{n} \sum_{j=1}^m \frac{N_j k_j(y)}{[\mathcal{K}f_1](B_j)} \quad y \in \mathcal{Y}. \quad (84)$$

The EM algorithm is then obtained by iterative applying of the EM-step (84).

Discretizing the EM algorithm: Note that a discretized EM algorithm may be derived by restricting the minimization in (74) to step functions on a partition $\{C_j\}_{j=1}^\ell$ of a set containing the support of Y . With \mathcal{P}_m as in (64), the restricted maximum likelihood problem with binned data is

$$\text{minimize} \quad -\frac{1}{n} \sum_{j=1}^\ell N_j \log[\mathcal{K}f](C_j) \quad \text{subject to} \quad f \in \mathcal{P}_m. \quad (85)$$

One then derives the EM algorithm as in section “A Deconvolution Problem,” leading to

$$x_j^{[k+1]} = x_j^{[k]} \cdot \frac{1}{n} \sum_{p=1}^\ell \frac{N_p k_{ip}}{\left(\sum_{q=1}^\ell a_{iq} x_q^{[k]} \right)}, \quad j = 1, 2, \dots, \ell, \quad (86)$$

where for $p = 1, 2, \dots, m$ and $q = 1, 2, \dots, \ell$,

$$a_{pq} = \int_{C_p} \left\{ \int_{B_q} k(w - y) d\mu(y) \right\} d\mu(w).$$

The estimators for f_Y are then

$$f_k(y) = \sum_{j=1}^{\ell} x_j^{[k]} |C_j|^{-1} \mathbf{1}(y \in C_j), \quad y \in \mathcal{Y}. \quad (87)$$

Finite Mixtures of Unknown Distributions

The final simple case to be discussed is that of a mixture with a small number of densities belonging to some parametric family.

Consider a random variable Y in a statistical space $(\mathcal{Y}, \mathcal{B}_{\mathcal{Y}}, \mathcal{P})$, with

$$\mathcal{P} = \{f(\cdot | x) : x \in \mathcal{X}\}, \quad (88)$$

a family of probability measures indexed by the (low-dimensional) parameter $x \in \mathcal{X}$. Assume that \mathcal{P} is dominated by some measure P_{∞} and that

$$\left[\frac{dP(\cdot | x)}{dP_{\infty}} \right] (y) = f_{\mathcal{Y}}(y|x), \quad y \in \mathcal{Y}. \quad (89)$$

So, let Y be a random variable with density

$$f_Y(y) = \sum_{j=1}^m w_o(j) f_{\mathcal{Y}}(y|x_o(j)), \quad y \in \mathcal{Y}. \quad (90)$$

Here, $w_o = (w_{o_1}, w_{o_2}, \dots, w_{o_m}) \in V_m$, the space of probability vectors (see (43)), and $x_o = (x_{o,1}, x_{o,2}, \dots, x_{o,m}) \in \mathcal{X}_m$, thus defining \mathcal{X}_m . (The notations $x_{o,j}$ and $x_o(j)$ are used interchangeably.)

Given a random sample Y_1, Y_2, \dots, Y_m , the maximum likelihood problem for estimating w_o and x_o is then

$$\begin{aligned} & \text{minimize} && -\frac{1}{n} \sum_{i=1}^n \log \left(\sum_{j=1}^m w_j f_{\mathcal{Y}}(Y_i|x_j) \right) \\ & \text{subject to} && w \in V_m, \quad x \in \mathcal{X}_m. \end{aligned} \quad (91)$$

To derive an EM algorithm, one must introduce the missing data. As in section “Mixtures of Known Densities,” the random index $J \in \mathcal{M} = \{1, 2, \dots, m\}$ would be a useful information because $f_{Y|J}(y|j) = f_{\mathcal{Y}}(y|x_{o,j})$.

So considering $(Y_1, J_1), (Y_2, J_2), \dots, (Y_n, J_n)$ to be the complete data, the maximum likelihood problem is

$$\begin{aligned} & \text{minimize} && -\frac{1}{n} \sum_{i=1}^n \log\{w(J_i) f_{\mathcal{Y}}(Y_i | x(J_i))\} \\ & \text{subject to} && W \in V_m, x \in \mathcal{X}_m. \end{aligned} \quad (92)$$

Similar to the development in section ‘‘Mixtures of Known Densities,’’ now with initial guesses $w^{[1]}$ and $x^{[1]}$, one obtains that

$$\begin{aligned} & \mathbb{E}\left[\log\{w(J) f_{\mathcal{Y}}(Y | x(j))\} \mid Y, w^{[1]}, x^{[1]}\right] \\ & = \sum_{j \in \mathcal{M}} \frac{w^{[1]}(j) f_{\mathcal{Y}}(Y | x^{[1]}(j))}{\left(\sum_{p=1}^m w^{[1]}(p) f_{\mathcal{Y}}(Y | x^{[1]}(p))\right)} \log\{w(j) f_{\mathcal{Y}}(Y | x^{[1]}(j))\}. \end{aligned}$$

It follows that

$$\begin{aligned} & \mathbb{E}\left[-\frac{1}{n} \sum_{i=1}^n \log\{w(J_i) f_{\mathcal{Y}}(Y_i | x(J_i))\} \mid Y_1, Y_2, \dots, Y_n, w^{[1]}, x^{[1]}\right] \\ & = -\sum_{j \in \mathcal{M}} w^{[2]}(j) \log w(j) + \mathfrak{L}_n(x | x^{[1]}, w^{[1]}), \end{aligned} \quad (93)$$

where

$$w^{[2]}(j) = w^{[1]}(j) \cdot \frac{1}{n} \sum_{i=1}^n \frac{f_{\mathcal{Y}}(Y_i | x^{[1]}(j))}{\left(\sum_{p \in \mathcal{M}} w^{[1]}(p) f_{\mathcal{Y}}(Y_i | x^{[1]}(p))\right)}, \quad j \in \mathcal{M}, \quad (94)$$

and

$$\mathfrak{L}_n(x | x^{[1]}, w^{[1]}) = -\frac{1}{n} \sum_{i=1}^n \frac{f_{\mathcal{Y}}(Y_i | x^{[1]}(j)) \log f_{\mathcal{Y}}(Y_i | x(j))}{\left(\sum_{p \in \mathcal{M}} w^{[1]}(p) f_{\mathcal{Y}}(Y_i | x^{[1]}(p))\right)}. \quad (95)$$

This is essentially the E-step of the EM algorithm. Note that the definition of $w^{[2]}$ is in the by-now-familiar form. For the M-step, one must solve

$$\begin{aligned} \text{minimize} \quad & - \sum_{j \in \mathcal{M}} w^{[2]}(j) \log w(j) + \mathfrak{L}_n(x|x^{[1]}, w^{[1]}) \\ \text{subject to} \quad & w \in V_m, \quad x \in \mathcal{X}_m, \end{aligned} \quad (96)$$

and this nicely separates. The minimization over w gives $w = w^{[2]}$ as always, and $x = x^{[2]}$ is the solution of

$$\text{minimize} \quad \mathfrak{L}_n(x|x^{[1]}, w^{[1]}) \quad \text{subject to} \quad x \in \mathcal{X}_m. \quad (97)$$

Unfortunately, in general, there is no closed form solution of this problem.

There are numerous examples of this type of mixture problems. See, e.g., [58, 79].

Empirical Bayes Estimation

There is another way of deriving EM algorithms for the mixture problem under consideration. Of course, that means one must introduce a different collection of missing data. The following development is from Eggermont and LaRiccia [39].

Starting from the beginning, consider the random variable Y with density $f_Y(\cdot | x_o)$ with respect to P_∞ . Given a random sample Y_1, Y_2, \dots, Y_n of the random variable Y , one wishes to estimate x_o . The maximum likelihood problem is

$$\text{minimize} \quad -\frac{1}{n} \sum_{i=1}^n \log f_Y(Y_i | x) \quad \text{subject to} \quad x \in \mathcal{X}. \quad (98)$$

So, what is the missing data in this case? It was already alluded to: the missing information is x_o ! In the so-called empirical Bayes approach, one considers x_o to be a random variable in the statistical space $(\mathcal{X}, \mathcal{B}_{\mathcal{X}}, \mathcal{T})$, with \mathcal{T} a collection of probability measures on $\mathcal{B}_{\mathcal{X}}$, dominated by some measure T_∞ . The complete data is the random sample $(Y_1, X_1), (Y_2, X_2), \dots, (Y_n, X_n)$ of the random variable (Y, X) , with density

$$f_{Y,X}(y, x) = f_X(x) f_{Y|X}(y|x) = f_X(x) f_Y(y|x). \quad (99)$$

So, f_X is the marginal density of X , but instead of prescribing a prior distribution on X , one's task is to estimate this distribution without using prior information. The estimator of f_X will tell us whether one parameter $X = x_o$ suffices for all Y_i , viz., if the estimator of f_X has most of its mass near $x = x_o$ or if one has (mostly) a mixture with a few components, or indeed a continuous mixture.

Note that

$$f_Y(y) = \int_{\mathcal{X}} f_Y(y|x) f_X(x) dT_\infty(x). \quad (100)$$

Defining the integral operator \mathcal{K} by

$$[\mathcal{K}f](y) = \int_{\mathcal{X}} f_{\mathcal{Y}}(y|x) f(x) dT_{\infty}(x), \quad y \in \mathcal{Y}, \quad (101)$$

the maximum likelihood problem for estimating f_X is

$$\text{minimize} \quad -\frac{1}{n} \sum_{i=1}^n \log[\mathcal{K}f](Y_i) \quad \text{subject to} \quad f \in \mathcal{T}. \quad (102)$$

Note that the problem (102) is very much like the problem (57). Indeed, in very much the same way as in section “A Deconvolution Problem,” one derives the EM algorithm

$$f_{k+1}(x) = f_k(x) \cdot \frac{1}{n} \sum_{i=1}^n \frac{f_{\mathcal{Y}}(Y_i|x)}{[\mathcal{K}f_k](Y_i)}, \quad x \in \mathcal{X}. \quad (103)$$

This pretty much exhausts the simple examples that lead to this “same old” EM algorithm.

5 Emission Tomography

Flavors of Emission Tomography

There are at least three flavors of emission tomography, viz., single photon emission tomography or SPECT (the C stands for “computerized”), positron emission tomography or PET, and time-of-flight PET (TOFPET). In all of these cases, given measurements of the emissions, the objective is to reconstruct the three-dimensional distribution of a radiopharmaceutical compound in the brain, giving insight into the metabolism in general and blood flow, in particular, in the brain.

In the single photon version, single photons are emitted in random locations in the brain and are detected (or not, as the case may be) by detectors situated around the head. In the positron version, single positrons are emitted in random locations. The positrons travel short distances until they are annihilated by single electrons, at which instances pairs of photons are created which fly off in nearly opposite random directions. The pairs of photons may then be detected by pairs of detectors. Thus, positron emission tomography amounts to double photon emission tomography. In the time-of-flight version of PET, the arrival times of the pairs of photons are recorded as well, which gives some information on the location of the emission. The time-of-flight version will not be considered further. Although the specifics are different, in their idealized form, the reconstruction problems for SPECT and PET are just about the same. For some of the details of the not-so-ideal circumstances in actual practice, see, e.g., [55, 97].

The Emission Tomography Experiment

The data collection experiment for emission tomography may be described as follows. Consider a three-dimensional Poisson random field living in an open ball $\Omega \in \mathbb{R}^d$ (with $d = 3$). Here, “events” (viz., the creation of a single or double photon) happen with spatial intensity per unit time denoted by $f_Z(z)$, $z \in \Omega$. This means that for any Borel subset C of Ω , the number $N(C, t, \delta t)$ of events that happen inside C during a time interval $(t, t + \delta t)$ does not depend on t and is a Poisson random variable with mean

$$\mathbb{E}[N(C, t, \delta t)] = \delta t \int_C f_Z(z) d\mu(z). \quad (104)$$

Moreover, if C_1, C_2, \dots, C_m are disjoint Borel subsets of Ω and $(t_i, t_i + \delta t_i)$, $i = 1, 2, \dots, m$, denote arbitrary (deterministic) time intervals, then the counts $N(C_1, t_1, \delta t_1), N(C_2, t_2, \delta t_2), \dots, N(C_m, t_m, \delta t_m)$, are independent. One may choose the unit of time ΔT in such a way that f_Z is the density of a probability measure with respect to Lebesgue measure on Ω . Then, in a time interval $(t, t + \lambda \Delta T)$, the number $N = N(\Omega, t, \lambda \Delta T)$ of events that occur throughout Ω is a Poisson random variable with mean

$$\lambda \int_{\Omega} f_Z(z) d\mu(z) = \lambda.$$

This may be written succinctly as

$$N \sim \text{Poisson}(\lambda). \quad (105)$$

For more on spatial Poisson processes, see, e.g., [24], section “The Shepp–Vardi EM Algorithm for PET.”

Returning to the experiment, conditional on $N = n$, during the time interval $(0, \lambda \Delta T)$, one collects a random sample Z_1, Z_2, \dots, Z_n (of sample size n) of the random variable Z , the random location of an event, with density f_Z with respect to Lebesgue measure. The random variable Z lives in the statistical space $(\Omega, \mathcal{B}_{\Omega}, \mathcal{P}_{\Omega})$ with \mathcal{B}_{Ω} the σ -algebra of Borel subsets of Ω and \mathcal{P}_{Ω} the collection of probability measures that are absolutely continuous with respect to Lebesgue measure. The events themselves are detected by detectors or pairs of detectors, denoted by B_1, B_1, \dots, B_m , which one may view as disjoint subsets (or antipodal subsets) of a sphere surrounding Ω . For each event at a location Z_i , there is a random index $J \in \mathcal{M} = \{1, 2, \dots, m\}$ such that the event is detected by the detector (pair) B_J . Thus, J lives in the statistical space $(\mathcal{M}, 2^{\mathcal{M}}, V_m)$; see (46). The random variable (Z, J) is absolutely continuous with respect to the product measure $\mu \times \alpha$, and its density is

$$f_{Z,J}(z, j) = f_{J|Z}(j|z) f_Z(z), \quad z \in \Omega, \quad j \in \mathcal{M}, \quad (106)$$

with $f_{J|Z}$ determined by geometric considerations. See, e.g., [97]. Assume that this is known. Assuming that every event is detected, then $f_{J|Z}$ is a conditional density, so

$$\sum_{j=1}^m f_{J|Z}(j|z) = 1 \quad \text{for all } z. \quad (107)$$

Note that then

$$f_J(j) = \int_{\Omega} f_{J|Z}(j|z) f_Z(z) d\mu(z), \quad j \in \mathcal{M}. \quad (108)$$

So, conditional on $N = n$, one may pretend to have a random sample $(Z_1, J_1), (Z_2, J_2), \dots, (Z_n, J_n)$ of the random variable (Z, J) . This gives rise to the usual form of the actual data to wit the bin counts

$$N_j = \sum_{i=1}^n \mathbf{1}(J_i = j). \quad (109)$$

Continuing (and no longer conditioning on $N = n$), then N_1, N_2, \dots, N_m are independent Poisson random variables with $\mathbb{E}[N_j] = [\mathcal{K}f_Z](j)$,

$$N_j \sim \text{Poisson}(\lambda [\mathcal{K}f_Z](j)), \quad j \in \mathcal{M}, \quad (110)$$

where $\mathcal{K} : L^1(\Omega, d\mu) \longrightarrow L^1(\mathcal{M}, d\alpha)$ is defined by

$$[\mathcal{K}\varphi](j) = \int_{\Omega} f_{J|Z}(j|z) \varphi(z) d\mu(z), \quad j \in \mathcal{M}. \quad (111)$$

This concludes the description of the ideal emission tomography experiment. In reality, quite a few extra things need to be taken into account, such as the attenuation of photons by tissue and bone in the head; see, e.g., [55]. For the treatment of background noise, see, e.g., [42] and references therein.

The Shepp–Vardi EM Algorithm for PET

After these preparations, the maximum likelihood problem for estimating f_Z may be formulated. The observed data are the count data N_1, N_2, \dots, N_m , which leads to the problem

$$\text{minimize} \quad -\frac{1}{N} \sum_{j=1}^m N_j \log[\mathcal{K}f](j) \quad \text{subject to} \quad f \in \mathcal{P}_{\Omega}. \quad (112)$$

Alternatively, and this is actually more convenient, one may view the total number of detected events N and J_1, J_1, \dots, J_N as the actual data, which gives

$$\text{minimize} \quad -\frac{1}{N} \sum_{i=1}^N \log[\mathcal{K}f](J_i) \quad \text{subject to} \quad f \in \mathcal{P}_\Omega. \quad (113)$$

In view of Remark 2 following Remark (75), these two problems are equivalent.

So far, nothing has been said about approximating/representing the estimators in terms of pixels or voxels. Let $\{C_p\}_{p=1}^\ell$ be a partition of Ω , and let $\mathcal{P}_\ell \subset \mathcal{P}_\Omega$ be the space of step functions that are constant on each C_p . Thus, with V_ℓ defined as in (43),

$$\mathcal{P}_\ell = \left\{ \sum_{p=1}^\ell x_p b_p(\cdot) \mid x \in V_\ell \right\}, \quad (114)$$

$$\text{where} \quad b_p(z) = |C_p|^{-1} \mathbf{1}(z \in C_p), \quad z \in \Omega.$$

(Note however that one may take other basis functions.) The discretized maximum likelihood problem is then obtained by restriction

$$\text{minimize} \quad -\frac{1}{N} \sum_{i=1}^N \log[\mathcal{K}f](J_i) \quad \text{subject to} \quad f \in \mathcal{P}_\ell. \quad (115)$$

From the description of the experiment, it is clear that the missing data are the Z_i , so the complete data set is $(Z_1, J_1), (Z_2, J_2), \dots, (Z_N, J_N)$, a random sample (of random sample size N) of the random variable (Z, J) . The joint density of $N, (Z_1, J_1), (Z_2, J_2), \dots, (Z_N, J_N)$ is then

$$\frac{\lambda^n}{n!} e^{-\lambda} \prod_{i=1}^n \left\{ f_{J|Z}(j_i|z_i) f_Z(z_i) \right\}, \quad (116)$$

so that the complete maximum likelihood problem is

$$\text{minimize} \quad -\frac{1}{N} \sum_{i=1}^N \log \left\{ f_{J|Z}(j_i|z_i) f(Z_i) \right\} \quad \text{subject to} \quad f \in \mathcal{P}_\ell. \quad (117)$$

In the objective function, the terms corresponding to the Poisson distribution of N have been omitted, and the scaling $1/N$ was applied.

For the E-step of the EM algorithm, consider the computation of

$$\mathbb{E} \left[-\log \left\{ f_{J|Z}(j|z) f(Z) \right\} \mid J, f_1 \right], \quad (118)$$

assuming the approximation f_1 to f_Z . Since

$$f_{Z|J}(z|j) = \frac{f_{J|Z}(j|z) f_Z(z)}{f_J(j)}, \quad (119)$$

this gives for the conditional expectation (118) the expression

$$-\int_{\Omega} \frac{f_{J|Z}(j|z) f_Z(z)}{f_J(j)} \log f(z) d\mu(z), \quad (120)$$

where the contribution involving the known $f_{J|Z}$ may be ignored, since it does not depend on f .

Consequently, the E-step leads to the problem

$$\text{minimize } -\int_{\Omega} f_2(z) \log f(z) d\mu(z) \quad \text{subject to} \quad f \in \mathcal{P}_{\ell}, \quad (121)$$

where

$$f_2(z) = f_1(z) \cdot \frac{1}{N} \sum_{i=1}^N \frac{f_{J|Z}(J_i|z)}{\left(\int_{\Omega} f_{J|Z}(J_i|s) f_1(s) d\mu(s) \right)}. \quad (122)$$

Note that f_2 is a density.

In terms of the representation of elements in \mathcal{P}_{ℓ} ,

$$f(z) = \sum_{p=1}^{\ell} x_p a_p(z), \quad (123)$$

with $a_p(z) = |C_p|^{-1} \mathbf{1}(z \in C_p)$ as in (62), and likewise for f_1 and f_2 , this leads to

$$\begin{aligned} \int_{\Omega} f_2(z) \log f(z) d\mu(z) &= \sum_{p=1}^{\ell} x_p^{[2]} \log \{x_p |C_p|^{-1}\} \\ &= \sum_{p=1}^{\ell} x_p^{[2]} \log x_p - \log |C_p| \sum_{p=1}^{\ell} x_p^{[2]} \quad (124) \\ &= \sum_{p=1}^{\ell} x_p^{[2]} \log x_p - \log |C_p|, \end{aligned}$$

where

$$x_p^{[2]} = x_p^{[1]} \cdot \frac{1}{N} \sum_{i=1}^N \frac{a(J_i, p)}{\left(\sum_{q=1}^{\ell} a(J_i, q) x_q^{[1]} \right)}, \quad (125)$$

with

$$a(j, p) = \int_{\mathbb{R}^d} f_{J|Z}(j|z) a_p(z) d\mu(z) = \int_{C_p} f_{J|Z}(j|z) d\mu(z). \quad (126)$$

Note that $\sum_{p=1}^{\ell} x_p^{[2]} = 1$ and, by (107), that

$$\sum_{j=1}^m a(j, p) = 1 \quad \text{for all } p. \quad (127)$$

So, the E-step gives

$$\text{minimize} \quad - \sum_{p=1}^{\ell} x_p^{[2]} \log x_p \quad \text{subject to} \quad x \in V_{\ell}. \quad (128)$$

In section ‘‘Mixtures of Known Densities,’’ it was already shown that the solution of the problem (128) is given by $x = x^{[2]}$. So (125) is the iterative step of the EM algorithm. Of course, using Remark 2, the iterative step for $x^{[2]}$ may be rewritten in terms of the bin counts as

$$x_p^{[2]} = x_p^{[1]} \cdot \frac{1}{N} \sum_{j=1}^m \frac{N_j a(j, p)}{\left(\sum_{q=1}^{\ell} a(j, q) x_q^{[1]} \right)}. \quad (129)$$

Observe again the similarity with the EM algorithms for the simple examples in Sect. 4.

Remark 3. The problem (115) is not really discretized. The actual discretized problem is

$$\text{minimize} \quad -\frac{1}{N} \sum_{j=1}^m N_j \log[Ax]_j + \sum_{p=1}^{\ell} x_p \quad \text{subject to} \quad x \in V_{\ell}, \quad (130)$$

with V_{ℓ} given by (43), and $A \in \mathbb{R}^{m \times \ell}$ has components $a(j, p)$ given by (126). This uses Remark 2.

Remark 4. To finish, note that the original derivation by Shepp and Vardi [88] involved the missing data $M(j, p)$, the number of events in each “cell” of Ω that contribute to the counts N_j ,

$$M(j, p) = \sum_{i=1}^m \mathbf{1}(J_i = j) \mathbf{1}(Z_i \in C_p), \quad p = 1, 2, \dots, \ell.$$

This calls for a rather complicated relation between the $M(j, p)$ and the N_j . In particular, one does not have random samples of the appropriate random variables. It gets much simplified if one introduces the random variables I_1, I_2, \dots, I_m which indicate to what “cell” the event Z_i belongs to. So, $I_i = p$ if

$$\mathbf{1}(Z_i \in C_p) = 1.$$

Then, for the complete data, one gets back to considering random samples of random variables, viz., (J, I) . This would provide for an alternative approach to discretization but would lead to the same EM algorithm. This is essentially the “list mode” approach of Parra and Barrett [77]. See also [10].

Prehistory of the Shepp–Vardi EM Algorithm

The earliest reference to maximum likelihood estimation in emission tomography is the aforementioned paper by Rockmore and Macovski [82]. In astronomy, an early reference is Lucy [70]. The EM algorithm for these maximum likelihood problems was introduced by Shepp and Vardi [88] and independently by Lange and Carson [64]. See also [20] for a completely different setting. The EM algorithm for SPECT is essentially the same; see, e.g., [60] and references therein.

The algorithm itself may be viewed as a method for approximately solving the integral equation with moment discretization

$$[\mathcal{K}f](j) = \frac{N_j}{N}, \quad j = 1, 2, \dots, m, \quad (131)$$

with \mathcal{K} as in (111). In particular, this may be applied to Fredholm integral equations of the first kind. As such it was independently discovered in various settings many times over, by Tarasko [93] and Kondor [61] in Physics, by Richardson [81] and Lucy [70] in Astronomy, and perhaps other authors. It is interesting to note that both Richardson [81] and Lucy [70] derive the algorithm based on probabilistic

considerations involving Bayes' theorem, as in (119). For more on the integral equations aspect, see also [74].

6 Electron Microscopy

In this section, a recent application of EM algorithms at the bleeding edge of science is considered. As far as the EM algorithm is concerned, the foundation is far from complete, whether it be practical or theoretical.

Imaging Macromolecular Assemblies

Structural biologists are interested in the shape of biological objects at the macromolecular level. The tail of the T4 bacteriophage is a famous example. Such objects are referred to as macromolecular assemblies. To view objects that are this tiny, electron microscopy seems to be the only tool available. Its use in structural biology goes back to DeRosier and Klug; see [21]. Ideally, one would like to take a single tail of the T4 bacteriophage, say, obtain electron micrographs (projections) from many directions, and reconstruct the three-dimensional structure of the tail. Unfortunately, the bombardment with electrons destroys the object, so that only one projection can be taken. The biologists have found a way around this, but it comes at a price. Very roughly speaking, many tails are isolated and suspended in a thin layer of water, which is then rapidly cooled to below freezing. This results in vitreous water, with the tails suspended in it *but randomly located and oriented*. A single electron micrograph of this layer is then taken. This is equivalent to taking projections of a single tail in many different directions, corresponding to the random orientations. For a precise description and analysis of the procedure, see [44]. Now, the price one pays is that one has many projections of the tail but in random unknown directions. Since these random directions may be viewed as missing data, it is clear that EM algorithms may be used. This was first realized by Scheres et al. [85]. A complication is that the objects can appear in conformational states, which means that one has a mixture of finitely many (different) objects. Another complication is that the signal-to-noise ratio is typically quite small, in the 10 % range.

The Maximum Likelihood Problem

Mathematically, following Scheres et al. [83, 84], the setup may be described as follows. Each object in the thin layer may be considered as being randomly chosen from a finite collection $x_1^o, x_2^o, \dots, x_\kappa^o$ of κ objects. Its position and orientation in the thin layer is described by five real-valued parameters: two location parameters and three Eulerian angles describing its orientation. Denote them by Θ and the set of all possible Θ by Ξ . The problem of finding the location parameters is referred to as the problem of alignment. For low signal-to-noise ratios, maximum likelihood methods seem to be preferable [89].

So, for a random object, one observes the projection in the form of a discretized image Y ,

$$Y = C * R_{\Theta} x_K^o + \varepsilon. \quad (132)$$

Here, K is the random index into the collection of possible objects, $R_{\Theta} x_K$ is the projection data of the object in the “direction” Θ , C is the (known) contrast transfer function (due to the experimental setup), and $*$ denotes the two-dimensional discretized convolution operation. Finally, ε is the noise, assumed to be normal and isotropic, i.e., the components of ε are jointly normal and the components of the variance–covariance matrix V_o satisfy

$$\mathbb{E}[\varepsilon_{p,q} \varepsilon_{r,s}] = \Sigma_{p-r,q-s}, \quad (133)$$

where $\Sigma_{p-r,q-s}$ is a function of $(p-r)^2 + (q-s)^2$, the (squared) Euclidean distance, only. In terms of the two-dimensional discrete Fourier transform, this means that (ignoring boundary effects)

$$\mathbb{E}\left[\hat{\varepsilon}_{P,Q} \overline{\hat{\varepsilon}_{R,S}}\right] = [\sigma_o^2]_{P,Q} \quad \text{for } P = R \text{ and } Q = S, \quad (134)$$

and = 0 otherwise. Moreover, $\sigma_{P,Q}^2$ is rotationally symmetric, i.e., it is a function of $P^2 + Q^2$. Unfortunately, $\sigma_{P,Q}^2$ is unknown; it must be estimated. Moreover, σ^2 varies with Y .

So, the distribution of Y conditional on $K = k$ and $\Theta = \theta$ is given by

$$f_{Y|\Theta,K}(y|\theta, x_k^o) = \frac{\exp\left(-\frac{1}{2} \|C * R_{\theta} x_k^o - y\|_{V_o}^2\right)}{(2\pi)^{N/2} \det(V_o)}, \quad (135)$$

where N is the size of Y (or y) and $\|z\|_V^2 = z^T V^{-1} z$. In terms of Fourier transforms, this reads as

$$\|C * R_{\theta} x_k^o - y\|_{V_o}^2 = \sum_{P,Q} [\sigma_o^{-2}]_{P,Q} \left| \left[\hat{C} \right]_{P,Q} \left[R_{\theta} x_k^o \right]_{P,Q}^{\wedge} - [\hat{y}]_{P,Q} \right|^2, \quad (136)$$

$$\log \det(V_o) = \sum_{P,Q} \log [\sigma_o^2]_{P,Q}.$$

Now introduce the state of the system Y one wishes to estimate and the initial state of one’s understanding of the system,

$$S = \left\{ \varpi^o, f_{\Theta|K}, x^o, \sigma_o \right\} \quad \text{and} \quad S^{[1]} = \left\{ \text{bar} \varpi^{[1]}, \varphi^{[1]}, x^{[1]}, \sigma^{[1]} \right\}, \quad (137)$$

where $\varpi_k^o = \mathbb{P}[K = k]$, $f_{\Theta|K}$ is the density of Θ conditional on K , and x^o and σ_o are as before. The current understanding of the system is comprised of one's best guesses so far for the true system.

The distribution of Y may be expressed as

$$f_Y(y) = \sum_{k=1}^{\kappa} \varpi_k^o \int_{\Xi} f_{Y|\Theta,K}(y|\theta, x_k) f_{\Theta|K}(\theta|k) d\nu(\theta), \quad (138)$$

where $\nu = \mu \times \omega$, with μ the Lebesgue measure on \mathbb{R}^2 and ω the surface measure on the sphere in \mathbb{R}^3 . Since it is reasonable to assume that the random location parameters are independent of the random orientation, then

$$f_{\Theta}(\theta_1, \theta_2, \theta_3, \theta_4, \theta_5) = g(\theta_1, \theta_2) h(\theta_3, \theta_4, \theta_5), \quad (139)$$

for appropriate densities g and h . This reduces the actual dimension of the problem, but for notational ease, such a specialization will not be made.

Given a random sample Y_1, Y_2, \dots, Y_n , of Y , the maximum likelihood problem for estimating the unknown objects $x_1, x_2, \dots, x_{\kappa}$ may then be formulated:

$$\text{minimize } -\frac{1}{n} \sum_{i=1}^n \log \left(\sum_{k=1}^{\kappa} \varpi_k \int_{\Xi} \varphi(\Theta_i|k) f_{Y|K,\Theta}(Y_i|x_k, \theta) d\nu(\theta) \right). \quad (140)$$

The unknowns are the probability vector ϖ , the densities $\varphi(\theta|k)$ (keep (139) in mind), the unknown objects $x_1, x_2, \dots, x_{\kappa}$, and the variances $[\sigma_i^2]_{P,Q}$. Note that there is some similarity with the empirical Bayes problem of section ‘‘Empirical Bayes Estimation.’’

The EM Algorithm, up to a Point

Obviously, the goal is to derive an EM algorithm for the solution of (139), but the final algorithm is not quite the real thing. It is clear that the missing data for each observed projection Y_i consists of the orientation, denoted by Θ_i , and which kind of object one is looking at, encoded in the index K_i . The σ_i^2 and the objects x_k are considered as parameters. So, the complete data set is (Y_i, Θ_i, K_i) , $i = 1, 2, \dots, n$, and the complete maximum likelihood problem is then to minimize

$$\Lambda_n(S) \stackrel{\text{def}}{=} -\frac{1}{n} \sum_{i=1}^n \log \left(\varpi_{K_i} \varphi(\Theta_i|K_i) f_{Y|\Theta,K}(Y_i|\Theta_i, x_{K_i}, \sigma_i) \right) \quad (141)$$

over all probability vectors ϖ , all densities $\varphi(\cdot|k)$, all variance matrices σ_i^2 , and all $x_1, x_2, \dots, x_{\kappa}$. However, recall that the $\varphi(\cdot|k)$ have a simple structure.

For the E-step, the conditional expectation $\mathbb{E}[\Lambda_n(S) | Y]$ is needed. By Bayes' rule, the distribution of (K, Θ) conditional on Y is described by

$$\mathbb{P}[K=k|Y=y] f_{\Theta|Y,K}(\theta|y, x_k) = \frac{\varpi_k^\rho f_{\Theta|k}(\theta|k) f_{Y|\Theta,K}(y|\theta, x_k, \sigma)}{f_Y(y)}.$$

So, with the current state $S^{[1]}$, and setting $\mathbb{Y}_n = \{Y_1, Y_2, \dots, Y_n\}$, one gets

$$\begin{aligned} \mathbb{E}[\Lambda_n(S) | \mathbb{Y}_n, S^{[1]}] &= \\ \sum_{k=1}^{\kappa} \int_{\Xi} g_k^{[2]}(\theta, Y_i) \log \left(\varpi_k \varphi(\theta|k) f_{Y|\Theta,K}(Y_i|\theta, x_k^{[1]}, \sigma_i^{[1]}) \right) d\nu(\theta), \end{aligned} \quad (142)$$

where

$$g_k^{[2]}(\theta, Y_i) = \frac{\varpi_k^{[1]} \varphi^{[1]}(\theta|k) f_{Y|\Theta,K}(Y_i|\theta, x_k^{[1]}, \sigma_i^{[1]})}{f_Y^{[1]}(Y_i)}, \quad \text{with} \quad (143)$$

$$f_Y^{[1]}(y) = \sum_{k=1}^{\kappa} \varpi_k^{[1]} \int_{\Xi} \varphi^{[1]}(\theta|k) f_{Y|\Theta,K}(y|\theta^{[1]}, x_k^{[1]}) d\nu(\theta). \quad (144)$$

This completes the E-step.

The M-step deals with the minimization of $\mathbb{E}[\Lambda_n(S) | \mathbb{Y}_n, S^{[1]}]$ over S . This separates into three problems. First, estimating ϖ may be done by solving

$$\text{minimize } - \sum_{k=1}^{\kappa} (\log \varpi_k) \int_{\Xi} h_k^{[2]}(\theta) d\nu(\theta) \quad (145)$$

subject to ϖ is a probability vector,

where

$$h_k^{[2]}(\theta) = \frac{1}{n} \sum_{i=1}^n g_k^{[2]}(\theta|Y_i). \quad (146)$$

One verifies that the solution is $\varpi = \varpi^{[2]}$,

$$\varpi_k^{[2]} = \int_{\Xi} h_k^{[2]}(\theta) d\nu(\theta), \quad k = 1, 2, \dots, \kappa. \quad (147)$$

Second, estimating the $\varphi(\cdot|k)$ may be done by solving

$$\text{minimize } - \sum_{k=1}^{\kappa} \int_{\Xi} h_k^{[2]}(\theta, Y_i) \log \varphi(\theta|k) d\nu(\theta) \quad (148)$$

subject to $\varphi(\cdot|k)$ is a pdf, $k = 1, 2, \dots, \kappa$.

This separates into κ minimization problems for the $\varphi(\cdot|k)$. One verifies that the solutions are for $k = 1, 2, \dots, \kappa$,

$$\varphi^{[2]}(\theta|k) = \varphi^{[1]}(\theta|k) \cdot \frac{1}{n} \sum_{i=1}^n \frac{f_{Y|\Theta,K}(Y_i|\theta, x_k^{[1]}, \sigma_i^{[1]})}{f_{Y|K}(Y_i|k)}, \quad (149)$$

where

$$f_{Y|K}(Y_i|k) = \int_{\Xi} \varphi^{[1]}(\theta|k) f_{Y|\Theta,K}(Y_i|\theta, x_k^{[1]}, \sigma_i^{[1]}) d\nu(\theta). \quad (150)$$

Note that (147) and (148) are again multiplicative algorithms.

Third and last, one must estimate $f_{Y|\Theta,K}$, which boils down to estimating the x_k and σ_i . The problem is to minimize

$$-\sum_{k=1}^{\kappa} \int_{\Xi} \frac{1}{n} \sum_{i=1}^n g_k^{[2]}(\theta, Y_i) \log f_{Y|\Theta,K}(Y_i|\theta, x_k, \sigma_i) d\nu(\theta) \quad (151)$$

over x_k and σ_i . Since $\log f_{Y|\Theta,K}(Y_i|\theta, x_k, \sigma_i)$ equals

$$\left. \begin{aligned} & \left\{ \frac{\left| \hat{C}_{P,Q} \cdot [(R_\theta x_k)^\wedge]_{P,Q} - [\hat{Y}_i]_{P,Q} \right|^2}{[2\sigma_i^2]_{P,Q}} + \log [\sigma_i^2]_{P,Q} \right\}, \end{aligned} \right.$$

here too the minimization problems separate. This may be solved for each x_k by minimizing

$$\text{WLS}_k(x_k) = \int_{\Xi} \frac{1}{n} \sum_{i=1}^n g_k^{[2]}(\theta, Y_i) \left\{ \frac{\left| \hat{C}_{P,Q} \cdot [(R_\theta x_k)^\wedge]_{P,Q} - [\hat{Y}_i]_{P,Q} \right|^2}{[2\sigma_i^2]_{P,Q}} \right\} d\nu(\theta).$$

Denoting the minimizing x_k by $x_k^{[2]}$, then the new σ_i is $\sigma_i = \sigma_i^{[2]}$ with

$$\begin{aligned} [\sigma_i^{[2]}]_{P,Q} &= \sum_{k=1}^{\kappa} \int_{\Xi} \frac{1}{n} \sum_{i=1}^n g_k^{[2]}(\theta, Y_i) \\ &\times \left\{ \left| \hat{C}_{P,Q} \cdot \left[(R_\theta x_k^{[2]})^\wedge \right]_{P,Q} - [\hat{Y}_i]_{P,Q} \right|^2 \right\} d\nu(\theta). \end{aligned}$$

The Ill-Posed Weighted Least-Squares Problem

Up to this point, the M-step has been carried out exactly. The last part is to minimize $\text{WLS}_k(x_k)$. This is a weighted least-squares problem, which is nice, but it is ill-posed (or ill conditioned after discretization), which implies that one cannot and should not solve it exactly. In fact, Scheres et al. [84] employ a Wiener filter to stably implement the “exact” deconvolution procedure

$$\left[\left(R_\theta x_k^{[2]} \right)^\wedge \right]_{P,Q} = \frac{[\hat{Y}_i]_{P,Q}}{\hat{C}_{P,Q}} \quad \text{for all } P, Q,$$

as in Penczek et al. [78], compared with Byrne and Fiddy [14], after which a weighted least-squares version of ART (WLSART) is applied.

It should be observed that these problems are very large and are computationally very expensive. It is clear that there is much room for algorithmic development, but the present discussion ends here.

7 Regularization in Emission Tomography

The Need for Regularization

It is clear that the simple deconvolution problem (57) and the more complicated PET problem (112) are ill-posed, let alone the electron microscopy problem of Sect. 6. As already observed, in the PET problem (112), one is trying to solve the compact operator equation with moment discretization

$$[\mathcal{K}f](j) = b_j, \quad j = 1, 2, \dots, m, \tag{152}$$

where $b_j = N_j/N$. The possible nonexistence of solutions is dealt with by considering the maximum likelihood problem, which may be reformulated as

$$\text{minimize } \text{KL}(b, \mathfrak{K}f) \quad \text{subject to } f \in \mathcal{P}, \tag{153}$$

where KL is the discrete Kullback–Leibler divergence (see (54)) and

$$\mathfrak{K}f = ([\mathcal{K}f](1), [\mathcal{K}f](2), \dots, [\mathcal{K}f](m))^T.$$

The problem (153) is similar to a least-squares problem. However, as in the case of the least-squares approach to compact operator equations, this still does not take care of the ill-posedness of the problem. So, the problem (153) must be regularized.

The standard and practically the most often used method is to use the EM algorithm and stop the algorithm at some appropriate point in the iteration. See, e.g., [69] for practical aspects and [80] and [51] for some theoretical results. The alternative is

essentially Tikhonov regularization of the negative log-likelihood, which also comes in the guises of Bayesian or maximum a posteriori (MAP) likelihood estimation, Gibbs smoothing, or just roughness penalization. See [36, 46, 54, 63, 73]. A new twist is the use of total variation regularization and nonlinear diffusion filtering in connection with maximum likelihood estimation and EM algorithms (see, e.g., [3, 6, 31, 87, 100]), but unfortunately, this will not be discussed further.

In many cases, the E-step of the EM algorithm may be carried out explicitly, but not so for the M-step. Here, some obvious modifications of the EM algorithm or extraneous iterative methods must be introduced. However, a few examples of explicit honest-to-goodness EM algorithms for regularized maximum likelihood problems are discussed: the NEMS modification of the EMS method of Silverman et al. [90] and two EM algorithms for Good's roughness penalization.

Smoothed EM Algorithms

In this section, the discussion centers on the EMS algorithm of Silverman et al. [90] and the nonlinearly smoothed NEMS variant of Eggermont and LaRiccia [36] in the context of the deconvolution problem of section “A Deconvolution Problem.” Silverman et al. [90] realized the necessity for regularization of the maximum likelihood problem in that the EM algorithm produces increasingly rougher estimators. Initially, this is good since one typically starts out with a uniform estimator and more features of the signal appear. However, as the iteration progresses, the estimator becomes increasingly nonsmooth, giving rise to spurious features. But Silverman et al. [90] figured they knew how to fix the nonsmoothness: Add a smoothing step to the EM algorithm.

So, let \mathcal{S}_h be a smoothing operator in the form

$$[\mathcal{S}_h f](y) = \int_{\mathbb{R}^d} S_h(y - z) f(z) d\mu(z), \quad y \in \mathbb{R}^d, \quad (154)$$

where $S_h(z) = h^{-d} S(h^{-1}z)$ for some bounded, continuous, symmetric pdf $S \in L^1(\mathbb{R}^d)$, possibly with compact support. The EMS algorithm then takes the form

$$f_{k+1/2}(z) = f_k(z) \cdot \frac{1}{n} \sum_{i=1}^n \frac{k(Y_i - z)}{[\mathcal{K}f_k](Y_i)}, \quad (155)$$

$$f_{k+1} = \mathcal{S}_h f_{k+1/2}.$$

So the general step of the EMS algorithm is one step of the EM algorithm followed by one smoothing step.

Silverman et al. [90] apply this algorithm to the simple problem of stereology (a integral equation on a compact interval) and to positron emission tomography. In both cases, it seems to work quite well. Of course, the question is whether the algorithm (155) converges and, if so, what it converges to. Regarding the first

question, see [65, 99]. Characterizing the limit is not so easy, e.g., if one has a fixed point of the iteration, does one then have a point where the gradient of some log-likelihood-like function vanishes?

In retrospect, it is clear that adding a smoothing step to the EM algorithm is a fundamentally sound idea, but the way it is implemented is not “right.” Indeed, in view of the multiplicative character of the EM algorithm, it seems that multiplicative smoothing is called for. So, with \mathcal{S}_h as before but with $S_h(z) \geq 0$ everywhere, define the nonlinear smoothing operator \mathcal{N} on nonnegative functions f by

$$[\mathcal{N}(f)](y) = \exp([\mathcal{S}_h(\log f)](y)), \quad y \in \mathbb{R}^d. \quad (156)$$

Note that by convexity, $[\mathcal{N}(f)](y) \leq [\mathcal{S}_h f](y)$, so that $\mathcal{N}(f)$ is always well defined. One verifies that \mathcal{N} performs multiplicative smoothing, i.e.,

$$\mathcal{N}(f \cdot g) = \mathcal{N}(f) \cdot \mathcal{N}(g), \quad (157)$$

where the dot means pointwise multiplication: $[f \cdot g](y) = f(y)g(y)$ for all y . It now turns out that the smoothed maximum likelihood problem

$$\text{minimize} \quad -\sum_{i=1}^n \log[\mathcal{K}\mathcal{N}(f)](Y_i) \quad \text{subject to} \quad f \in \mathcal{P} \quad (158)$$

admits the EM algorithm

$$\begin{aligned} f_{k+1/3} &= \mathcal{N}(f_k), \\ f_{k+2/3}(z) &= f_{k+1/3}(z) \cdot \frac{1}{n} \sum_{i=1}^n \frac{k(Y_i - z)}{[\mathcal{K}f_{k+1/3}](Y_i)}, \\ f_{k+1} &= S_h f_{k+2/3}, \end{aligned} \quad (159)$$

see [36]. In addition, the problem (158) has a solution and it is unique, and the algorithm (159) converges to this solution in the Kullback–Leibler sense. See section “Monotonicity of the Smoothed EM Algorithm.”

The algorithm (159) is referred to as the NEMS algorithm: The general step consists of a nonlinear smoothing step, one step of the original EM algorithm, and a final (linear) smoothing step. The practical performance on the toy stereology problem is just about indistinguishable from the NEMS algorithm except that with the same smoothing operator \mathcal{S}_h , the NEMS algorithm does about twice the smoothing of the EMS algorithm. Note that the question about the proper choice of the smoothing operator (or smoothing matrix in the discrete case) arises. This is in effect a question about the selection of the regularization parameter in ill-posed problems. Unfortunately, this is not addressed in this chapter.

Good's Roughness Penalization

Good's roughness penalization of the deconvolution problem is a particular form of Tikhonov regularization. The roughness penalty function of Good [47] is

$$\Phi(f) = \frac{1}{4} \int_{\mathbb{R}^d} \frac{|\nabla f(z)|^2}{f(z)} d\mu(z). \quad (160)$$

(The factor $\frac{1}{4}$ is for convenience only.) The maximum penalized likelihood problem is then

$$\begin{aligned} & \text{minimize} && -\frac{1}{n} \sum_{i=1}^n \log[\mathcal{K}f](Y_i) + \int_{\mathbb{R}^d} f(z) d\mu(z) + h^2 \Phi(f) \\ & \text{subject to} && f \in \mathcal{P}. \end{aligned} \quad (161)$$

One can now perform the E-step as in section “A Deconvolution Problem” to arrive at the problem

$$\begin{aligned} & \text{minimize} && - \int_{\mathbb{R}^d} f_2(y) \log f(y) d\mu(y) + \int_{\mathbb{R}^d} f(y) dy + h^2 \Phi(f) \\ & \text{subject to} && f \in \mathcal{P}, \end{aligned} \quad (162)$$

where

$$f_2(y) = f_1(y) \cdot \frac{1}{n} \sum_{i=1}^n \frac{k(W_i - y)}{[\mathcal{K}f_1](W_i)}, \quad y \in \mathbb{R}^d. \quad (163)$$

At this stage, the change of variable $u = \sqrt{f}$ is obviously(?) useful. The problem then becomes

$$\begin{aligned} & \text{minimize} && -2 \int_{\mathbb{R}^d} f_2(y) \log u(y) d\mu(y) + \|u\|^2 + h^2 \|\nabla u\|^2 \\ & \text{subject to} && u \in L^2(\mathbb{R}^d), u \geq 0, \end{aligned} \quad (164)$$

where $\|\cdot\|$ denotes the $L^2(\mathbb{R})$ norm. Here, it is convenient to drop the constraint $\|u\| = 1$. Note that (164) is a convex minimization problem. The Euler equations are given by the boundary value problem

$$\begin{aligned} -h^2 \Delta u + u &= \frac{f_2}{u} \quad \text{in } \mathbb{R}^d, \\ \nabla u(y) &\rightarrow 0 \quad \text{for } |y| \rightarrow \infty, \end{aligned} \quad (165)$$

where u is nonnegative. The M-step amounts to solving the boundary value problem.

The resulting algorithm converges, by arguments similar to those for the related discrete case of the next section. See section ‘‘Monotonicity for Exact Gibbs Smoothing.’’

For the positron emission tomography problem, Miller and Roysam [73] arrived at the analogue of this equation and solved the boundary value problem by finite differences, using Jacobi’s method on a massively parallel computer. Of course, other methods come to mind.

Another EM algorithm: There is another way to proceed. With the change of variable $u = \sqrt{f}$ as before, the objective function in (161) becomes

$$-\frac{1}{n} \sum_{i=1}^n \log[\mathcal{K}(u^2)](Y_i) + \|u\|^2 + h^2 \|\nabla u\|^2. \quad (166)$$

Now, introduce the convolution operator \mathcal{S}_h with kernel $S_h(z) = h^{-1} S(h^{-1}z)$, defined via its Fourier transform as

$$\hat{S}(\omega) = \int_{\mathbb{R}^d} S(z) e^{-2\pi i \langle z, \omega \rangle} d\mu(z) = \{1 + |2\pi\omega|^2\}^{-1/2}, \quad (167)$$

for $\omega \in \mathbb{R}^d$. Here and below, $|\omega|$ denotes the Euclidean norm of ω , and $\langle \omega, z \rangle$ denotes the inner product on \mathbb{R}^d . In fact, then

$$S(z) = 2^{-(d-1)/2} \pi^{-(d+1)/2} |z|^{-(d-1)/2} K_{(d-1)/2}(|z|), \quad z \in \mathbb{R}^d, \quad (168)$$

where K_v is the modified Bessel function of the second kind of order v . Aronszajn and Smith [1] turn out to be the ideal reference for this.

The convolution operator is defined as

$$[\mathcal{S}_h f](z) = \int_{\mathbb{R}^d} S_h(z-s) f(s) d\mu(s), \quad z \in \mathbb{R}^d, \quad (169)$$

and satisfies $(S_h f)^{\wedge}(\omega) = \{1 + (2\pi h |\omega|)^2\}^{-1/2} \hat{f}(\omega)$ for $\omega \in \mathbb{R}^d$.

The net effect is that $v = \mathcal{S}_h u$ satisfies

$$\|u\|^2 + h^2 \|\nabla u\|^2 = \|v\|^2, \quad (170)$$

so that the final change of variable $f = \mathfrak{M}(w)$, where

$$[\mathfrak{M}(w)](y) = \{[\mathcal{S}_h \sqrt{w}](y)\}^2, \quad y \in \mathbb{R}^d, \quad (171)$$

transforms the original maximum likelihood problem (161) into

$$\begin{aligned} \text{minimize } & -\frac{1}{n} \sum_{i=1}^n \log[\mathcal{KM}(w)](Y_i) + \int_{\mathbb{R}^d} w(y) d\mu(y) \\ \text{subject to } & w \in \mathcal{P}. \end{aligned} \quad (172)$$

(Actually, the pdf constraints are treated a bit cavalierly. Obviously f and w cannot both be pdfs, but let it pass.)

It now turns out that there is an EM algorithm for the smoothed maximum likelihood problem (172) to wit

$$\begin{aligned} w_{k+1/3} &= \mathfrak{M}(w_k), \\ w_{k+2/3}(z) &= \left\{w_{k+1/3}(y)\right\}^{1/2} \cdot \frac{1}{n} \sum_{i=1}^n \frac{k(Y_i - z)}{[\mathcal{K}w_{k+1/3}](Y_j)}, \\ w_{k+1}(z) &= \left\{w_k(z)\right\}^{1/2} [\mathcal{S}_h w_{k+2/3}](z). \end{aligned} \quad (173)$$

It has the same monotonicity properties as the NEMS algorithm; see section ‘‘Monotonicity of the Smoothed EM Algorithm.’’ The original method of Miller and Roysam [73] satisfies similar monotonicity properties (assuming that (165) is solved exactly). See section ‘‘Monotonicity for Exact Gibbs Smoothing.’’

Gibbs Smoothing

Whereas Good’s roughness penalization was essentially aimed at the continuous setting, attention now turns to a purely discrete point of view. So, let us consider the discrete maximum penalized likelihood problem

$$\begin{aligned} \text{minimize } & -\sum_{j=1}^m b_j \log[Ax]_j + \sum_{p=1}^\ell x_p + \lambda G(x) \\ \text{subject to } & x \in V_\ell, \end{aligned} \quad (174)$$

with V_ℓ given by (43) and $A \in \mathbb{R}^{m \times \ell}$ has components $a(j, p)$ given by (127) and $\lambda > 0$ is the regularization parameter. The typical form of the penalization associated with the name of Gibbs smoothing is

$$G(x) = \sum_{p,q} w_{pq} \phi(\sigma^{-1}(x_p - x_q)), \quad (175)$$

for some convex function ϕ and nonnegative weights w_{pq} and positive σ . Some typical examples for ϕ are $\phi(t) = \log \cosh(t)$ and $\phi(t) = |t|$ for $t \in \mathbb{R}$. The nonzero weights w_{pq} determine a neighborhood system. The neighborhood of the p -

th component of x is given by $\{q \mid w_{pq} > 0\}$. Although x was encoded as a column vector, one should think of x as a two-dimensional image or three-dimensional structure, so that neighboring image elements may have widely differing indices p and q . See [45, 46, 66]. The approach of (174) originated with Green [49].

The role of the penalty term is to penalize differences in neighboring components of x , but large differences are not penalized much more. In fact, this is an argument for choosing $\phi(t) = \min(|t|, \delta)$ for some δ .

To solve the problem (174), again proceed iteratively, and perform the E-step of the EM algorithm. As before, this gives

$$\begin{aligned} \text{minimize} \quad & - \sum_{p=1}^{\ell} \tilde{x}_p^{[k]} \log x_p + \sum_{p=1}^{\ell} x_p + \lambda G(x) \\ \text{subject to} \quad & x \in V_{\ell}, \end{aligned} \quad (176)$$

with $\tilde{x}^{[2]}$ given by (129). For convenience, the constraint that $x \in V_{\ell}$ is now dropped. To solve the resulting problem, set the gradient equal to 0,

$$-\frac{\tilde{x}_p^{[2]}}{x_p} + 1 + \lambda \nabla G(x) = 0. \quad (177)$$

Now, the one-step-late idea of Green [49] is to approximately solve this equation by

$$x_p^{[2]} = \frac{\tilde{x}_p^{[2]}}{1 + \lambda [\nabla G(x^{[1]})]_p}, \quad p = 1, 2, \dots, \ell. \quad (178)$$

This is referred to as OSL-EM. Green [49] reports that this works well for small λ . Regarding its convergence under appropriate conditions, see [62]. If (177) is solved exactly, then the resulting algorithm has the usual nice monotonicity properties; see section ‘‘Monotonicity for Exact Gibbs Smoothing.’’

Hebert and Leahy [54] observed that (178) is similar in spirit to Jacobi’s method for solving systems of linear equations, and they noticed that the Gauss–Seidel analogue of sequentially solving (177) speeds up the computations. See also [41]. For other ways to accelerate EM algorithms, see Sect. 10.

8 Convergence of EM Algorithms

The convergence of the Shepp–Vardi EM algorithm is based on two rather remarkable monotonicity properties of the EM algorithm, established using analytical methods by Mülthei and Schorr [75]. Unfortunately, the geometric approach of Csiszár and Tusnády [23] that seems to explain why the Mülthei–Schorr approach works is not discussed. See [38]. However, the methods generalize in different ways. See Sect. 9.

The Two Monotonicity Properties

Consider the discretized maximum likelihood problem of positron emission tomography, repeated here for convenience:

$$\begin{aligned} \text{minimize } \quad L(x) &\stackrel{\text{def}}{=} -\sum_{j=1}^m b_j \log[Ax]_j + \sum_{p=1}^{\ell} x_p \\ \text{subject to } \quad x &\in V_{\ell}, \end{aligned} \quad (179)$$

where $b_j = N_j/N$. Here, V_{ℓ} is given by (43) and $A \in \mathbb{R}^{m \times \ell}$ has nonnegative components $a(j, p)$ given by (126), with unit column sums

$$\sum_{j=1}^m a(j, p) = 1, \quad p = 1, 2, \dots, \ell. \quad (180)$$

It is clear that the problem (179) is convex and that solutions exist. The uniqueness is guaranteed only if A has full column rank. Regardless, the set of minimizers, denoted by \mathcal{C} , is convex.

Recall that the EM algorithm for solving (179) is, for $k = 1, 2, \dots$,

$$\begin{aligned} x_p^{[k+1]} &= x_p^{[k]} \cdot [A^T r^{[k]}]_p, \quad p = 1, 2, \dots, \ell, \\ r_p^{[k]} &= \frac{b_j}{[Ax^{[k]}]_j}, \quad j = 1, 2, \dots, m. \end{aligned} \quad (181)$$

starting from some initial strictly positive probability vector $x^{[1]}$.

The two monotonicity properties are as follows:

$$L(x^{[k]}) - L(x^{[k+1]}) \geq \text{KL}(x^{[k+1]}, x^{[k]}) \geq 0, \quad (182)$$

and, if x^* is any solution of (179),

$$\text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) \geq L(x^{[k]}) - L(x^*) \geq 0. \quad (183)$$

The meaning of the first monotonicity property is clear: It says that the likelihood decreases if successive iterates are different. The second one says that the iterates get closer to every minimizer as measured by the Kullback–Leibler “distance.” The everyday image is that if one thinks of the set of minimizers as an airport, then the iterates land like a helicopter, not like an airplane. This kind of monotonicity is called Féjér monotonicity.

The two monotonicity properties imply that the EM algorithm converges.

Theorem 1. If $x^{[1]}$ is strictly positive, then the sequence $\{x^{[k]}\}_k$ generated by the EM algorithm (181) converges to a solution, say x^{**} , of the maximum likelihood problem (179). In particular,

$$\lim_{k \rightarrow \infty} \text{KL}(x^{**}, x^{[k]}) = 0.$$

Proof. The first inequality says that the negative log-likelihood is strictly decreasing, unless $x^{[k]} = x^{[k+1]}$. If $x^{[k]} = x^{[k+1]}$ does indeed hold, then the second inequality says that $L(x^{[k]}) = L(x^*)$, so that $x^{[k]}$ is a solution of (179). In general, the second inequality implies that $\{\text{KL}(x^*, x^{[k]})\}_k$ is a decreasing sequence. Since the sequence is bounded from below (by 0), it must have a limit, but then $\text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) \rightarrow 0$, which implies that

$$L(x^{[k]}) \rightarrow L(x^*). \quad (184)$$

So, the negative log-likelihood converges. Finally, since $\sum x_p^{[k]} = 1$, the sequence $\{x^{[k]}\}_p$ is bounded and hence has a convergent subsequence, say, with limit x^{**} . By (184), then $L(x^{**}) = L(x^*)$, so that x^{**} is a minimizer also. Now, in the second monotonicity property, one may replace x^* by x^{**} , and then $\{\text{KL}(x^{**}, x^{[k]})\}_k$ is decreasing. Since a subsequence converges to 0, then the whole sequence converges to 0. ■

It should be observed that the theorem is actually not very useful: When using the algorithm (181), one will always stop the algorithm well short of convergence. See, e.g., [69, 80]. Thus, the existence of maximum likelihood estimators is moot. One may think of this as an unfortunate side effect of discretization. For the continuous version, say, for the deconvolution problem, one does indeed have the analogues of the above two monotonicity properties, but the second one is vacuous, since the continuous maximum likelihood problem has no solutions. For the NEMS algorithm, one can show the existence of solutions as well as its convergence by way of the two monotonicity properties. See section ‘‘Monotonicity of the Smoothed EM Algorithm.’’

In the following subsections, the two monotonicity properties are proved for the standard discrete Shepp–Vardi EM algorithm, for the continuous version of the NEMS algorithm, and for the exact version of Gibbs smoothing (but not for the one-step-late version). The basic tool is the analytical proof of Mülthei and Schorr [75], which is actually quite versatile, as demonstrated in Sect. 9.

Monotonicity of the Shepp–Vardi EM Algorithm

Here, the two monotonicity properties of the EM algorithm are exhibited, following the proof of Mülthei and Schorr [75]. The first monotonicity property (182) follows from the derivation of the E-step of the EM algorithm. However, here a purely

analytical proof is explained. Vardi et al. [96] prove the two monotonicity properties using the geometric results of Csiszár and Tusnády [23].

It is useful to define the operator R on nonnegative vectors $x \in \mathbb{R}^\ell$ by

$$[R x]_p = x_p [A^T (b/Ax)]_p, \quad p = 1, 2, \dots, \ell, \quad (185)$$

where b/Ax denotes the vector of componentwise quotients.

Lemma 1. *For all nonnegative x and y , with y strictly positive,*

$$L(x) \leq L(y) + \text{KL}(Ry, x) - \text{KL}(Ry, y).$$

Proof. Note that for all nonnegative vectors x and y ,

$$L(x) - L(y) = - \sum_{j=1}^m b_j \log \frac{[Ax]_j}{[Ay]_j} + \sum_{p=1}^\ell x_p - y_p.$$

Now, for strictly positive y , one may write

$$\frac{[Ax]_j}{[Ay]_j} = \sum_{p=1}^\ell \frac{a(j, p) y_p}{[Ay]_j} \cdot \frac{x_p}{y_p}.$$

For each j , this is a convex combination of the points x_p/y_p , $p = 1, 2, \dots, \ell$. Since $t \mapsto -\log t$ is convex, then by Jensen's inequality

$$\begin{aligned} L(x) - L(y) &\leq - \sum_{j=1}^m b_j \sum_{p=1}^\ell \frac{a(j, p) y_p}{[Ay]_j} \log \frac{x_p}{y_p} + \sum_{p=1}^\ell x_p - y_p \\ &\leq \sum_{p=1}^\ell -y_p [A^T r]_p \log \frac{x_p}{y_p} + x_p - y_p, \end{aligned}$$

where in the last step the order of summation was interchanged. The lemma follows. ■

Proof of the first monotonicity property (182). In the inequality of the lemma above, take $y = x^{[k]}$ and $x = R y = R x^{[k]} = x^{[k+1]}$. Then, $L(x^{[k+1]}) - L(x^{[k]}) \leq -\text{KL}(x^{[k+1]}, x^{[k]})$. ■

Proof of the second monotonicity property (183). Start with

$$\begin{aligned} \text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) &= \sum_{p=1}^{\ell} x_p^* \log \frac{x_p^{[k+1]}}{x_p^{[k]}} \\ &= \sum_{p=1}^{\ell} x_p^* \log \left[A^T \left\{ \frac{b}{Ax^{[k]}} \right\} \right]_p. \end{aligned}$$

Now, if x^* solves (179), then it must satisfy the necessary and sufficient conditions for a minimum

$$x^* \geq 0, \quad \nabla L(x^*) \geq 0, \quad x_p^* [\nabla L(x^*)]_p = 0 \quad \text{for all } p.$$

The last condition says that $x_p^* (-[A^T r^*]_p + 1) = 0$, where $r_j^* = b_j/[Ax^*]_j$ for all j , so that if $x_p^* > 0$, then $[A^T r^*]_p = 1$. So, for $x_p^* > 0$, write

$$\left[A^T \left\{ \frac{b}{Ax^{[k]}} \right\} \right]_p = \sum_{j=1}^m \frac{a(j, p) b_j}{[Ax^*]_j} \cdot \frac{[Ax^*]_j}{[Ax^{[k]}]_j},$$

which is a convex combination of the points $[Ax^*]_j / [Ax^{[k]}]_j$, so by the concavity of the logarithm,

$$\begin{aligned} \sum_{p=1}^{\ell} x_p^* \log \left[A^T \left\{ \frac{b}{Ax^{[k]}} \right\} \right]_p &\geq \sum_{p=1}^{\ell} x_p^* \sum_{j=1}^m \frac{a(j, p) b_j}{[Ax^*]_j} \cdot \log \frac{[Ax^*]_j}{[Ax^{[k]}]_j} \\ &\geq \sum_{j=1}^m b_j \log \frac{[Ax^*]_j}{[Ax^{[k]}]_j} = \text{KL}(b, Ax^{[k]}) - \text{KL}(b, Ax^{[k+1]}), \end{aligned}$$

where the last equality follows from $\sum x_p^{[k]} = \sum x_p^{[k+1]} = \sum b_j$. ■

Monotonicity for Mixtures

Here, the two monotonicity properties of the EM algorithm for mixtures of known densities are discussed. The difference with the Shepp–Vardi EM algorithm is that the system matrix is not normalized to have unit column sums. It will transpire that this does not make any difference.

Recall that the problem is to estimate the pdf

$$f_Y(y) = \sum_{j=1}^m x_{o,j} a_j(y), \quad y \in \mathbb{R}^d, \quad (186)$$

where the a_j are known pdfs and x_o is an unknown probability vector, given a random sample Y_1, Y_2, \dots, Y_n of the random variable Y with density f_Y . Define the matrix $A \in \mathbb{R}^{n \times m}$ by

$$A_{ij} = a_j(Y_i) \quad \text{for all } i \text{ and } j. \quad (187)$$

The EM algorithm for estimating x_o is, starting from the uniform vector $x^{[1]}$,

$$x^{[k+1]} = M x^{[k]}, \quad (188)$$

where the iteration operator M is defined as

$$[Mx]_j = x_j \cdot \frac{1}{n} \sum_{i=1}^n \frac{a_{ij}}{[Ax]_i}, \quad j = 1, 2, \dots, m. \quad (189)$$

One begins again with deriving the majorizing function inequality. However, first replace the maximum likelihood problem (44) by the equivalent

$$\begin{aligned} \text{minimize} \quad L_n(x) &\stackrel{\text{def}}{=} -\frac{1}{n} \sum_{i=1}^n \log \left(\sum_{j=1}^m x_j a_{ij} \right) + \sum_{j=1}^m x_j \\ \text{subject to} \quad x &\geq 0. \end{aligned} \quad (190)$$

Note that the constraint that x be a probability vector was traded for the added sum in the objective function.

The majorizing function inequality is the same as before, as is its proof. Then, the first monotonicity property follows.

Lemma 2. *If x and y are nonnegative probability vectors, with y strictly positive, then*

$$L_n(x) \leq L_n(y) + \text{KL}(M y, x) - \text{KL}(M y, y).$$

Note that the minimizer of the right-hand side (over x) is $x = My$.

Lemma 3. *Starting from a strictly positive $x^{[1]}$, the iterates of the EM algorithm (188) satisfy*

$$L_n(x^{[k]}) - L_n(x^{[k+1]}) \geq \text{KL}(x^{[k+1]}, x^{[k]}) \geq 0.$$

The second monotonicity property is the same also, but there is a slight change in its proof.

Lemma 4. Let x^* be a solution of (190). Starting from a strictly positive $x^{[1]}$, the iterates of the EM algorithm (188) satisfy

$$\text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) \geq L_n(x^{[k]}) - L_n(x^*) \geq 0.$$

Proof. Since $\sum x_j^{[k]} = \sum x_j^{[k+1]} = 1$, one has as usual

$$\begin{aligned} \text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) &= \sum_{j=1}^m x_j^* \log \frac{x_p^{[k+1]}}{x_p^{[k]}} \\ &= \sum_{j=1}^{\ell} x_j^* \log \left[A^T \left\{ \frac{(1/n)}{Ax^{[k]}} \right\} \right]_j. \end{aligned}$$

Now, if x^* solves (179), then it must satisfy the necessary and sufficient conditions for a minimum

$$x^* \geq 0, \quad \nabla L_n(x^*) \geq 0, \quad x_j^* [\nabla L_n(x^*)]_j = 0 \quad \text{for all } j.$$

The last condition says that $x_j^* (-[A^T r^*]_j + 1) = 0$, where $r_i^* = (1/n)/[Ax^*]_i$ for all i , so that if $x_j^* > 0$, then $[A^T r^*]_j = 1$. So, for $x_j^* > 0$, write

$$\left[A^T \left\{ \frac{(1/n)}{Ax^{[k]}} \right\} \right]_j = \sum_{i=1}^n \frac{(1/n) a_{ij}}{[Ax^*]_i} \cdot \frac{[Ax^*]_i}{[Ax^{[k]}]_i},$$

which is a convex combination of the points $[Ax^*]_i/[Ax^{[k]}]_i$, so by the concavity of the logarithm,

$$\begin{aligned} \sum_{j=1}^m x_j^* \log \left[A^T \left\{ \frac{(1/n)}{Ax^{[k]}} \right\} \right]_j &\geq \sum_{j=1}^m x_j^* \sum_{i=1}^n \frac{(1/n) a_{ij}}{[Ax^*]_i} \cdot \log \frac{[Ax^*]_i}{[Ax^{[k]}]_i} \\ &\geq \sum_{i=1}^n (1/n) \log \frac{[Ax^*]_i}{[Ax^{[k]}]_i} + \sum_{j=1}^m x_j^{[k]} - x_j^* = L_n(x^{[k]}) - L_n(x^*), \end{aligned}$$

where the last equality follows from $\sum x_j^{[k]} = \sum x_j^* = 1$. ■

The convergence of the iterates of the EM algorithm follows.

Monotonicity of the Smoothed EM Algorithm

Here, the monotonicity properties of the NEMS algorithm for the smoothed maximum likelihood problem (158) are proved. The problem is

$$\begin{aligned} \text{minimize } L_n(f) &\stackrel{\text{def}}{=} -\frac{1}{n} \sum_{i=1}^n \log[\mathcal{K}\mathcal{N}(f)](W_i) + \int_{\mathbb{R}^d} f(y) d\mu(y) \\ \text{subject to } f &\in L^1(\mathbb{R}^d), \quad f \geq 0. \end{aligned} \quad (191)$$

Since this is an infinite-dimensional problem, showing that the iterates of the NEMS algorithm converge to a solution of (191) is a bit more involved. In particular, it requires us to show the existence of solutions. The only remarkable thing about the proofs of the two monotonicity properties for the NEMS algorithm is that apart from a few cosmetic changes, they are exactly the same as for the Shepp–Vardi EM algorithm. The argument follows Eggermont [34].

The NEMS algorithm (159) may be represented as

$$g_{k+1} = \mathcal{T}_h f_k, \quad f_{k+1} = \mathcal{S}_h g_{k+1}, \quad (192)$$

starting from a strictly positive initial guess f_1 , assumed to be a pdf. Here, the map \mathcal{T}_h is defined as

$$[\mathcal{T}_h f](z) = [\mathcal{N}(f)](z) \cdot \frac{1}{n} \sum_{i=1}^n \frac{k(W_i - z)}{[\mathcal{K}\mathcal{N}(f)](W_i)}. \quad (193)$$

The claim is now that the iterates of the NEMS algorithm satisfy the same two monotonicity properties (182) and (183). The crux is again an analytical proof of what amounts to the E-step of the EM algorithm.

Lemma 5. *For all densities φ and ψ ,*

$$L_n(\varphi) \leq L_n(\psi) + \text{KL}(\mathcal{S}_h \mathcal{T}_h \psi, \varphi) - \text{KL}(\mathcal{S}_h \mathcal{T}_h \psi, \psi).$$

Proof. Similar to the proof of Lemma 1, one gets that

$$L_n(\varphi) - L_n(\psi) \leq - \int_{\mathbb{R}^d} [\mathcal{T}_h \psi](z) \log \frac{[\mathcal{N}(\varphi)](z)}{[\mathcal{N}(\psi)](z)} d\mu(z).$$

Since

$$\log([\mathcal{N}(\varphi)](z)/[\mathcal{N}(\psi)](z)) = [\mathcal{S}_h \log(\varphi/\psi)](z),$$

and \mathcal{S}_h is a symmetric operator, then

$$-\int_{\mathbb{R}^d} [\mathcal{T}_h \psi](z) \log \frac{[\mathcal{N}(\varphi)](z)}{[\mathcal{N}(\psi)](z)} d\mu(z) = - \int_{\mathbb{R}^d} [\mathcal{S}_h \mathcal{T}_h \psi](y) \log \frac{\varphi(y)}{\psi(y)} d\mu(y),$$

and the lemma follows. \blacksquare

Lemma 6. *The iterates f_k generated by the NEMS algorithm (192) satisfy*

$$L_n(f_k) - L_n(f_{k+1}) \geq \text{KL}(f_{k+1}, f_k) \geq 0.$$

Proof. In Lemma 5, take $\varphi = f_{k+1}$ and $\psi = f_k$. Then, $\mathcal{S}_h \mathcal{T}_h \psi = f_{k+1}$. \blacksquare

The second monotonicity property is actually a little bit stronger than the one for the Shepp–Vardi EM algorithm. Note that by the convexity of the KL function jointly in both its arguments, $\text{KL}(\mathcal{S}_h \varphi, \mathcal{S}_h \psi) \leq \text{KL}(\varphi, \psi)$.

Lemma 7. *Let f^* be a solution of (191), with $\text{KL}(f^*, f_1) < \infty$. Then, the iterates f_k generated by the NEMS algorithm (192) satisfy*

$$\begin{aligned} \text{KL}(f^*, f_k) - \text{KL}(f^*, f_{k+1}) &\geq \text{KL}(f^*, f_k) - \text{KL}(\mathcal{T}_h f^*, \mathcal{T}_h f_k) \\ &\geq L_n(f_k) - L_n(f^*) \geq 0. \end{aligned}$$

Proof. Start in the usual fashion and obtain

$$\begin{aligned} L_n(f_k) - L_n(f^*) &= \frac{1}{n} \sum_{i=1}^n \log \frac{[\mathcal{K}\mathcal{N}f^*](W_i)}{[\mathcal{K}\mathcal{N}f^*](W_i)} \\ &= \frac{1}{n} \sum_{i=1}^n \frac{[\mathcal{K}\mathcal{N}f^*](W_i)}{[\mathcal{K}\mathcal{N}f^*](W_i)} \log \frac{[\mathcal{K}\mathcal{N}f^*](W_i)}{[\mathcal{K}\mathcal{N}f_k](W_i)} \\ &= \int_{\mathbb{R}^d} [\mathcal{N}f^*](z) \cdot \frac{1}{n} \sum_{i=1}^n \frac{k(W_i - z)}{[\mathcal{K}\mathcal{N}f^*](z)} \log \frac{[\mathcal{K}\mathcal{N}f^*](W_i)}{[\mathcal{K}\mathcal{N}f_k](W_i)} d\mu(z). \end{aligned}$$

Now, one would like to get a convex combination, so multiply and divide by the sum of the weights $k(W_i - z)/[\mathcal{K}\mathcal{N}f^*](W_i)$. Then, the concavity of the logarithm gives that the last expression is dominated by

$$\int_{\mathbb{R}^d} [\mathcal{N}f^*](z) \cdot \frac{1}{n} \sum_{i=1}^n \frac{k(W_i - z)}{[\mathcal{K}\mathcal{N}f^*](z)} \log \left(\frac{\frac{1}{n} \sum_{i=1}^n \frac{k(W_i - z)}{[\mathcal{K}\mathcal{N}f_k](z)}}{\frac{1}{n} \sum_{i=1}^n \frac{k(W_i - z)}{[\mathcal{K}\mathcal{N}f^*](z)}} \right) d\mu(z).$$

Now, this expression may be cleaned up as

$$\int_{\mathbb{R}^d} [\mathcal{T}_h f^*](z) \log \left(\frac{[\mathcal{T}_h f_k](z)}{[\mathcal{N}f_k](z)} \cdot \frac{[\mathcal{N}f^*](z)}{[\mathcal{T}_h f^*](z)} \right) d\mu(z).$$

After splitting up the logarithm, note that

$$\int_{\mathbb{R}^d} [\mathcal{T}_h f^*](z) \log \left(\frac{[\mathcal{T}_h f_k](z)}{[\mathcal{T}_h f^*](z)} \right) d\mu(z) = -\text{KL}(\mathcal{T}_h f^*, \mathcal{T}_h f_k)$$

because $\mathcal{T}_h \varphi$ is a pdf if φ is one and also

$$\begin{aligned} \int_{\mathbb{R}^d} [\mathcal{T}_h f^*](z) \log \left(\frac{[\mathcal{N} f^*](z)}{[\mathcal{N} f_k](z)} \right) d\mu(z) &= \int_{\mathbb{R}^d} [\mathcal{T}_h g^*](z) \left[\mathcal{S}_h \log \frac{f^*(y)}{f_k(y)} \right] d\mu(z) \\ &= \int_{\mathbb{R}^d} [\mathcal{S}_h \mathcal{T}_h f^*](y) \log \frac{f^*(y)}{f_k(y)} d\mu(y) = \text{KL}(f^*, f_k), \end{aligned}$$

since $\mathcal{S}_h \mathcal{T}_h f^* = f^*$. Putting all of this together shows that

$$L_n(f_k) - L_n(f^*) \leq \text{KL}(f^*, f_k) - \text{KL}(\mathcal{T}_h f^*, \mathcal{T}_h f_k),$$

and the lemma follows. \blacksquare

The two monotonicity properties imply that the NEMS algorithm converges to a solution of the smoothed maximum likelihood problem (191) and that this problem actually has a solution.

Theorem 2. *The smoothed maximum likelihood problem (191) has a solution $f^* \in L^1(\mathbb{R}^d)$.*

Proof. One first shows that $L_n(f)$ is bounded from below. Let f be a pdf on \mathbb{R}^d such that $[\mathcal{K}\mathcal{N}f](W_i) > 0$ for all i . Let $\mathbf{1} \in \mathbb{R}^n$ be the vector of all ones, and let $v_i = [\mathcal{K}\mathcal{N}f](W_i)$. Then,

$$L_n(f) = \text{KL} \left(\frac{1}{n} \mathbf{1}, v \right) - \frac{1}{n} \sum_{i=1}^n \log [\mathcal{K}\mathcal{N}f](W_i) + \int_{\mathbb{R}^d} f(y) d\mu(y).$$

Now, by convexity $[\mathcal{N}f](z) \leq [\mathcal{S}_h f](z)$ for all z , so that

$$\begin{aligned} [\mathcal{K}\mathcal{N}f](z) &= \int_{\mathbb{R}^d} k(W_i - z) [\mathcal{N}f](z) d\mu(z) \\ &\leq \int_{\mathbb{R}^d} k(W_i - z) [\mathcal{S}_h f](z) d\mu(z) \\ &= \int_{\mathbb{R}^d} f(y) \int_{\mathbb{R}^d} k(W_i - z) S_h(z - y) d\mu(y) d\mu(z) \\ &\leq \mu_h \int_{\mathbb{R}^d} f(y) d\mu(y) = \mu_h, \end{aligned}$$

where

$$\mu_h = \sup_{y \in \mathbb{R}^d} \int_{\mathbb{R}^d} k(W_i - z) S_h(z - y) d\mu(y) d\mu(z) \leq \sup_{y \in \mathbb{R}^d} S_h(z),$$

since k is a pdf. Since $S_h(z) = h^{-d} S(h^{-1}z)$, the boundedness of S then gives that $\mu_h < \infty$ for fixed $h > 0$. It follows that $L_n(f)$ is bounded from below.

Now, let $\{\varphi_k\}_k$ be a minimizing sequence for $L_n(f)$. Apply one step of the NEMS algorithm to each φ_k , so $\psi_k = S_h \mathcal{T}_h \varphi_k$, $k = 1, 2, \dots$. By the first monotonicity property, then $\{\psi_k\}_k$ is a minimizing sequence also. Since each $\mathcal{T}_h \varphi_k$ is a pdf, then the ψ_k are uniformly continuous on \mathbb{R}^d , and so it has a subsequence which converges in the strict topology, i.e., uniformly on every compact subset of \mathbb{R}^d , say, with limit ψ^* . This is the Arzelà–Ascoli theorem for the strict topology; see [2]. Then, along this subsequence

$$[\mathcal{KN}(\psi_k)](W_i) \longrightarrow [\mathcal{KN}(\psi^*)](W_i),$$

and it follows that again along this same subsequence

$$L_n(\psi_k) \longrightarrow L_n(\psi^*).$$

Since the whole sequence $\{\psi_k\}_k$ was a minimizing sequence, this shows that ψ^* solves the problem (191). ■

Theorem 3. *For $f^{[1]}$ strictly positive with $\text{KL}(f^*, f^{[1]}) < \infty$, the NEMS algorithm converges to a solution of (191).*

Proof. The proof is just about the same as for the discrete EM algorithm. Thus, the first monotonicity property shows that $\{L_n(f_k)\}$ is decreasing. The second monotonicity property shows that $\{\text{KL}(f^*, f_k)\}_k$ is decreasing as well and so has a nonnegative limit. But then $\text{KL}(f^*, f_k) - \text{KL}(f^*, f_{k+1})$ converges to 0, so that again the second monotonicity property gives that the NEMS sequence $\{f_k\}_k$ is a minimizing sequence. All one has to do is extract a convergent subsequence, but that follows from the argument in the proof of the existence of convergent subsequences. Thus, there exists a subsequence which converges to some element f^{**} in the strict topology. Then, $[\mathcal{KN}(f_k)](W_i) \longrightarrow [\mathcal{KN}(f^{**})](W_i)$ for all i , and then $L_n(f_k) \longrightarrow L_n(f^{**})$ initially only along the subsequence, but since $\{L_n(f_k)\}_k$ is decreasing, then along the whole sequence. Now, if $\text{KL}(f^{**}, f_1) < \infty$, then apply the second monotonicity property with the solution f^{**} , and then one finds that $\text{KL}(f^{**}, f_k) \longrightarrow 0$ along the subsequence, but since $\{\text{KL}(f^{**}, f_k)\}_k$ is decreasing, then along the whole sequence.

If $\text{KL}(f^{**}, f_1) = \infty$, then for $0 < \varepsilon < 1$ but arbitrary, apply the second monotonicity property with the solution $f_\varepsilon^* = \varepsilon f^* + (1 - \varepsilon)f^{**}$. Then, $\text{KL}(f_\varepsilon^*, f_1) < \infty$ and $\text{KL}(f_\varepsilon^*, f_k)$ converges, and it is easy to see that

$$\lim_{k \rightarrow \infty} \text{KL}(f_\varepsilon^*, f_k) = \text{KL}(f_\varepsilon^*, f^{**}) = o(1) \quad \text{for } \varepsilon \rightarrow 0.$$

It follows that $\text{KL}(f^{**}, f_k) \rightarrow 0$. ■

Monotonicity for Exact Gibbs Smoothing

The two monotonicity properties also hold for penalized maximum likelihood estimation with Gibbs smoothing, at least if the M-step of the EM algorithm is performed exactly; see (196) below. This is at least approximately the case in the approach of Miller and Roysam [73] but not so for the one-step-late approach of Green [49].

Here, the monotonicity properties are proved for “arbitrary” Gibbs functionals. So, consider the maximum penalized likelihood problem for emission tomography

$$\begin{aligned} \text{minimize } \Lambda(x) &\stackrel{\text{def}}{=} -\sum_{j=1}^m b_j \log[Ax]_j + \sum_{p=1}^\ell x_p + G(x) \\ \text{subject to } x &\geq 0, \end{aligned} \tag{194}$$

where $G(x)$ is convex and differentiable and satisfies

$$\lim_{\|x\| \rightarrow \infty} G(x) = +\infty. \tag{195}$$

Assume that b is strictly positive and that A satisfies the usual conditions (126). Note that typically, the roughness prior will be of the form $\lambda G(x)$ for some small positive parameter λ . In the present context, one may as well take $\lambda = 1$.

The goal is again to derive the two monotonicity properties. The majorizing functional inequality is just about the same as for the Shepp–Vardi EM algorithm; see (180). Recall the definition of the operator R from (185).

Lemma 8. *For all probability vectors x and y ,*

$$\Lambda(x) \leq \Lambda(y) + \text{KL}(Ry, x) - \text{KL}(Ry, y) + G(x) - G(y),$$

where $r_j = b_j/[Ay]_j$ for $j = 1, 2, \dots, m$.

Now, to minimize the right-hand side, set the gradient with respect to x equal to 0. With $y = x^{[k]}$, this gives the next iterate implicitly as

$$x_p^{[k+1]} = \frac{x_p^{[k]} [A^T r^{[k]}]_p}{1 + [\nabla G(x^{[k+1]})]_p}, \quad p = 1, 2, \dots, \ell, \tag{196}$$

with $r_j^{[k]} = b_j/[Ax^{[k]}]_j$ for all j . Note that $1 + [\nabla G(x^{[k+1]})]_p > 0$ for all p , since the equations

$$x_p^{[k+1]} \left(1 + [\nabla G(x^{[k+1]})]_p \right) = x_p^{[k]}, \quad p = 1, 2, \dots, \ell,$$

have a solution (the minimization problem has a solution) and $x^{[k]}$ is strictly positive (by induction).

The first monotonicity property is almost immediate. The second one takes more work. For nonnegative vectors x , y , and w , define

$$\text{KL}(x, y|w) = \sum_{p=1}^{\ell} w_p \left\{ x_p \log \frac{x_p}{y_p} + y_p - x_p \right\}. \quad (197)$$

Lemma 9. *Starting with a strictly positive initial vector $x^{[1]}$,*

$$\Lambda(x^{[k]}) - \Lambda(x^{[k+1]}) \geq \text{KL}(x^{[k+1]}, x^{[k]} | w^{[k+1]}) \geq 0,$$

where $w^{[k+1]} = 1 + \nabla G(x^{[k+1]})$.

Proof. From Lemma 8, one gets

$$\begin{aligned} \Lambda(x^{[k+1]}) - \Lambda(x^{[k]}) \\ \leq \sum_{p=1}^{\ell} \left\{ \left(w_p^{[k+1]} x_p^{[k+1]} \log \frac{x_p^{[k+1]}}{x_p^{[k]}} \right) + x_p^{[k+1]} - x_p^{[k]} \right\} \\ + G(x^{[k+1]}) - G(x^{[k]}). \end{aligned}$$

Now use that $G(x^{[k+1]}) - G(x^{[k]}) \leq \langle \nabla G(x^{[k+1]}), x^{[k+1]} - x^{[k]} \rangle$. ■

Lemma 10. *Let x^* be a solution of (194). Then, starting from a strictly positive initial guess $x^{[1]}$,*

$$\text{KL}(w^* \cdot x^*, w^{[k]} \cdot x^{[k]}) - \text{KL}(w^* \cdot x^*, w^{[k+1]} \cdot x^{[k+1]}) \geq \Lambda(x^{[k]}) - \Lambda(x^*) \geq 0,$$

where $w^* = 1 + \nabla G(x^*)$.

Proof. Write $\Lambda(x) = L(x) + G(x)$. So $L(x)$ is the unpenalized negative log-likelihood. Now, as in section ‘‘Monotonicity of the Shepp–Vardi EM Algorithm,’’ one has

$$\begin{aligned}
L(x^{[k]}) - L(x^*) &= \sum_{j=1}^m \left\{ b_j \log \frac{[Ax^*]_j}{[Ax^{[k]}]_j} + [Ax^{[k]}]_j - [Ax^*]_j \right\} \\
&= \sum_{p=1}^{\ell} \left\{ x_p^* \left[A^T \left\{ r^* \log \frac{Ax^*}{Ax^{[k]}} \right\} \right]_p + x_p^{[k]} - x_p^* \right\},
\end{aligned}$$

with $r_j^* = b_j/[Ax^*]_j$ for all j . Now, x^* solves the problem (194), so by the previous lemma, it must be a fixed point of the algorithm. So,

$$x_p^* = \frac{x_p^* [A^T r^*]_p}{1 + [\nabla G(x^*)]_p}, \quad p = 1, 2, \dots, \ell.$$

Then, if $x_p^* > 0$, one must have $[A^T r^*]_p / (1 + [\nabla G(x^*)]_p) = 1$. Consequently, by convexity

$$\frac{\left[A^T \left\{ r^* \log \frac{Ax^*}{Ax^{[k]}} \right\} \right]_p}{1 + [\nabla G(x^*)]_p} \leq \log \frac{\left[A^T \left\{ r^* \frac{Ax^*}{Ax^{[k]}} \right\} \right]_p}{1 + [\nabla G(x^*)]_p},$$

which equals

$$\log \left(\frac{x_p^{[k+1]}}{x_p^{[k]}} \cdot \frac{w_p^{[k+1]}}{w_p^*} \right) = \log \left(\frac{w_p^{[k+1]} x_p^{[k+1]}}{w_p^{[k]} x_p^{[k]}} \right) + \log \frac{w_p^{[k]}}{w_p^*}.$$

Now, substitute this in the upper bound for $L(x^{[k]}) - L(x^*)$. This yields

$$\begin{aligned}
L(x^{[k]}) - L(x^*) &\leq \sum_{p=1}^{\ell} w_p^* x_p^* \log \frac{w_p^{[k+1]} x_p^{[k+1]}}{w_p^{[k]} x_p^{[k]}} + \\
&\quad \sum_{p=1}^{\ell} \left\{ w_p^* x_p^* \log \frac{w_p^{[k]}}{w_p^*} + x_p^{[k]} - x_p^* \right\}.
\end{aligned}$$

Now, after some bookkeeping, the first sum is seen to be equal to

$$\begin{aligned}
&\text{KL}(w^* \cdot x^*, w^{[k]} \cdot x^{[k]}) - \text{KL}(w^* \cdot x^*, w^{[k+1]} \cdot x^{[k+1]}) \\
&+ \sum_{p=1}^{\ell} \left\{ w_p^{[k+1]} x_p^{[k+1]} - w_p^{[k]} x_p^{[k]} \right\}.
\end{aligned}$$

Using the inequality $\log t \leq t - 1$, one gets that

$$L(x^{[k]}) - L(x^*) \leq \text{KL}(w^* \cdot x^*, w^{[k]} \cdot x^{[k]}) - \text{KL}(w^* \cdot x^*, w^{[k+1]} \cdot x^{[k+1]}) + \text{rem} \quad (198)$$

with the remainder

$$\text{rem} = \sum_{p=1}^{\ell} \left\{ (w^{[k]} - 1) \left(x_p^* - x_p^{[k]} \right) - w_p^* x_p^* + w_p^{[k+1]} x_p^{[k+1]} \right\}.$$

Now, since $w_p^{[k+1]} x_p^{[k+1]} = x_p^{[k]} [A^T r^{[k]}]_p$ and likewise for $w_p^* x_p^*$, then

$$\sum_{p=1}^{\ell} w_p^* x_p^* = \sum_{j=1}^m b_j = \sum_{p=1}^{\ell} w_p^{[k+1]} x_p^{[k+1]}.$$

The remaining terms add up to $\langle \nabla G(x^{[k]}), x^* - x^{[k]} \rangle$ which is bounded by $G(x^*) - G(x^{[k]})$ (by convexity). Moving this to the left-hand side of the resulting inequality proves the lemma. ■

The convergence of the exact EM algorithm with Gibbs smoothing now follows. Lange [62] proves the convergence of the one-step-late version of the algorithm by essentially “soft” methods. It would be nice to see under what conditions the two monotonicity properties carry over to this version.

9 EM-Like Algorithms

The analytical proofs of the inequalities of Lemmas 1 and 5 may be extended to other interesting minimization problems. Rather surprisingly, some of these algorithms enjoy the “same” two monotonicity properties as the EM and NEMS algorithms (and the proofs appear to be simpler). The problems under consideration are “positive” least-squares problems and minimum cross-entropy problems. The main idea is that of majorizing functions, as originally exploited by De Pierro [29] in the maximum penalized likelihood approach for emission tomography.

Again, it would have been nice to also outline the geometric approach of Csiszár and Tusnády [23], which, just like the analytical approach of Mülthei and Schorr [75], is applicable to the minimum cross-entropy problems. However, it is not clear that the Csiszár–Tusnády approach works for the “positive” least-squares problem: The Kullback–Leibler distance shows up in the monotonicity properties. This is in effect due to the multiplicative nature of the algorithms, as explained in the last section.

Minimum Cross-Entropy Problems

Consider again the system of equations

$$Ax = b, \quad (199)$$

in the emission tomography setup (see (126)), with b a nonnegative vector. The interest is in the following minimization problem:

$$\text{minimize } \text{CE}(x) \stackrel{\text{def}}{=} \text{KL}(Ax, b) \quad \text{subject to } x \in \mathbb{R}^\ell, x \geq 0. \quad (200)$$

Here, “CE” stands for cross-entropy. (Why it makes sense to consider $\text{KL}(Ax, b)$ instead of $\text{KL}(b, Ax)$ or even $\|Ax - b\|^2$ is not the issue here.)

The objective is to obtain a majorizing function for $\text{CE}(x)$ that would result in a nice algorithm satisfying the “two” monotonicity properties similar to the EM algorithm.

Prejudicing the proceedings somewhat, it is useful to define the operator R on nonnegative vectors by

$$[Ry]_p = y_p \exp \left(\left[A^T \log \frac{b}{Ay} \right]_p \right), \quad p = 1, 2, \dots, \ell. \quad (201)$$

Here, and elsewhere, $A^T \log(Ay/b) = A^T v$, with $v_j = \log([Ay]_j/b_j)$ for all j .

Lemma 11. *For all nonnegative $x, y \in \mathbb{R}^\ell$,*

$$\text{CE}(x) \leq \text{CE}(y) + \text{KL}(x, Ry) - \text{KL}(y, Ry).$$

Proof. The starting point is the straightforward identity

$$\text{CE}(x) = \text{CE}(y) + \text{KL}(Ax, Ay) + \langle x - y, A^T r \rangle,$$

with $r_j = \log([Ay]_j/b_j)$ for all j .

Now, by convexity of the KL function jointly in both its arguments, the conditions (126) and (127) on A imply that

$$\text{KL}(Ax, Ay) \leq \text{KL}(x, y). \quad (202)$$

Finally, since $[A^T r]_p = -\log([Ry]_p/y_p)$, for all p , then

$$\text{KL}(x, y) + \langle x - y, A^T r \rangle = \text{KL}(x, Ry) - \text{KL}(y, Ry).$$

This completes the proof of the lemma. ■

The inequality of the lemma immediately suggests an iterative algorithm for the minimization of $\text{CE}(x)$. Minimizing the right-hand side gives the optimal x as $x = Ry$ with R given by (201). Thus, the iterative algorithm is, starting from a strictly positive $x^{[1]} \in \mathbb{R}^\ell$,

$$x_p^{[k+1]} = [Rx^{[k]}]_p, \quad p = 1, 2, \dots \quad (203)$$

This is the simultaneous multiplicative algebraic reconstruction technique (SMART algorithm). It first appeared in [86]; see (also) Holte et al. [57] and Darroch and Ratcliff [25], who called it the iterative rescaling algorithm. The row-action version (MART) originated with Gordon et al. [48]. Byrne [7] developed block-iterative Versions; see section “The MART and SMART Methods.” The starting point of Censor and Segman [18] was entropy maximization subject to the linear constraints $Ax = b$ and arrived at various versions of MART including simultaneous and block-iterative versions.

Onto the two monotonicity properties, the first one is immediate.

Lemma 12. *If $x^{[1]}$ is strictly positive, then the iterates of the SMART algorithm (203) satisfy*

$$\text{CE}(x^{[k]}) - \text{CE}(x^{[k+1]}) \geq \text{KL}(x^{[k]}, x^{[k+1]}).$$

Note the difference with the first monotonicity property (182) for the Shepp–Vardi EM algorithm. The second monotonicity property is equally simple, but the precise form must be guessed. (Actually, it follows from the proof.)

Lemma 13. *If x^* is a solution of the nonnegatively constrained least-squares problem (207), then, with $x^{[1]}$ strictly positive,*

$$\text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) \geq \text{CE}(x^{[k+1]}) - \text{CE}(x^*) \geq 0.$$

Proof. Observe that

$$\begin{aligned} & \text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) \\ &= \sum_{p=1}^{\ell} \left\{ x_p^* \log \frac{x_p^{[k+1]}}{x_p^{[k]}} + x_p^{[k]} - x_p^{[k+1]} \right\} \\ &= \sum_{p=1}^{\ell} \left(x_p^{[k]} - x_p^* \right) \log \frac{x_p^{[k]}}{x_p^{[k+1]}} - \sum_{p=1}^{\ell} \left\{ x_p^{[k]} \log \frac{x_p^{[k]}}{x_p^{[k+1]}} + x_p^{[k+1]} - x_p^{[k]} \right\} \end{aligned} \quad (204)$$

The last sum equals $\text{KL}(x^{[k]}, x^{[k+1]})$, and by Lemma 12, then

$$-\text{KL}(x^{[k]}, x^{[k+1]}) \geq \text{CE}(x^{[k+1]}) - \text{CE}(x^{[k]}).$$

The first sum equals

$$\sum_{p=1}^{\ell} \left(x_p^{[k]} - x_p^* \right) \left[A^T \log \frac{Ax^{[k]}}{b} \right]_p = \langle x^{[k]} - x^*, \nabla \text{CE}(x^{[k]}) \rangle,$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product on \mathbb{R}^ℓ and ∇CE is the gradient of $\text{CE}(x)$. By the convexity of CE , then

$$\langle x^{[k]} - x^*, \nabla \text{CE}(x^{[k]}) \rangle \geq \text{CE}(x^{[k]}) - \text{CE}(x^*).$$

Summarizing, the above shows that

$$\begin{aligned} \text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) &\geq \text{CE}(x^{[k]}) - \text{CE}(x^*) + \text{CE}(x^{[k+1]}) - \text{CE}(x^{[k]}) \\ &= \text{CE}(x^{[k+1]}) - \text{CE}(x^*). \end{aligned}$$

This is the lemma. ■

As before, the convergence of the SMART algorithm follows starting from any strictly positive vector $x^{[1]}$.

Minimizing Burg's entropy: Compared with the minimum cross-entropy problem from the previous section, the case of Burg's entropy is problematic. For the positive system

$$Ax = b$$

with the normalization (126), the minimum Burg entropy problem is

$$\text{minimize } \text{BE}(x) \stackrel{\text{def}}{=} \sum_{j=1}^m \left\{ -\log \frac{b_j}{[Ax]_j} + \frac{b_j}{[Ax]_j} \right\} \quad (205)$$

subject to $x \geq 0$.

The first thing one notices is that it is not a convex problem. Then, it is conceivable that the solution set is not convex, and so a “second” monotonicity property is not likely to hold. However, there is a majorizing function, which suggests a multiplicative algorithm, and there is a “first” monotonicity property.

Lemma 14. *For all nonnegative x and y ,*

$$\text{BE}(x) \leq \text{BE}(y) + \sum_{p=1}^{\ell} \left\{ [A^T q]_p - [A^T r]_p \frac{y_p}{x_p} \right\} (x_p - y_p),$$

where

$$r_j = \frac{b_j}{([Ay]_j)^2}, \quad q_j = \frac{1}{[Ay]_j}, \quad j = 1, 2, \dots, m.$$

The algorithm suggested by the lemma comes about by minimizing the upper bound on $\text{BE}(x)$ with $y = x^{[k]}$, the current guess for the solution. This gives the minimizer as $x = x^{[k+1]}$,

$$x_p^{[k+1]} = x_p^{[k]} \cdot \left\{ \frac{[A^T r^{[k]}]_p}{[A^T q^{[k]}]_p} \right\}^{1/2}, \quad (206)$$

where

$$r_j^{[k]} = \frac{b_j}{([Ax^{[k]}]_j)^2}, \quad q_j^{[k]} = \frac{1}{[Ax^{[k]}]_j}, \quad j = 1, 2, \dots, m.$$

The “first” monotonicity property reads as follows.

Lemma 15. *Starting with a strictly positive initial guess $x^{[1]}$, the iterates generated by (206) satisfy*

$$\text{BE}(x^{[k]}) - \text{BE}(x^{[k+1]}) \geq \sum_{p=1}^{\ell} [A^T q^{[k]}]_p \frac{|x_p^{[k+1]} - x_p^{[k]}|^2}{x_p^{[k]}}.$$

It follows that the objective function decreases as the iteration proceeds, unless one has a fixed point of the iteration. It would seem reasonable to conjecture that one then gets convergence of the iterates to a local minimum, but in the absence of a second monotonicity property, this is where it ends.

Some reconstructions from simulated and real data are shown in [15]. The proofs of the above two lemmas are shown there as well.

Nonnegative Least Squares

The absence of EM algorithms for least-squares problems sooner or later had to be addressed. Here, consider positive least-squares problems, and as in section “Minimum Cross-Entropy Problems,” one may as well consider them for the discrete emission tomography case. Thus, the interest is in solving the problem

$$\text{minimize } \text{LS}(x) \stackrel{\text{def}}{=} \|Ax - b\|^2 \quad \text{subject to } x \geq 0. \quad (207)$$

Recall the properties (126) and (127) of the nonnegative matrix $A \in \mathbb{R}^{m \times \ell}$, and that b is a nonnegative vector. It is useful to define the operator T on nonnegative vectors by

$$[Ty]_p = y_p \frac{[A^T b]_p}{[A^T A y]_p}, \quad p = 1, 2, \dots, \ell. \quad (208)$$

The following discussion of the convergence of this algorithm follows De Pierro [28] and Eggermont [33]. The first item on the agenda is to prove an analogue of Lemma 1.

Lemma 16. *For all nonnegative $x, y \in \mathbb{R}^\ell$, with y strictly positive,*

$$\text{LS}(x) \leq \text{LS}(y) + \sum_{p=1}^{\ell} [A^T b]_p \left\{ \frac{(x_p - [Ty]_p)^2}{[Ty]_p} - \frac{(y_p - [Ty]_p)^2}{[Ty]_p} \right\}.$$

Proof. Observe that

$$\text{LS}(x) = \text{LS}(y) + 2 \langle x - y, A^T(Ay - b) \rangle + \|A(x - y)\|^2.$$

Let $z = x - y$. Write $Az = A\{y^{1/2}(z/y^{1/2})\}$ (with componentwise vector operations) and use Cauchy–Schwarz. Then,

$$\|Az\|^2 \leq \sum_{j=1}^m [Ay]_j [A(z^2/y)]_j = \sum_{p=1}^{\ell} z_p^2 \frac{[A^T A y]_p}{y_p}.$$

Now, consider $\|Az\|^2 + 2 \langle z, A^T(Ay - b) \rangle$. Completing the square gives

$$\begin{aligned} \|Az\|^2 + 2 \langle z, A^T(Ay - b) \rangle &\leq \sum_{p=1}^{\ell} \frac{[A^T A y]_p}{y_p} \left(z_p + y_p \frac{[A^T(Ay - b)]_p}{[A^T A y]_p} \right)^2 \\ &\quad - \sum_{p=1}^{\ell} \frac{y_p}{[A^T A y]_p} [A^T(Ay - b)]_p^2. \end{aligned} \quad (209)$$

For the first sum, note that the expression inside the parentheses equals $x_p - [Ty]_p$. Also, $[A^T A y]_p / y_p = [A^T b]_p / [Ty]_p$, so that takes care of the first sum. For the second sum, note that

$$\frac{y_p}{[A^T A y]_p} [A^T(Ay - b)]_p^2 = \frac{[A^T A y]_p}{y_p} \left(y_p - y_p \frac{[A^T b]_p}{[A^T A y]_p} \right)^2,$$

and the expression for the second sum follows. ■

It is now clear how one may construct an algorithm. Take $y = x^{[1]}$, a strictly positive vector, and minimize the upper bound on $\text{LS}(x)$ given by the lemma. Setting the gradient equal to 0 gives $x^{[k+1]} = Tx^{[k]}$ or

$$x_p^{[k+1]} = x_p^{[k]} \cdot \frac{[A^T b]_p}{[A^T A x^{[k]}]_p}, \quad p = 1, 2, \dots, \ell. \quad (210)$$

Note that then all $x^{[k]}$ are strictly positive because A is nonnegative and has unit column sums.

This algorithm is due to Daube-Witherspoon and Muehllehner [26] for emission tomography with the acronym ISRA.

Onward to the monotonicity properties of the algorithm, the following lemma is immediate.

Lemma 17. *If $x^{[1]}$ is strictly positive, then the iterates of the ISRA algorithm (210) satisfy*

$$\text{LS}(x^{[k]}) - \text{LS}(x^{[k+1]}) \geq \sum_{p=1}^{\ell} [A^T b]_p \frac{(x_p^{[k]} - x_p^{[k+1]})^2}{x_p^{[k+1]}}.$$

The “second” monotonicity property is a bit more involved than for the EM algorithm but still involves Kullback–Leibler distances. Let

$$\text{KLS}(x, y) = \text{KL}(c \cdot x, c \cdot y) + \text{LS}(y) - \text{LS}(y^*), \quad (211)$$

where $x = y^*$ is any minimizer of $\|Ax - b\|^2$ over $x \geq 0$. Here, $c = A^T b$ and the dot means componentwise multiplication.

Lemma 18. *If x^* is a solution of the nonnegatively constrained least-squares problem (207), then*

$$\text{KLS}(c \cdot x^*, c \cdot x^{[k]}) - \text{KLS}(c \cdot x^*, c \cdot x^{[k+1]}) \geq \frac{1}{2} \text{LS}(x^{[k]}) - \frac{1}{2} \text{LS}(x^*) \geq 0.$$

Proof. As before, one has

$$\begin{aligned} & \text{KLS}(c \cdot x^*, c \cdot x^{[k]}) - \text{KLS}(c \cdot x^*, c \cdot x^{[k+1]}) \\ &= \sum_{p=1}^{\ell} c_p x_p^* \log \frac{x_p^{[k+1]}}{x_p^{[k]}} + c_p (x_p^{[k]} - x_p^{[k+1]}) \\ &\geq \sum_{p=1}^m c_p x_p^* \left(1 - \frac{x_p^{[k]}}{x_p^{[k+1]}}\right) + c_p (x_p^{[k]} - x_p^{[k+1]}) \\ &\geq \sum_{p=1}^{\ell} \frac{c_p (x_p^{[k+1]} - x_p^*) (x_p^{[k]} - x_p^{[k+1]})}{x_p^{[k+1]}}. \end{aligned} \quad (212)$$

Here, in the second line, the inequality $\log t = -\log(t^{-1}) \geq 1 - t^{-1}$ was used.

Now, let $C \in \mathbb{R}^{\ell \times \ell}$ be the diagonal matrix with diagonal components

$$C_{p,p} = \frac{[A^T b]_p}{x_p^{[k+1]}}, \quad p = 1, 2, \dots, \ell.$$

Then, the least expression equals

$$\begin{aligned} & \langle x^{[k+1]} - x^*, C(x^{[k]} - x^{[k+1]}) \rangle = \\ & \langle x^{[k+1]} - x^{[k]}, C(x^{[k]} - x^{[k+1]}) \rangle + \langle x^{[k]} - x^*, C(x^{[k]} - x^{[k+1]}) \rangle. \end{aligned}$$

Since $C(x^{[k]} - x^{[k+1]}) = A^T(Ax^{[k]} - b)$, then

$$\begin{aligned} \langle x^{[k]} - x^*, C(x^{[k]} - x^{[k+1]}) \rangle &= \langle x^{[k]} - x^*, A^T(Ax^{[k]} - b) \rangle \\ &\geq \frac{1}{2} \text{LS}(x^{[k]}) - \frac{1}{2} \text{LS}(x^*), \end{aligned}$$

the last inequality by convexity. Finally,

$$\langle x^{[k+1]} - x^{[k]}, C(x^{[k]} - x^{[k+1]}) \rangle = - \sum_{p=1}^{\ell} \frac{[A^T b]_p}{x_p^{[k+1]}} \left(x_p^{[k]} - x_p^{[k+1]} \right)^2.$$

which by Lemma 17 dominates $\text{LS}(x^{[k+1]}) - \text{LS}(x^{[k]})$. This shows that

$$\begin{aligned} \text{KL}(c \cdot x^*, c \cdot x^{[k]}) - \text{KL}(c \cdot x^*, c \cdot x^{[k+1]}) &\geq \frac{1}{2} \text{LS}(x^{[k]}) - \frac{1}{2} \text{LS}(x^*) \\ &\quad - \text{LS}(x^{[k]}) + \text{LS}(x^{[k+1]}). \end{aligned}$$

and the lemma follows. ■

The convergence of the algorithm now follows similar to the EM case.

Multiplicative Iterative Algorithms

This final section concerns the observation that multiplicative iterative algorithms may be constructed by way of proximal point algorithms as in [33] and that Kullback–Leibler distances naturally appear in this context. For arbitrary convex functions F on \mathbb{R}^{ℓ} , one may solve the problem with nonnegativity constraints

$$\text{minimize } F(x) \quad \text{subject to } x \geq 0 \tag{213}$$

by computing a sequence $\{x^{[k]}\}_k$, with $x^{[k+1]}$ the solution of

$$\text{minimize } F(x) + (\omega_k)^{-1} \text{KL}(x^{[k]}, x) \quad \text{subject to } x \geq 0, \quad (214)$$

starting from some $x^{[1]}$ with strictly positive components. Here, $\omega_k > 0$. One verifies that $x^{[k+1]}$ satisfies

$$x_p^{[k+1]} = \frac{1}{1 + \omega_k [\nabla F(x^{[k+1]})]_p}, \quad p = 1, 2, \dots, \ell. \quad (215)$$

This is an implicit equation for $x^{[k+1]}$, but explicit versions suggest themselves. Note that the objective function in (214) is strictly convex, so that the solution is unique, assuming solutions exist. Of course, other proximal functions suggest themselves, such as $\text{KL}(x, x^{[k]})$. See, e.g., [19]. The classical one is $\|x - x^{[k]}\|^2$, the squared Euclidean distance, due to Rockafellar. See, e.g., [13].

It is interesting to note that the implicit algorithm (215) satisfies the two monotonicity properties. The first one is obvious,

$$F(x^{[k]}) - F(x^{[k+1]}) \geq (\omega_k)^{-1} \text{KL}(x^{[k]}, x^{[k+1]}), \quad (216)$$

since $x^{[k+1]}$ is the minimizer of (214).

For the second monotonicity property, assume that x^* is a solution of (213). Note that

$$\begin{aligned} \text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) &= \sum_{p=1}^{\ell} x_p^* \log \frac{x_p^{[k+1]}}{x_p^{[k]}} + x_p^{[k]} - x_p^{[k+1]} \\ &= \sum_{p=1}^{\ell} x^* \log \frac{1}{1 + \omega_k [\nabla F(x^{[k+1]})]_p} \\ &\quad + \omega_k x^{[k+1]} [\nabla F(x^{[k+1]})]_p \\ &\geq \sum_{p=1}^{\ell} -x_p^* \omega_k [\nabla F(x^{[k+1]})]_p + \omega_k x^{[k+1]} [\nabla F(x^{[k+1]})]_p \\ &= \omega_k \langle x^{[k+1]} - x^*, \nabla F(x^{[k+1]}) \rangle \geq \omega_k (F(x^{[k+1]}) - F(x^*)). \end{aligned}$$

To summarize,

$$\text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) \geq \omega_k (F(x^{[k+1]}) - F(x^*)). \quad (217)$$

The convergence of the algorithm follows. Practically speaking, one has to devise explicit versions of the algorithm and see how they behave.

10 Accelerating the EM Algorithm

The Ordered Subset EM Algorithm

It is well known that EM algorithms converge very slowly, even if one wants to stop the iteration “early.” For the general EM algorithm of section “The Bare-Bones EM Algorithm Fleshed Out,” some attempts at acceleration have been made along the lines of coordinate descent methods or more generally descent along groups of coordinates. In particular, the M-step (34) is replaced by a sequence of M-steps, for $j = 1, 2, \dots, m$, with $x_1 = x^{[k]}$,

$$\begin{aligned} \text{minimize } \mathcal{L}(x|x_{j-1}) &\stackrel{\text{def}}{=} - \int_{\mathcal{Z}} \varphi_{\mathcal{Z}}(z|x_{j-1}) \log f_{\mathcal{Z}}(z|x) d\mu(z) \\ \text{subject to } x &\in \mathcal{X}_j, \end{aligned} \quad (218)$$

and then $x^{[k+1]} = x_m$. Here $\{\mathcal{X}_j\}_{j=1}^m$ is a not necessarily disjoint division of the parameter space \mathcal{X} . See [68] and references therein. In the context of emission tomography, the more generally accepted route to accelerating the EM algorithm has been via the ordered subset approach of Hudson and Larkin [59]. Without putting too fine a point to it, this amounts to partitioning the data space rather than the parameter space. The acceleration achieved by these methods seems to be twofold. The ordered subset approach allows for more efficient computer implementations and, the convergence itself is speeded up. See, e.g., [60].

The ordered subset EM algorithm (OSEM) of Hudson and Larkin [59] deals with the maximum likelihood problem of emission tomography (130). The starting point is to divide the data into blocks, characterized by the sets of indices $\Omega(1), \Omega(2), \dots, \Omega(s)$ such that

$$\Omega(1) \cup \Omega(2) \cup \dots \cup \Omega(s) = \{1, 2, \dots, m\}. \quad (219)$$

However, the sets need not be disjoint. Define the partial negative Kullback–Leibler functionals

$$L_r(x) = \sum_{j \in \Omega(r)} \left\{ b_j \log \frac{b_j}{[Ax]_j} + [Ax]_j - b_j \right\}, \quad r = 1, 2, \dots, s. \quad (220)$$

Note that for all r ,

$$\sum_{j \in \Omega(r)} [Ax]_j = \sum_{p=1}^{\ell} \alpha_{rp} x_p \quad \text{with} \quad \alpha_{rp} = \sum_{j \in \Omega(r)} a(j, p). \quad (221)$$

The OSEM algorithm now consists of successively applying one step of the Shepp–Vardi EM algorithm to each of the problems

$$\text{minimize } L_r(x) \quad \text{subject to } x \geq 0. \quad (222)$$

To spell out the OSEM iteration exactly, it is useful to introduce the data vectors B_r and the matrices A_r by

$$B_r = (b_j : j \in \Omega(r)) \quad \text{and} \quad A_r x = ([A x]_j : j \in \Omega(r)). \quad (223)$$

Then, $L_r(x) = \text{KL}(B_r, A_r x)$, and the OSEM algorithm takes the form

$$x_p^{[k+1]} = x_p^{[k]} \cdot \alpha_{rp}^{-1} [A_r^T \varrho^{[k]}]_p, \quad p = 1, 2, \dots, \ell, \quad (224)$$

where $r = k \bmod s$ (in the range $1 \leq r \leq s$) and $\varrho_q^{[k]} = B_{rq}/[A_r x^{[k]}]_q$ for all q . The slight complication of the α_{rp} arises because the matrices A_r do not have unit column sums. This is fixed by defining the matrices \mathbb{A}_r by

$$[\mathbb{A}_r]_{qp} = \alpha_{rp}^{-1} [A_r]_{qp} \quad \text{for all } q \text{ and } p. \quad (225)$$

Now, define $\mathbb{L}_r(y) = L_r(x) = \text{KL}(B_r, \mathbb{A}_r y)$, where $y_q = \alpha_{rq} x_q$ for all q . A convenient short-hand notation for this is $y = \alpha_r \cdot x$. Now, if x minimizes $L_r(x)$, then $y = \alpha_r \cdot x$ minimizes $\mathbb{L}_r(y)$ and vice versa. Since the matrices \mathbb{A}_r have unit column sums, the EM algorithm for minimizing $\mathbb{L}_r(y)$ is

$$y_p^{[k+1]} = y_p^{[k]} \cdot [\mathbb{A}_r^T \varrho^{[k]}]_p, \quad p = 1, 2, \dots, \ell, \quad (226)$$

with $\varrho_q^{[k]} = B_{rq}/[\mathbb{A}_r y^{[k]}]_q$ for all q . Transforming back gives (224).

Regarding the convergence of the OSEM algorithm, the best one can hope for is cyclic convergence, i.e., each of the subsequences $\{x^{[k+r s]}\}_{r \geq 1}$ converges. Proving this would be a daunting task. However, as observed by Byrne [9], it is useful to consider what happens if the system of equations $Ax = b$ is consistent in the sense that

$$\exists x^* \geq 0 : Ax^* = b, \quad (227)$$

when one should expect convergence of the whole sequence to a nonnegative solution of $Ax = b$. Hudson and Larkin [59] prove that this is so under the so-called subset-balancing condition

$$\alpha_{rp} = \alpha_{o,p}, \quad p = 1, 2, \dots, \ell \quad \text{and} \quad r = 1, 2, \dots, s. \quad (228)$$

That is, the column sums are the same for all blocks. This is a strong condition, even if one allows for overlapping blocks of data. Haltmeier et al. [51] make the same assumption in the continuous setting. Byrne [11] observed that the condition may be relaxed to that of *subset-separability*: There exist coefficients β_r and γ_p such that

$$\alpha_{rp} = \beta_r \gamma_p, \quad r = 1, 2, \dots, s \quad \text{and} \quad p = 1, 2, \dots, \ell. \quad (229)$$

The convergence proof of the OSEM algorithm (224) under the subset-separability condition (229) relies on the two monotonicity properties of the EM algorithm (226); see section ‘‘Monotonicity of the Shepp–Vardi EM Algorithm.’’ After translation, one gets the following monotonicity properties for (224).

Lemma 19. *Let x^* be a nonnegative solution of $Ax = b$. Starting from a strictly positive $x^{[1]} \in V_\ell$, then, with $r = k \bmod s$,*

$$\begin{aligned} L_r(x^{[k]}) - L_r(x^{[k+1]}) &\geq \text{KL}(\alpha_r \cdot x^{[k+1]}, \alpha_r \cdot x^{[k]}) \geq 0 \quad \text{and} \\ \text{KL}(\alpha_r \cdot x^*, \alpha_r \cdot x^{[k]}) - \text{KL}(\alpha_r \cdot x^*, \alpha_r \cdot x^{[k+1]}) &\geq L_r(x^{[k]}) - L_r(x^*) \geq 0. \end{aligned}$$

Now, if the α_{rp} change with r , then one cannot conclude much from the lemma. However, under the subset-separability condition (229), one obtains for all nonnegative x and y

$$\text{KL}(\alpha_r \cdot x, \alpha_r \cdot y) = \beta_r \text{KL}(\gamma \cdot x, \gamma \cdot y),$$

and the inequalities of the lemma translate as follows.

Corollary 1. *Under the conditions of Lemma 19 and the subset-separability condition (229),*

$$\begin{aligned} \beta_r^{-1} \{L_r(x^{[k]}) - L_r(x^{[k+1]})\} &\geq \text{KL}(\gamma \cdot x^{[k+1]}, \gamma \cdot x^{[k]}) \geq 0 \quad \text{and} \\ \text{KL}(\gamma \cdot x^*, \gamma \cdot x^{[k]}) - \text{KL}(\gamma \cdot x^*, \gamma \cdot x^{[k+1]}) &\geq \beta_r^{-1} \{L_r(x^{[k]}) - L_r(x^*)\} \geq 0. \end{aligned}$$

As in Theorem 1, one may conclude that the sequence $\{\gamma \cdot x^{[k]}\}_k$ converges to a nonnegative solution x^{**} of $Ax = b$. Note that there is another way of looking at this; see Remark 5 at the end of this chapter.

As remarked, the subset-separability condition (228) is very strong. It fails dramatically in the extreme case of the OSEM algorithm when each block consists of a single row. In that case, the OSEM algorithm (224) reduces to

$$x_p^{[k+1]} = x_p^{[k]} \cdot \frac{b_j}{[Ax^{[k]}]_j}, \quad p = 1, 2, \dots, \ell, \quad (230)$$

where $j = k \bmod m$. So, $x^{[k+1]}$ is a multiple of $x^{[k]}$, and the OSEM algorithm produces only multiples of the initial guess $x^{[1]}$. So, certainly in this case, the algorithm does not converge, but more seriously, it does not do anything useful.

So, what is one to do? Following Byrne [9] (see also [13]), the next section turns to row-action methods (where the blocks consist of a single datum), that is, the (additive) algebraic reconstruction technique (ART) and the multiplicative version (MART) of Gordon et al. [48], as well as block-iterative variants. (The

simultaneous version (SMART) of the multiplicative version was already discussed in section ‘‘Minimum Cross-Entropy Problems.’’) This points into the direction of relaxation and scaling. After that, the table is set for block-iterative versions of the EM algorithm.

The ART and Cimmino–Landweber Methods

It is useful to discuss the situation in regard to the so-called *algebraic reconstruction technique* (ART) of Gordon et al. [48], and the Cimmino–Landweber iteration, a reasonable version of the original SIRT method. Herman [55] is the authoritative source, but see [95] for a comparison with conjugate gradient method. The ART and Cimmino–Landweber algorithms were designed to solve systems of linear equations of the form

$$A x = b \quad (231)$$

with b the measured nonnegative data and $A \in \mathbb{R}^{m \times \ell}$ with nonnegative components $a(j, p)$ but not necessarily unit column sums. Of course, for inconsistent systems of equations, this must be replaced by the least-squares problem

$$\text{minimize } \|Ax - b\|^2 \quad \text{subject to } x \in \mathbb{R}^m, \quad (232)$$

but in fact, the ART method solves the weighted least-squares problem

$$\text{minimize } \sum_{j=1}^m \frac{|\langle a(j, \cdot), x \rangle - b_j|^2}{\|a(j, \cdot)\|^2} \quad \text{subject to } x \in \mathbb{R}^m, \quad (233)$$

A standard method for the solution of (232) is the Cimmino–Landweber iteration

$$x^{[k+1]} = x^{[k]} + \omega_k A^T(b - Ax^{[k]}), \quad (234)$$

for suitably small but not too small positive relaxation parameters ω_k . It is mentioned here for its analogy with the EM algorithm. The Cimmino–Landweber iteration is a well-studied method for the regularization of the least-squares problem (232) and is itself subject to acceleration; see, e.g., Hanke [52] and references therein.

At the other end of the spectrum is Kaczmarz’ method, which consists of sequential orthogonal projections onto the hyperplanes

$$H_j = \{x \in \mathbb{R}^\ell \mid \langle a(j, \cdot), x \rangle = b_j\}.$$

Formally, this is achieved by computing the new iterate $x^{[k+1]}$ from the previous one $x^{[k]}$ by solving

$$\text{minimize } \|x - x^{[k]}\|^2 \quad \text{subject to} \quad \langle a(j, \cdot), x \rangle = b_j. \quad (235)$$

The iteration then takes the form, with $j = k \bmod m$,

$$x^{[k+1]} = x^{[k]} + \omega_k \frac{b_j - \langle a(j, \cdot), x^{[k]}\rangle}{\|a(j, \cdot)\|^2} a(j, \cdot) \quad (236)$$

for $\omega_k = 1$. The relaxation parameter ω_k is included to see whether choices other than $\omega_k = 1$ might be advantageous. Geometrically, a requirement is $0 < \omega_k < 2$. The choice $\omega_k = 0$ would not do anything; the choice $\omega_k = 2$ implements reflection with respect to the hyperplane H_j . The algorithm (236) with relaxation originated with Gordon et al. [48].

Typically, one takes the hyperplanes in cyclic order $j = k \bmod m$, but Herman and Meyer [56] show experimentally that carefully reordering the hyperplanes has a big effect on the quality of the reconstruction when the number of iterations is fixed before hand. The choice of $\omega (= \omega_k \text{ for all } k)$ also matters greatly, but the optimal one seems to depend on everything (the experimental setup leading to the matrix A , the noise level, etc.), so that the optimal ω can be very close to 0 or close to 2 or in between.

Byrne [8, 9] observes that the scaling of the ART algorithm is just about optimal, as follows. Actually, it is difficult to say much for inconsistent systems, other than experimentally (see [56]), but for consistent systems, one has the following two monotonicity properties, which are reminiscent of the monotonicity properties for the Shepp–Vardi EM algorithm. However, they are much less impressive since they only hold for consistent systems. Define

$$\text{LS}_j(x) = \frac{|\langle a(j, \cdot), x \rangle - b_j|^2}{\|a(j, \cdot)\|^2}, \quad j = 1, 2, \dots, m. \quad (237)$$

Lemma 20. *If x^* satisfies $Ax^* = b$, then*

$$\begin{aligned} \text{LS}_j(x^{[k]}) - \text{LS}_j(x^{[k+1]}) &= \omega_k(2 - \omega_k) \text{LS}_j(x^{[k]}), \\ \|x^{[k]} - x^*\|^2 - \|x^{[k+1]} - x^*\|^2 &= \omega_k(2 - \omega_k) \text{LS}_j(x^{[k]}). \end{aligned}$$

The proofs involve only (exact) quadratic Taylor expansions and are omitted. The conclusion is that ART converges in the consistent case if $\omega_k = \omega$ is constant and $0 < \omega < 2$. Following Byrne [8], one notes that the second monotonicity property suggests that $\omega_k(2 - \omega_k)$ should be as large as possible. This is achieved by $\omega_k = 1$. In other words, the original Kaczmarz procedure (236) with $\omega_k = 1$ is optimally scaled. However, as already remarked above, a choice other than $\omega_k = 1$ may speed things up initially.

Despite the good news that ART is much faster than the Cimmino–Landweber type methods, it is still “slow.” Now, in transmission tomography as in emission

tomography, the system of equations $Ax = b$ naturally decomposes into a number of blocks

$$A_r x = B_r, \quad r = 1, 2, \dots, s, \quad (238)$$

(see (223)), and then one has the block version of (235)

$$\text{minimize} \quad \|x - x^{[k]}\|^2 \quad \text{subject to} \quad A_r x = B_r, \quad (239)$$

with the solution

$$x^{[k+1]} = x^{[k]} + \omega_k A_r^T (A_r A_r^T)^\dagger (B_r - A_r x^{[k]}), \quad (240)$$

where \dagger denotes the Moore–Penrose inverse. Now, computing $(A_r^T A_r)^\dagger w$ (for any vector w) would be expensive, but it seems reasonable that $A_r^T A_r$ should be close to diagonal, in which case one may just replace it with its diagonal. This leads to the algorithm

$$x^{[k+1]} = x^{[k]} + \omega_k A_r^T D_r^{-1} (B_r - A_r x^{[k]}), \quad (241)$$

where D_r is a diagonal matrix with $[D_r]_{qq} = [A_r A_r^T]_{qq}$.

Now, it turns out that computing $A_r x$ is not much more expensive than computing a single $\langle a(j, \cdot), x \rangle$ and that the matrices $A_r^T A_r$ are very close to diagonal, so that one step of the block method (241) practically achieves as much as the combined ART steps for all the equations in one block. So, methods that process naturally ordered blocks are appreciably faster than the two extreme methods. See [35].

It is not clear how to choose the optimal relaxation parameters. Regarding (241), it is known that the algorithm converges cyclically provided the blocks and the relaxation parameters are chosen cyclically, i.e., if $r = k \bmod s$ and $\omega_k \equiv \omega_r$, and

$$\max_{1 \leq r \leq s} \|I - \omega_r A_r D_r^{-1} A_r^T\|_2 < 1, \quad (242)$$

then $\{x^{[r+ks]}\}_k$ converges for each $r = 1, 2, \dots, s$; see [35]. Moreover, if the relaxation parameter is kept fixed, say,

$$\omega_k = \omega \quad \text{for all } k, \quad (243)$$

and denoting the iterates by $x^{[i+kI]}(\omega)$ to show the dependence on ω , then

$$\lim_{\omega \rightarrow 0} \lim_{k \rightarrow \infty} x^{[i+kI]}(\omega) = x^*, \quad (244)$$

the minimum norm solution of (233), provided the initial guess belongs to the range of A^T . See [16]. At about the same time, Trummer [94] showed for the relaxed ART method (236) that

$$\lim_{k \rightarrow \infty} x^{[k]}(\omega_k) = x^*, \quad (245)$$

provided

$$\omega_k > 0, \quad \sum_{k=1}^{\infty} \omega_k^2 < \infty \quad \text{and} \quad \sum_{k=1}^{\infty} \omega_k = +\infty. \quad (246)$$

Note the difference between (245) and (246).

The MART and SMART Methods

Consider again the system of equations $Ax = b$ as it arises in the PET setting, with A and b having nonnegative components and A having unit column sums. In section “Minimum Cross-Entropy Problems,” the SMART algorithm was discussed for the solution of

$$\text{minimize} \quad \text{KL}(Ax, b) \quad \text{subject to} \quad x \geq 0, \quad (247)$$

i.e.,

$$x_p^{[k+1]} = x_p^{[k+1]} \cdot \exp \left(\left[A^T \log \frac{b}{Ax^{[k]}} \right]_p \right), \quad p = 1, 2, \dots, \ell. \quad (248)$$

The multiplicative ART algorithm (MART) of Gordon et al. [48] formally arises as the multiplicative version of the additive ART algorithm, to wit

$$x_p^{[k+1]} = x_p^{[k]} \cdot \left(\frac{b_j}{\langle a(j, \cdot), x^{[k]} \rangle} \right)^{a(j,p)}, \quad p = 1, 2, \dots, \ell$$

or equivalently for $p = 1, 2, \dots, \ell$

$$x_p^{[k+1]} = x_p^{[k]} \cdot \exp \left(\omega_k a(j, p) \log \frac{b_j}{\langle a(j, \cdot), x^{[k]} \rangle} \right) \quad (249)$$

with $\omega_k = 1$. Again, the relaxation parameter ω_k was included to explore whether choices other than $\omega_k = 1$ would be advantageous. Byrne [9] observes that the MART algorithm typically does not enjoy the same speedup compared to the simultaneous SMART version that ART has over Cimmino–Landweber. To get some insight into this, it is useful to consider a projection method analogous to the Kaczmarz method of orthogonal projections onto hyperplanes. The method in question is well known (see, e.g., [17]),

$$\text{minimize} \quad \text{KL}(x, x^{[k]}) \quad \text{subject to} \quad \langle a(j, \cdot), x^{[k]} \rangle = b_j. \quad (250)$$

One may approximately solve this as follows. With the unrestricted Lagrange multiplier λ , one gets the equations $\log(x_p/x_p^{[k]}) + \lambda a(j, p) = 0$ for all p , so that

$$x_p = x_p^{[k]} \exp(\lambda a(j, p)), \quad p = 1, 2, \dots, \ell.$$

To enforce the constraint, take inner products with $a(j, \cdot)$. This results in

$$b_j = \langle a(j, \cdot), x \rangle = \sum_{p=1}^{\ell} a(j, p) x_p^{[k]} \exp(\lambda a(j, p)), \quad (251)$$

and one would like to solve this for λ . That does not appear manageable, but it can be done approximately as follows. Since the $a(j, p)$ and $x_p^{[k]}$ are nonnegative, by the mean value theorem, there exists a θ , with

$$0 < \theta < \max \{a(j, p) : 1 \leq p \leq \ell\}, \quad (252)$$

such that the right-hand side of (251) equals $\exp(\lambda \theta) \langle a(j, \cdot), x^{[k]} \rangle$. Then, solving (251) for λ gives the iteration

$$x_p^{[k+1]} = x_p^{[k]} \exp \left(\omega a(j, p) \log \frac{b_j}{\langle a(j, \cdot), x^{[k]} \rangle} \right), \quad (253)$$

with $\omega = 1/\theta$. The conservative choice, the one that changes $x^{[k]}$ the least, is to choose ω as small as possible. In view of (252), this gives $\omega = \omega_j$,

$$\omega_j = \frac{1}{\max_{1 \leq p \leq \ell} a(j, p)}. \quad (254)$$

Note that if A has unit column sums, then one may expect ω to be quite large. This may explain why the original MART algorithm is not greatly faster than the SMART version. In defense of Gordon et al. [48], one should mention that they considered matrices with components 0 or 1, in which case $\omega = 1$!

Following Byrne [8], the block-iterative version of (253) is as follows. In the partitioned data setup of (223), the BI-MART algorithm is

$$x_p^{[k+1]} = x_p^{[k]} \cdot \exp \left(\frac{\omega_k}{\alpha_r} \left[A_r^T \log \left\{ \frac{B_r}{A_r x^{[k]}} \right\} \right]_p \right) \quad (255)$$

for $p = 1, 2, \dots, \ell$, where

$$\alpha_r = \max \{\alpha_{rp} : 1 \leq p \leq \ell\} \quad (256)$$

is the maximal column sum of A_r . One would expect that $\omega_k = 1$ should be the optimal choice. This is the rescaled BI-MART (or RBI-MART) algorithm of Byrne [8]. Following the template of section ‘‘Minimum Cross-Entropy Problems,’’ one proves the following majorizing inequality and the two monotonicity properties. For nonnegative vectors y and $\omega > 0$, define $R_\omega y$ by

$$[R_\omega y]_p = y_p \exp\left(\frac{\omega}{\alpha_r} \left[A_r^T \log \left\{ \frac{B_r}{A_r y} \right\}\right]_p\right) \quad (257)$$

for $p = 1, 2, \dots, \ell$.

Lemma 21. *For all nonnegative x and y ,*

$$\text{KL}(A_r x, B_r) \leq \text{KL}(A_r y, B_r) + \frac{\alpha_r}{\omega} \{\text{KL}(x, R_\omega y) - \text{KL}(y, R_\omega y)\}.$$

Note that the minimizer of the right-hand side is $x = R_\omega y$. This would give rise to the algorithm (255).

Proof. Recall the identity from section ‘‘Minimum Cross-Entropy Problems,’’

$$\text{KL}(A_r x, B_r) = \text{KL}(A_r y, B_r) + \text{KL}(A_r x, A_r y) + \langle x - y, A_r^T \varrho \rangle,$$

with $\varrho_j = \log([A_r y]_j / [B_r]_j)$. Now, a convexity argument gives that

$$\text{KL}(A_r x, A_r y) \leq \alpha_r \text{KL}(x, y),$$

so that one gets the inequality

$$\text{KL}(A_r x, B_r) \leq \text{KL}(A_r y, B_r) + \alpha_r \text{KL}(x, y) + \langle x - y, A_r^T \varrho \rangle.$$

The definition of the operator R_ω gives that

$$\log \frac{[R_\omega y]_p}{y_p} = -\frac{\omega}{\alpha_r} A_r^T \varrho,$$

so then, with $\theta \equiv 1/\omega$,

$$\begin{aligned} & \alpha_r \text{KL}(x, y) + \langle x - y, A_r^T \varrho \rangle \\ &= \alpha_r \left\{ \text{KL}(x, y) - \theta \langle x - y, \log \frac{R_\omega y}{y} \rangle \right\} \\ &= \alpha_r \{(1 - \theta) \text{KL}(x, y) + \theta (\text{KL}(x, R_\omega y) - \text{KL}(y, R_\omega y))\}. \end{aligned}$$

The last line follows after some lengthy bookkeeping. So, for $\theta \leq 1$ or $\omega \geq 1$, the conclusion follows. ■

The first monotonicity property then follows.

Lemma 22. *For $\omega \geq 1$ and $r = k \bmod s$,*

$$\text{KL}(A_r x^{[k]}, B_r) - \text{KL}(A_r x^{[k+1]}, B_r) \geq \frac{\alpha_r}{\omega} \text{KL}(x^{[k]}, x^{[k+1]}) \geq 0.$$

The second monotonicity property follows after some work (omitted).

Lemma 23. *If $x^* \geq 0$ satisfies $Ax^* = b$, then for all k and $r = k \bmod s$,*

$$\text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) \geq \frac{\omega}{\alpha_r} \text{KL}(A_r x^{[k+1]}, B_r) \geq 0. \quad (258)$$

Now, regardless of whether $\omega = 1$ maximizes the right-hand side of the inequality (258), the presence of the factor α_r , which should be small if the original matrix A has unit column sums, suggests that the choice $\omega = 1$ in (258) is a tremendous improvement over the case $\omega = \alpha_r$, which would arise if one ignored the non-unit column sums of A_r .

Row-Action and Block-Iterative EM Algorithms

Attention now turns to the construction of the row-action version of the EM algorithm and the associated block-iterative versions. Recall the formulation (130) of the maximum likelihood problem for the PET problem as

$$\text{minimize } \text{KL}(b, Ax) \quad \text{subject to } x \in V_\ell, \quad (259)$$

with $b \in \mathbb{R}^m$ and $A \in \mathbb{R}^{m \times \ell}$ nonnegative, with A having unit column sums.

Now, construct a row-action version by considering the following iterative projection method, where the new iterate $x^{[k+1]}$ is obtained by projecting the previous iterate $x^{[k]}$ onto the hyperplane $\langle a(j, \cdot), x \rangle = b_j$. The particular projection is obtained by

$$\text{minimize } \text{KL}(x^{[k]}, x) \quad \text{subject to } \langle a(j, \cdot), x \rangle = b_j. \quad (260)$$

Again, with λ , an unrestricted Lagrange multiplier, one must solve the equations $-x_p^{[k]}/x_p + 1 + \lambda a(j, p) = 0$, or

$$x_p = x_p^{[k]} - \lambda a(j, p) x_p, \quad p = 1, 2, \dots, \ell. \quad (261)$$

At this point, one must make the simplification where x_p on the right-hand side is replaced by $x_p^{[k]}$. This gives the equation

$$x_p = x_p^{[k]} - \lambda a(j, p) x_p^{[k]}, \quad p = 1, 2, \dots, \ell.$$

To enforce the constraint, multiply by $a(j, p)$ and sum over p . Then,

$$b_j = \langle a(j, \cdot), x^{[k]} \rangle - \lambda \sum_{p=1}^{\ell} a(j, p)^2 x_p^{[k]} = (1 - \lambda \theta) \langle a(j, \cdot), x^{[k]} \rangle. \quad (262)$$

where in the last line the mean value theorem was used, for some θ satisfying

$$0 < \theta < \max \{a(j, p) : 1 \leq p \leq \ell\}. \quad (263)$$

Solving for λ gives the iterative step

$$x^{[k+1]} = (1 - \omega a(j, p)) x_p^{[k]} + \omega x_p^{[k]} \frac{a(j, p) b_j}{\langle a(j, \cdot), x^{[k]} \rangle}, \quad (264)$$

for $p = 1, 2, \dots, \ell$, where $\omega \equiv 1/\theta$. In the notation of (223), with some imagination, the block-iterative version is then

$$x^{[k+1]} = R_{\omega,r} x^{[k]}, \quad (265)$$

where the operators $R_{\omega,r}$ are defined by

$$[R_{\omega,r} x]_p = \left(1 - \omega \alpha_{rp}\right) x_p + \omega x_p \left[A_r^T (B_r / A_r x)\right]_p, \quad (266)$$

for $p = 1, 2, \dots, \ell$. So now, ω is considered to be a relaxation parameter.

The algorithm (266) was obtained by Byrne [8, 9] after carefully examining the analogy with MART vs. RBI-SMART. His choice for the relaxation parameter ω is to take it depending on the block, so $\omega = \omega_r$ with

$$\omega_r = \frac{1}{\max_{1 \leq p \leq \ell} \alpha_{rp}}, \quad (267)$$

which he obtained by deriving the two monotonicity properties discussed below. Byrne [8, 9] designated the resulting algorithm (266)–(267) as rescaled block-iterative EM for maximum likelihood algorithm (RBI-EMML). At about the same time, Browne and De Pierro [5] discovered the algorithm (264)–(266). They named (264) the RAMLA (row-action maximum likelihood algorithm). For the latest on this, see [92].

The above considerations strongly suggest that algorithm (266)–(267) is the correct one. This is corroborated by practical experience. The following monotonicity properties lend even more weight to it. A slight drawback is that they require that the system $Ax = b$ has a nonnegative solution. The first item is again a majorizing

inequality. Note that the majorizing inequality is suggested by the algorithm, not the other way around. Define

$$\text{BI}_r(x, y) \stackrel{\text{def}}{=} \omega L_r(x) + \sum_{p=1}^{\ell} (1 - \omega \alpha_{rp}) \left\{ x_p \log \frac{x_p}{y_p} + y_p - x_p \right\}. \quad (268)$$

Lemma 24. *For nonnegative $x, y \in \mathbb{R}^{\ell}$,*

$$\text{BI}_r(x, y) \leq \text{BI}_r(y, y) + \text{KL}(R_{\omega} y, x) - \text{KL}(R_{\omega} y, y),$$

provided $\omega \leq 1/\max\{\alpha_{rp} : 1 \leq p \leq \ell\}$.

Proof. Apply Lemma 1 to $\omega \{\text{KL}(B_r, A_r x) - \text{KL}(B_r, A_r y)\}$. Also observe that

$$\sum_q [A_r x]_q = \sum_{p=1}^{\ell} \alpha_{rp} x_p,$$

and likewise for $[A_r y]_q$. This gives

$$\text{BI}_r(x, y) \leq \text{BI}_r(y, y) + \sum_{p=1}^{\ell} [R_{\omega} y]_p \log \frac{y_p}{x_p} + x_p - y_p,$$

and the lemma follows. Note that the condition on ω is used implicitly to assure that $R_{\omega,r} y$ is nonnegative. \blacksquare

The first monotonicity property is an easy consequence.

Lemma 25. *For $r = k \bmod s$ and $\omega \leq 1/\max\{\alpha_{rp} : 1 \leq p \leq \ell\}$,*

$$L_r(x^{[k]}) - L_r(x^{[k+1]}) \geq \omega^{-1} \text{KL}(x^{[k+1]}, x^{[k]}) \geq 0$$

Proof. Take $y = x^{[k]}$ and $x = R_{\omega} y = R_{\omega} x^{[k]} = x^{[k+1]}$. Then, one gets $\text{BI}(x^{[k+1]}, x^{[k]}) - \text{BI}(x^{[k]}, x^{[k]}) \leq -\text{KL}(x^{[k+1]}, x^{[k]})$, so that

$$\omega (L_r(x^{[k]}) - L_r(x^{[k+1]})) \geq \sum_{p=1}^{\ell} (2 - \omega \alpha_{rp}) \left\{ x_p \log \frac{x_p}{y_p} + y_p - x_p \right\}.$$

Since $\omega \alpha_{rp} \leq 1$, the conclusion follows. \blacksquare

The second monotonicity property reads as follows.

Lemma 26. If $x^* \geq 0$ satisfies $Ax^* = b$, then with $r = k \bmod s$,

$$\text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) \geq \omega \{L_r(x^{[k]}) - L_r(x^*)\},$$

provided $\omega \leq 1 / \max\{\alpha_{rp} : 1 \leq p \leq \ell\}$.

The lemma suggests that one should take ω as large as possible. This is how Byrne [9] arrived at the choice (267).

Proof of Lemma 26. Since x^* satisfies $Ax^* = b$, so $A_r x^* = B_r$ for all r , the proof is actually simpler than for the original proof for the EM algorithm; see section ‘‘Monotonicity of the Shepp–Vardi EM Algorithm.’’ By the concavity of the logarithm (twice), one obtains

$$\begin{aligned} \log \frac{x_p^{[k+1]}}{x_p^{[k]}} &= \log \left((1 - \omega \alpha_{rp}) + \omega \left[A_r \left\{ \frac{B_r}{A_r x^{[k]}} \right\} \right]_p \right) \\ &\geq \omega \alpha_{rp} \log \left(\alpha_{rp}^{-1} \left[A_r \left\{ \frac{B_r}{A_r x^{[k]}} \right\} \right]_p \right) \geq \omega \left[A_r^T \log \left\{ \frac{B_r}{A_r x^{[k]}} \right\} \right]_p, \end{aligned}$$

so that

$$\begin{aligned} \text{KL}(x^*, x^{[k]}) - \text{KL}(x^*, x^{[k+1]}) &\geq \omega \sum_{p=1}^{\ell} x_p^* [A_r^T \log(B_r / A_r x^{[k]})]_p \\ &\quad + \sum_{p=1}^{\ell} x_p^{[k]} - x_p^{[k+1]}. \end{aligned}$$

Now, the first sum equals

$$\sum_q [A_r x^*]_q \log([B_r]_q / [A_r x^{[k]}]_q) = \sum_q [B_r]_q \log([B_r]_q / [A_r x^{[k]}]_q).$$

For the remaining sums, note that

$$\begin{aligned} \sum_{p=1}^{\ell} x_p^{[k+1]} &= \sum_{p=1}^{\ell} (1 - \omega \alpha_{rp}) x_p^{[k]} + \omega x_p^{[k]} [A_r^T (B_r / A_r x^{[k]})]_p \\ &= \sum_{p=1}^{\ell} x_p^{[k]} - \omega \sum_q [A_r x^{[k]}]_q + \omega \sum_q [B_r]_q. \end{aligned}$$

Putting the two together proves the lemma. ■

Remark 5. To wrap things up, note that Byrne [9] shows the convergence (in the consistent case) of a somewhat different version of (266), which, under the subset-separability condition (229), reduces to the OSEM algorithm (224), thus proving the convergence of OSEM under subset-separability (in the consistent case). See also Corollary 1.

Abstract

The EM algorithm is not a single algorithm, but a template for the construction of iterative algorithms. While it is always presented in stochastic language, relying on conditional expectations to obtain a method for estimating parameters in statistics, the essence of the EM algorithm is not stochastic. The conventional formulation of the EM algorithm given in many texts and papers on the subject is inadequate. A new formulation is given here based on the notion of acceptable data.

1 Introduction

The “expectation maximization” (EM) algorithm is a general framework for maximizing the likelihood function in statistical parameter estimation [1–3]. It is always presented in probabilistic terms, involving the maximization of a conditional expected value. The EM algorithm is not really a single algorithm, but a framework for the design of iterative likelihood maximization methods, or, as the authors of [4] put it, a “prescription for constructing an algorithm”; nevertheless, we shall continue to refer to the EM algorithm. As we shall demonstrate in Sect. 2, the essence of the EM algorithm is not stochastic. Our non-stochastic EM (NSEM) is a general approach for function maximization that has the stochastic EM methods as particular cases.

Maximizing the likelihood function is a well-studied procedure for estimating parameters from observed data. When a maximizer cannot be obtained in closed form, iterative maximization algorithms, such as the expectation maximization (EM) maximum likelihood algorithms, are needed. The standard formulation of the EM algorithms postulates that finding a maximizer of the likelihood is

complicated because the observed data is somehow incomplete or deficient, and the maximization would have been simpler had we observed the complete data. The EM algorithm involves repeated calculations involving complete data that has been estimated using the current parameter value and conditional expectation.

The standard formulation is adequate for the most common discrete case, in which the random variables involved are governed by finite or infinite probability functions, but unsatisfactory in general, particularly in the continuous case, in which probability density functions and integrals are needed.

We adopt the view that the observed data is not necessarily incomplete, but just difficult to work with, while different data, which we call the preferred data, leads to simpler calculations. To relate the preferred data to the observed data, we assume that the preferred data is *acceptable*, which means that the conditional distribution of the preferred data, given the observed data, is independent of the parameter. This extension of the EM algorithms contains the usual formulation for the discrete case, while removing the difficulties associated with the continuous case. Examples are given to illustrate this new approach.

2 A Non-stochastic Formulation of EM

The essence of the EM algorithm is not stochastic and leads to a general approach for function maximization, which we call the “non-stochastic,” EM algorithm (NSEM) [6]. In addition to being more general, this new approach also simplifies much of the development of the EM algorithm itself.

The Non-stochastic EM Algorithm

We present now the essential aspects of the EM algorithm without relying on statistical concepts. We shall use these results later to establish important facts about the statistical EM algorithm. For a broader treatment of the EM algorithm in the context of iterative optimization, see [5].

The Continuous Case

The problem is to maximize a nonnegative function $f : Z \rightarrow \mathbb{R}$, where Z is an arbitrary set. We assume that there is $z^* \in Z$ with $f(z^*) \geq f(z)$, for all $z \in Z$. We also assume that there is a nonnegative function $b : \mathbb{R}^N \times Z \rightarrow \mathbb{R}$ such that

$$f(z) = \int b(x, z) dx.$$

Having found z^k , we maximize the function

$$H(z^k, z) = \int b(x, z^k) \log b(x, z) dx \quad (1)$$

to get z^{k+1} . Adopting such an iterative approach presupposes that maximizing $H(z^k, z)$ is simpler than maximizing $f(z)$ itself. This is the case with the EM algorithm.

The cross-entropy or Kullback-Leibler distance [7] is a useful tool for analyzing the EM algorithm. For positive numbers u and v , the Kullback-Leibler distance from u to v is

$$KL(u, v) = u \log \frac{u}{v} + v - u. \quad (2)$$

We also define $KL(0, 0) = 0$, $KL(0, v) = v$, and $KL(u, 0) = +\infty$. The KL distance is extended to nonnegative vectors component-wise, so that for nonnegative vectors a and b , we have

$$KL(a, b) = \sum_{j=1}^J KL(a_j, b_j). \quad (3)$$

One of the most useful and easily proved facts about the KL distance is contained in the following lemma; we simplify the notation by setting $b(z) = b(x, z)$.

Lemma 1. *For nonnegative vectors a and b , with $b_+ = \sum_{j=1}^J b_j > 0$, we have*

$$KL(a, b) = KL(a_+, b_+) + KL(a, \frac{a_+}{b_+} b). \quad (4)$$

This lemma can be extended to obtain the following useful identity.

Lemma 2. *For $f(z)$ and $b(x, z)$ as above, and z and w in Z , with $f(w) > 0$, we have*

$$KL(b(z), b(w)) = KL(f(z), f(w)) + KL(b(z), (f(z)/f(w))b(w)). \quad (5)$$

Maximizing $H(z^k, z)$ is equivalent to minimizing

$$G(z^k, z) = KL(b(z^k), b(z)) - f(z), \quad (6)$$

where

$$KL(b(z^k), b(z)) = \int KL(b(x, z^k), b(x, z))dx. \quad (7)$$

Therefore,

$$-f(z^k) = KL(b(z^k), b(z^k)) - f(z^k) \geq KL(b(z^k), b(z^{k+1})) - f(z^{k+1}),$$

or

$$f(z^{k+1}) - f(z^k) \geq KL(b(z^k), b(z^{k+1})) \geq KL(f(z^k), f(z^{k+1})).$$

Consequently, the sequence $\{f(z^k)\}$ is increasing and bounded above, so that the sequence $\{KL(b(z^k), b(z^{k+1}))\}$ converges to zero. Without additional restrictions, we cannot conclude that $\{f(z^k)\}$ converges to $f(z^*)$.

We get z^{k+1} by minimizing $G(z^k, z)$. When we minimize $G(z, z^{k+1})$, we get z^{k+1} again. Therefore, we can put the NSEM algorithm into the alternating-minimization (AM) framework of Csiszár and Tusnády [12], to be discussed further Sect. 11.

The Discrete Case

Again, the problem is to maximize a nonnegative function $f : Z \rightarrow \mathbb{R}$, where Z is an arbitrary set. As previously, we assume that there is $z^* \in Z$ with $f(z^*) \geq f(z)$, for all $z \in Z$. We also assume that there is a finite or countably infinite set B and a nonnegative function $b : B \times Z \rightarrow \mathbb{R}$ such that

$$f(z) = \sum_{x \in B} b(x, z).$$

Having found z^k , we maximize the function

$$H(z^k, z) = \sum_{x \in B} b(x, z^k) \log b(x, z) \quad (8)$$

to get z^{k+1} .

We set $b(z) = b(x, z)$ again. Maximizing $H(z^k, z)$ is equivalent to minimizing

$$G(z^k, z) = KL(b(z^k), b(z)) - f(z), \quad (9)$$

where

$$KL(b(z^k), b(z)) = \sum_{x \in B} KL(b(x, z^k), b(x, z)). \quad (10)$$

As previously, we find that the sequence $\{f(z^k)\}$ is increasing, and $\{KL(b(z^k), b(z^{k+1}))\}$ converges to zero. Without additional restrictions, we cannot conclude that $\{f(z^k)\}$ converges to $f(z^*)$.

3 The Stochastic EM Algorithm

The E-Step and M-Step

In statistical parameter estimation, one typically has an *observable* random vector Y taking values in \mathbb{R}^N that is governed by a probability density function (pdf) or probability function (pf) of the form $f_Y(y|\theta)$, for some value of the parameter vector

$\theta \in \Theta$, where Θ is the set of all legitimate values of θ . Our *observed* data consists of one realization y of Y ; we do not exclude the possibility that the entries of y are independently obtained samples of a common real-valued random variable. The true vector of parameters is to be estimated by maximizing the likelihood function $L_y(\theta) = f_Y(y|\theta)$ over all $\theta \in \Theta$ to obtain a maximum likelihood estimate, θ_{ML} .

To employ the EM algorithmic approach, it is assumed that there is another related random vector X , which we shall call the *preferred* data, such that, had we been able to obtain one realization x of X , maximizing the likelihood function $L_x(\theta) = f_X(x|\theta)$ would have been simpler than maximizing the likelihood function $L_y(\theta) = f_Y(y|\theta)$. Of course, we do not have a realization x of X . The basic idea of the EM approach is to estimate x using the current estimate of θ , denoted θ^k , and to use each estimate x^k of x to get the next estimate θ^{k+1} .

The EM algorithm proceeds in two steps. Having selected the preferred data X , and having found θ^k , we form the function of θ given by

$$Q(\theta|\theta^k) = E(\log f_X(x|\theta)|y, \theta^k); \quad (11)$$

this is the E-step of the EM algorithm. Then we maximize $Q(\theta|\theta^k)$ over all θ to get θ^{k+1} ; this is the M-step of the EM algorithm. In this way, the EM algorithm based on X generates a sequence $\{\theta^k\}$ of parameter vectors.

For the discrete case of probability functions, we have

$$Q(\theta|\theta^k) = \sum_x f_{X|Y}(x|y, \theta^k) \log f_X(x|\theta), \quad (12)$$

and for the continuous case of probability density functions, we have

$$Q(\theta|\theta^k) = \int f_{X|Y}(x|y, \theta^k) \log f_X(x|\theta) dx. \quad (13)$$

In decreasing order of importance and difficulty, the goals are these:

1. To have the sequence of parameters $\{\theta^k\}$ converging to θ_{ML} ;
2. To have the sequence of functions $\{f_X(x|\theta^k)\}$ converging to $f_X(x|\theta_{ML})$;
3. To have the sequence of numbers $\{L_y(\theta^k)\}$ converging to $L_y(\theta_{ML})$;
4. To have the sequence of numbers $\{L_y(\theta^k)\}$ non-decreasing.

Our focus here is mainly on the fourth goal, with some discussion of the third goal. We do present some examples for which all four goals are attained. Clearly, the first goal requires a topology on the set Θ .

Difficulties with the Conventional Formulation

In [1] we are told that

$$f_{X|Y}(x|y, \theta) = f_X(x|\theta)/f_Y(y|\theta). \quad (14)$$

This is false; integrating with respect to x gives one on the left side and $1/f_Y(y|\theta)$ on the right side. Perhaps the equation is not meant to hold for all x , but just for some x . In fact, if there is a function h such that $Y = h(X)$, then Eq.(14) might hold for those x such that $h(x) = y$. In fact, this is what happens in the discrete case of probabilities; in that case we do have

$$f_Y(y|\theta) = \sum_{x \in h^{-1}\{y\}} f_X(x|\theta), \quad (15)$$

where

$$h^{-1}\{y\} = \{x|h(x) = y\}.$$

Consequently,

$$f_{X|Y}(x|y, \theta) = \begin{cases} f_X(x|\theta)/f_Y(y|\theta), & \text{if } x \in h^{-1}\{y\}; \\ 0, & \text{if } x \notin h^{-1}\{y\}. \end{cases} \quad (16)$$

However, this modification of Eq.(14) fails in the continuous case of probability density functions, since $h^{-1}\{y\}$ is often a subset of zero measure. Even if the set $h^{-1}\{y\}$ has positive measure, integrating both sides of Eq.(14) over $x \in h^{-1}\{y\}$ tells us that $f_Y(y|\theta) \leq 1$, which need not hold for probability density functions.

An Incorrect Proof

Everyone who works with the EM algorithm will say that the likelihood is non-decreasing for the EM algorithm. The proof of this fact usually proceeds as follows; we use the notation for the continuous case, but the proof for the discrete case is essentially the same. Use Eq.(14) to get

$$\log f_X(x|\theta) = \log f_{X|Y}(x|y, \theta) - \log f_Y(y|\theta). \quad (17)$$

Then replace the term $\log f_X(x|\theta)$ in Eq.(13) with the right side of Eq.(17), obtaining

$$\log f_Y(y|\theta) - Q(\theta|\theta^k) = - \int f_{X|Y}(x|y, \theta^k) \log f_{X|Y}(x|y, \theta) dx. \quad (18)$$

Jensen's Inequality tells us that

$$\int u(x) \log u(x) dx \geq \int u(x) \log v(x) dx, \quad (19)$$

for any probability density functions $u(x)$ and $v(x)$. Since $f_{X|Y}(x|y, \theta)$ is a probability density function, we have

$$\int f_{X|Y}(x|y, \theta^k) \log f_{X|Y}(x|y, \theta) dx \leq \int f_{X|Y}(x|y, \theta^k) \log f_{X|Y}(x|y, \theta^k) dx. \quad (20)$$

We conclude, therefore, that $\log f_Y(y|\theta) - Q(\theta|\theta^k)$ attains its minimum value at $\theta = \theta^k$. Then we have

$$\log f_Y(y|\theta^{k+1}) - \log f_Y(y|\theta^k) \geq Q(\theta^{k+1}|\theta^k) - Q(\theta^k|\theta^k) \geq 0. \quad (21)$$

This proof is incorrect; clearly it rests on the validity of Eq. (14), which is generally false. For the discrete case, with $Y = h(X)$, this proof is valid, when we use Eq. (16), instead of Eq. (14). In all other cases, however, the proof is incorrect.

Acceptable Data

We turn now to the question of how to repair the incorrect proof. Equation (14) should read

$$f_{X|Y}(x|y, \theta) = f_{X,Y}(x, y|\theta)/f_Y(y|\theta), \quad (22)$$

for all x . In order to replace $\log f_X(x|\theta)$ in Eq. (13), we write

$$f_{X,Y}(x, y|\theta) = f_{X|Y}(x|y, \theta) f_Y(y|\theta), \quad (23)$$

and

$$f_{X,Y}(x, y|\theta) = f_{Y|X}(y|x, \theta) f_X(x|\theta), \quad (24)$$

so that

$$\log f_X(x|\theta) = \log f_{X|Y}(x|y, \theta) + \log f_Y(y|\theta) - \log f_{Y|X}(y|x, \theta). \quad (25)$$

We say that the preferred data is *acceptable* if

$$f_{Y|X}(y|x, \theta) = f_{Y|X}(y|x); \quad (26)$$

that is, the dependence of Y on X is unrelated to the value of the parameter θ . This definition provides our generalization of the relationship $Y = h(X)$.

When X is acceptable, we have that $\log f_Y(y|\theta) - Q(\theta|\theta^k)$ again attains its minimum value at $\theta = \theta^k$. The assertion that the likelihood is non-decreasing then follows, using the same argument as in the previous incorrect proof.

4 The Discrete Case

In the discrete case, we assume that Y is a discrete random vector taking values in a finite or countably infinite set A , and governed by probability $f_Y(y|\theta)$. We assume, in addition, that there is a second discrete random vector X , taking values in a finite or countably infinite set B , and a function $h : B \rightarrow A$ such that $Y = h(X)$. We define the set

$$h^{-1}\{y\} = \{x \in B | h(x) = y\}. \quad (27)$$

Then we have

$$f_Y(y|\theta) = \sum_{x \in h^{-1}\{y\}} f_X(x|\theta). \quad (28)$$

The conditional probability function for X , given $Y = y$, is

$$f_{X|Y}(x|y, \theta) = \frac{f_X(x|\theta)}{f_Y(y|\theta)}, \quad (29)$$

for $x \in h^{-1}\{y\}$, and zero, otherwise. The so-called E-step of the EM algorithm is then to calculate

$$Q(\theta|\theta^k) = E((\log f_X(X|\theta)|y, \theta^k)) = \sum_{x \in h^{-1}\{y\}} f_{X|Y}(x|y, \theta^k) \log f_X(x|\theta), \quad (30)$$

and the M-step is to maximize $Q(\theta|\theta^k)$ as a function of θ to obtain θ^{k+1} .

Using Eq. (29), we can write

$$Q(\theta|\theta^k) = \sum_{x \in h^{-1}\{y\}} f_{X|Y}(x|y, \theta^k) \log f_{X|Y}(x|y, \theta) + \log f_Y(y|\theta). \quad (31)$$

Therefore,

$$\log f_Y(y|\theta) - Q(\theta|\theta^k) = - \sum_{x \in h^{-1}\{y\}} f_{X|Y}(x|y, \theta^k) \log f_{X|Y}(x|y, \theta).$$

Since

$$\sum_{x \in h^{-1}\{y\}} f_{X|Y}(x|y, \theta^k) = \sum_{x \in h^{-1}\{y\}} f_{X|Y}(x|y, \theta) = 1,$$

it follows from Jensen's Inequality that

$$\begin{aligned}
& - \sum_{x \in h^{-1}\{y\}} f_{X|Y}(x|y, \theta^k) \log f_{X|Y}(x|y, \theta) \\
& \geq - \sum_{x \in h^{-1}\{y\}} f_{X|Y}(x|y, \theta^k) \log f_{X|Y}(x|y, \theta^k).
\end{aligned}$$

Therefore, $\log f_Y(y|\theta) - Q(\theta|\theta^k)$ attains its minimum at $\theta = \theta^k$. We have the following result.

Proposition 1. *The sequence $\{f_Y(y|\theta^k)\}$ is non-decreasing.*

Proof. We have

$$\log f_Y(y|\theta^{k+1}) - Q(\theta^{k+1}|\theta^k) \geq \log f_Y(y|\theta^k) - Q(\theta^k|\theta^k),$$

or

$$\log f_Y(y|\theta^{k+1}) - \log f_Y(y|\theta^k) \geq Q(\theta^{k+1}|\theta^k) - Q(\theta^k|\theta^k) \geq 0.$$

■

Let $\chi_{h^{-1}\{y\}}(x)$ be the characteristic function of the set $h^{-1}\{y\}$, that is,

$$\chi_{h^{-1}\{y\}}(x) = \begin{cases} 1, & \text{if } x \in h^{-1}\{y\}; \\ 0, & \text{if } x \notin h^{-1}\{y\}. \end{cases} \quad (32)$$

With the choices $z = \theta$, $f(z) = f_Y(y|\theta)$, and $b(z) = f_X(x|\theta)\chi_{h^{-1}\{y\}}(x)$, the discrete EM algorithm fits into the framework of the non-stochastic EM algorithm. Consequently, we see once again that the sequence $\{f_Y(y|\theta^k)\}$ is non-decreasing and also that the sequence

$$\{KL(b(z^k), b(z^{k+1}))\} = \left\{ \sum_{x \in h^{-1}\{y\}} (KL(f_X(x|\theta^k), f_X(x|\theta^{k+1}))) \right\}$$

converges to zero.

5 Missing Data

We say that there is *missing data* if the preferred data X has the form $X = (Y, W)$, so that $Y = h(X) = h(Y, W)$, where h is the orthogonal projection onto the first component. The case of missing data for the discrete case is covered by the discussion in Sect. 4, so we consider here the continuous case in which probability density functions are involved.

Once again, the E-step is to calculate $Q(\theta|\theta^k)$ given by

$$Q(\theta|\theta^k) = E(\log f_X(X|\theta)|y, \theta^k). \quad (33)$$

Since $X = (Y, W)$, we have

$$f_X(x|\theta) = f_{Y,W}(y, w|\theta). \quad (34)$$

Since the set $h^{-1}\{y\}$ has measure zero, we cannot write

$$Q(\theta|\theta^k) = \int_{h^{-1}\{y\}} f_{X|Y}(x|y, \theta^k) \log f_X(x|\theta) dx.$$

Instead, following [8], we write

$$Q(\theta|\theta^k) = \int f_{Y,W}(y, w|\theta^k) \log f_{Y,W}(y, w|\theta) dw / f_Y(y|\theta^k). \quad (35)$$

Consequently, maximizing $Q(\theta|\theta^k)$ is equivalent to maximizing

$$\int f_{Y,W}(y, w|\theta^k) \log f_{Y,W}(y, w|\theta) dw.$$

With $b(\theta) = b(\theta, w) = f_{Y,W}(y, w|\theta)$ and

$$f_Y(y|\theta) = f(\theta) = \int f_{Y,W}(y, w|\theta) dw = \int b(\theta) dw,$$

we find that maximizing $Q(\theta|\theta^k)$ is equivalent to minimizing $KL(b(\theta^k), b(\theta)) - f(\theta)$. Therefore, the EM algorithm for the case of missing data falls into the framework of the non-stochastic EM algorithm. We conclude that the sequence $\{f(\theta^k)\}$ is non-decreasing and that the sequence $\{KL(b(\theta^k), b(\theta^{k+1}))\}$ converges to zero.

Most other instances of the continuous case in which we have $Y = h(X)$ can be handled using the missing-data model. For example, suppose that Z_1 and Z_2 are uniformly distributed on the interval $[0, \theta]$, for some positive θ and that $Y = Z_1 + Z_2$. We may, for example, then take W to be $W = Z_1 - Z_2$ and $X = (Y, W)$ as the preferred data. We shall discuss these instances further in Sect. 7.

6 The Continuous Case

We turn now to the general continuous case. We have a random vector Y taking values in \mathbb{R}^N and governed by the probability density function $f_Y(y|\theta)$. The objective, once again, is to maximize the likelihood function $L_y(\theta) = f_Y(y|\theta)$ to obtain the maximum likelihood estimate of θ .

Acceptable Preferred Data

For the continuous case, the vector θ^{k+1} is obtained from θ^k by maximizing the conditional expected value

$$Q(\theta|\theta^k) = E(\log f_X(X|\theta)|y, \theta^k) = \int f_{X|Y}(x|y, \theta^k) \log f_X(x|\theta) dx. \quad (36)$$

Assuming the acceptability condition and using

$$f_{X,Y}(x, y|\theta^k) = f_{X|Y}(x|y, \theta^k) f_Y(y|\theta^k),$$

and

$$\log f_X(x|\theta) = \log f_{X,Y}(x, y|\theta) - \log f_{Y|X}(y|x),$$

we find that maximizing $E(\log f_X(x|\theta)|y, \theta^k)$ is equivalent to minimizing

$$H(\theta^k, \theta) = \int f_{X,Y}(x, y|\theta^k) \log f_{X,Y}(x, y|\theta) dx. \quad (37)$$

With $f(\theta) = f_Y(y|\theta)$, and $b(\theta) = f_{X,Y}(x, y|\theta)$, this problem fits the framework of the non-stochastic EM algorithm and is equivalent to minimizing

$$G(\theta^k, \theta) = KL(b(\theta^k), b(\theta)) - f(\theta).$$

Once again, we may conclude that the likelihood function is non-decreasing and that the sequence $\{KL(b(\theta^k), b(\theta^{k+1}))\}$ converges to zero.

In the discrete case in which $Y = h(X)$, the conditional probability $f_{Y|X}(y|x, \theta)$ is $\delta(y - h(x))$, as a function of y , for given x , and is the characteristic function of the set $h^{-1}(y)$, as a function of x , for given y . Therefore, we can write $f_{X|Y}(x|y, \theta)$ using Eq. (16). For the continuous case in which $Y = h(X)$, the pdf $f_{Y|X}(y|x, \theta)$ is again a delta function of y , for given x ; the difficulty arises when we need to view this as a function of x , for given y . The acceptability property helps us avoid this difficulty.

When X is acceptable, we have

$$f_{X|Y}(x|y, \theta) = f_{Y|X}(y|x) f_X(x|\theta) / f_Y(y|\theta), \quad (38)$$

whenever $f_Y(y|\theta) \neq 0$, and is zero otherwise. Consequently, when X is acceptable, we have a kernel model for $f_Y(y|\theta)$ in terms of the $f_X(x|\theta)$:

$$f_Y(y|\theta) = \int f_{Y|X}(y|x) f_X(x|\theta) dx; \quad (39)$$

for the continuous case we view this as a corrected version of Eq. (15). In the discrete case the integral is replaced by a summation, of course, but when we are speaking generally about either case, we shall use the integral sign.

The acceptability of the missing data W is used in [9], but more for computational convenience and to involve the Kullback-Leibler distance in the formulation of the EM algorithm. It is not necessary that W be acceptable in order for likelihood to be non-decreasing, as we have seen.

Selecting Preferred Data

The popular example of multinomial data given below illustrates well the point that one can often choose to view the observed data as “incomplete” simply in order to introduce “complete” data that makes the calculations simpler, even when there is no suggestion, in the original problem, that the observed data is in any way inadequate or “incomplete.” It is in order to emphasize this desire for simplification that we refer to X as the preferred data, not the complete data.

In some applications, the preferred data X arises naturally from the problem, while in other cases the user must imagine preferred data. This choice in selecting the preferred data can be helpful in speeding up the algorithm (see [10]).

If, instead of maximizing

$$\int f_{X|Y}(x|y, \theta^k) \log f_X(x|\theta) dx,$$

at each M-step, we simply select θ^{k+1} so that

$$\begin{aligned} & \int f_{X|Y}(x|y, \theta^k) \log f_{X,Y}(x, y|\theta^{k+1}) dx \\ & - \int f_{X|Y}(x|y, \theta^k) \log f_{X,Y}(x, y|\theta^k) dx > 0, \end{aligned}$$

we say that we are using a *generalized* EM (GEM) algorithm. It is clear from the discussion in the previous subsection that whenever X is acceptable, a GEM also guarantees that likelihood is non-decreasing.

Preferred Data as Missing Data

As we have seen, when the EM algorithm is applied to the missing-data model, the likelihood is non-decreasing, which suggests that, for an arbitrary preferred data X , we could imagine X as W , the missing data, and imagine applying the EM algorithm to $Z = (Y, X)$. This approach would produce an EM sequence of parameter vectors for which likelihood is non-decreasing, but it need not be the

same sequence as obtained by applying the EM algorithm to X directly. It is the same sequence, provided that X is acceptable. We are not suggesting that applying the EM algorithm to $Z = (Y, X)$ would simplify calculations.

We know that, when the missing-data model is used and the M-step is defined as maximizing the function in (35), the likelihood is not decreasing. It would seem then that for any choice of preferred data X , we could view this data as missing and take as our complete data the pair $Z = (Y, X)$, with X now playing the role of W . Maximizing the function in (35) is then equivalent to maximizing

$$\int f_{X|Y}(x|y, \theta^k) \log f_{X,Y}(x, y|\theta) dx; \quad (40)$$

to get θ^{k+1} . It then follows that $L_y(\theta^{k+1}) \geq L_y(\theta^k)$. The obvious question is whether or not these two functions given in (11) and (40) have the same maximizers.

For acceptable X we have

$$\log f_{X,Y}(x, y|\theta) = \log f_X(x|\theta) + \log f_{Y|X}(y|x), \quad (41)$$

so the two functions given in (11) and (40) do have the same maximizers. It follows once again that whenever the preferred data is acceptable, we have $L_y(\theta^{k+1}) \geq L_y(\theta^k)$. Without additional assumptions, however, we cannot conclude that $\{\theta^k\}$ converges to θ_{ML} , nor that $\{f_Y(y|\theta^k)\}$ converges to $f_Y(y|\theta_{ML})$.

7 The Continuous Case with $Y = h(X)$

In this section we consider the continuous case in which the observed random vector Y takes values in \mathbb{R}^N ; the preferred random vector X takes values in \mathbb{R}^M ; the random vectors are governed by probability density functions $f_Y(y|\theta)$ and $f_X(x|\theta)$, respectively; and there is a function $h : \mathbb{R}^N \rightarrow \mathbb{R}^M$ such that $Y = h(X)$. In most cases, $M > N$ and $h^{-1}\{y\} = \{x|h(x) = y\}$ has measure zero in \mathbb{R}^M .

An Example

For example, suppose that Z_1 and Z_2 are independent and uniformly distributed on the interval $[0, \theta]$, for some $\theta > 0$ to be estimated. Let $Y = Z_1 + Z_2$. With $Z = (Z_1, Z_2)$, and $h : \mathbb{R}^2 \rightarrow \mathbb{R}$ given by $h(z_1, z_2) = z_1 + z_2$, we have $Y = h(Z)$. The pdf for Z is

$$f_Z(z|\theta) = f_Z(z_1, z_2|\theta) = \frac{1}{\theta^2} \chi_{[0,\theta]}(z_1) \chi_{[0,\theta]}(z_2). \quad (42)$$

The pdf for Y is

$$f_Y(y|\theta) = \begin{cases} \frac{y}{\theta^2}, & \text{if } 0 \leq y \leq \theta; \\ \frac{2\theta-y}{\theta^2}, & \text{if } \theta \leq y \leq 2\theta. \end{cases} \quad (43)$$

It is not the case that

$$f_Y(y|\theta) = \int_{h^{-1}\{y\}} f_Z(z|\theta), \quad (44)$$

since $h^{-1}\{y\}$ has measure zero in \mathbb{R}^2 .

The likelihood function is $L(\theta) = f_Y(y|\theta)$, viewed as a function of θ , and is given by

$$L(\theta) = \begin{cases} \frac{y}{\theta^2}, & \text{if } \theta \geq y; \\ \frac{2\theta-y}{\theta^2}, & \text{if } \frac{y}{2} \leq \theta \leq y. \end{cases} \quad (45)$$

Therefore, the maximum likelihood estimate of θ is $\theta_{ML} = y$.

Instead of using Z as our preferred data, suppose that we define the random variable $W = Z_2$, and let $X = (Y, W)$, a missing-data model. We then have $Y = h(X)$, where $h : \mathbb{R}^2 \rightarrow \mathbb{R}$ is given by $h(x) = h(y, w) = y$. The pdf for Y given in Eq. (43) can be written as

$$f_Y(y|\theta) = \int \frac{1}{\theta^2} \chi_{[0,\theta]}(y-w) \chi_{[0,\theta]}(w) dw. \quad (46)$$

The joint pdf is

$$f_{Y,W}(y, w|\theta) = \begin{cases} 1/\theta^2, & \text{for } w \leq y \leq \theta + w; \\ 0, & \text{otherwise.} \end{cases} \quad (47)$$

Censored Exponential Data

McLachlan and Krishnan [1] give the following example of a likelihood maximization problem involving probability density functions. This example provides a good illustration of the usefulness of the missing-data model.

Suppose that Z is the time until failure of a component, which we assume is governed by the exponential distribution

$$f(z|\theta) = \frac{1}{\theta} e^{-z/\theta}, \quad (48)$$

where the parameter $\theta > 0$ is the expected time until failure. We observe a random sample of N components and record their failure times, z_n . On the basis of this data, we must estimate θ , the mean time until failure.

It may well happen, however, that during the time allotted for observing the components, only r of the N components fail, which, for convenience, are taken to be the first r items in the record. Rather than wait longer, we record the failure times of those that failed and record the elapsed time for the experiment, say T , for those that had not yet failed. The *censored data* is then $y = (y_1, \dots, y_N)$, where $y_n = z_n$ is the time until failure for $n = 1, \dots, r$, and $y_n = T$ for $n = r+1, \dots, N$. The censored data is reasonably viewed as *incomplete*, relative to the *complete* data we would have had, had the trial lasted until all the components had failed.

Since the probability that a component will survive until time T is $e^{-T/\theta}$, the pdf for the vector y is

$$f_Y(y|\theta) = \left(\prod_{n=1}^r \frac{1}{\theta} e^{-y_n/\theta} \right) e^{-(N-r)T/\theta}, \quad (49)$$

and the log likelihood function for the censored, or incomplete, data is

$$\log f_Y(y|\theta) = -r \log \theta - \frac{1}{\theta} \sum_{n=1}^N y_n. \quad (50)$$

In this particular example, we are fortunate, in that we can maximize $f_Y(y|\theta)$ easily, and find that the ML solution based on the incomplete, censored data is

$$\theta_{MLi} = \frac{1}{r} \sum_{n=1}^N y_n = \frac{1}{r} \sum_{n=1}^r y_n + \frac{N-r}{r} T. \quad (51)$$

In most cases in which our data is incomplete, finding the ML estimate from the incomplete data is difficult, while finding it for the complete data is relatively easy.

We say that the missing data are the times until failure of those components that did not fail during the observation time. The preferred data is the complete data $x = (z_1, \dots, z_N)$ of actual times until failure. The pdf for the preferred data X is

$$f_X(x|\theta) = \prod_{n=1}^N \frac{1}{\theta} e^{-z_n/\theta}, \quad (52)$$

and the log likelihood function based on the complete data is

$$\log f_X(x|\theta) = -N \log \theta - \frac{1}{\theta} \sum_{n=1}^N z_n. \quad (53)$$

The ML estimate of θ from the complete data is easily seen to be

$$\theta_{MLc} = \frac{1}{N} \sum_{n=1}^N z_n. \quad (54)$$

In this example, both the incomplete-data vector y and the preferred-data vector x lie in \mathbb{R}^N . We have $y = h(x)$ where the function h operates by setting to T any component of x that exceeds T . Clearly, for a given y , the set $h^{-1}\{y\}$ consists of all vectors x with entries $x_n \geq T$ or $x_n = y_n < T$. For example, suppose that $N = 2$, and $y = (y_1, T)$, where $y_1 < T$. Then $h^{-1}\{y\}$ is the one-dimensional ray

$$h^{-1}\{y\} = \{x = (y_1, x_2) \mid x_2 \geq T\}.$$

Because this set has measure zero in \mathbb{R}^2 , Eq. (44) does not make sense in this case.

We need to calculate $E(\log f_X(X|\theta)|y, \theta^k)$. Following McLachlan and Krishnan [1], we note that since $\log f_X(x|\theta)$ is linear in the unobserved data Z_n , $n = r + 1, \dots, N$, to calculate $E(\log f_X(X|\theta)|y, \theta^k)$, we need only replace the unobserved values with their conditional expected values, given y and θ^k . The conditional distribution of $Z_n - T$, given that $Z_n > T$, is still exponential, with mean θ . Therefore, we replace the unobserved values, that is, all the Z_n for $n = r+1, \dots, N$, with $T + \theta^k$. Therefore, at the E-step we have

$$E(\log f_X(X|\theta)|y, \theta^k) = -N \log \theta - \frac{1}{\theta} \left(\left(\sum_{n=1}^N y_n \right) + (N-r)\theta^k \right). \quad (55)$$

The M-step is to maximize this function of θ , which leads to

$$\theta^{k+1} = \left(\left(\sum_{n=1}^N y_n \right) + (N-r)\theta^k \right) / N. \quad (56)$$

Let θ^* be a fixed point of this iteration. Then we have

$$\theta^* = \left(\left(\sum_{n=1}^N y_n \right) + (N-r)\theta^* \right) / N,$$

so that

$$\theta^* = \frac{1}{r} \sum_{n=1}^N y_n,$$

which, as we have seen, is the likelihood maximizer.

A More General Approach

Let X take values in \mathbb{R}^N and $Y = h(X)$ take values in \mathbb{R}^M , where $M < N$ and $h : \mathbb{R}^N \rightarrow \mathbb{R}^M$ is a (possibly) many-to-one function. Suppose that there is a second function $k : \mathbb{R}^N \rightarrow \mathbb{R}^{N-M}$ such that the function

$$G(x) = (h(x), k(x)) = (y, w) = u \quad (57)$$

has inverse $H(y, w) = x$. Denote by $J(y, w)$ the determinant of the Jacobian matrix associated with the transformation G . Let

$$\mathcal{W}(y) = \{w | w = k(x), \text{ and } y = h(x)\}.$$

Then

$$f_Y(y|\theta) = \int_{w \in \mathcal{W}(y)} f_X(H(y, w)) J(y, w) dw. \quad (58)$$

Then we apply the missing-data model for the EM algorithm, with $W = k(X)$ as the missing data.

8 A Multinomial Example

In many applications, the entries of the vector y are independent realizations of a single real-valued or vector-valued random variable V , as they are, at least initially, for finite mixture problems to be considered later. This is not always the case, however, as the following example shows.

A well-known example that was used in [11] and again in [1] to illustrate the EM algorithm concerns a multinomial model taken from genetics. Here there are four cells, with cell probabilities $\frac{1}{2} + \frac{1}{4}\theta_0$, $\frac{1}{4}(1 - \theta_0)$, $\frac{1}{4}(1 - \theta_0)$, and $\frac{1}{4}\theta_0$, for some $\theta_0 \in \Theta = [0, 1]$ to be estimated. The entries of y are the frequencies from a sample size of 197. We then have

$$f_Y(y|\theta) = \frac{197!}{y_1!y_2!y_3!y_4!} \left(\frac{1}{2} + \frac{1}{4}\theta_0\right)^{y_1} \left(\frac{1}{4}(1 - \theta_0)\right)^{y_2} \left(\frac{1}{4}(1 - \theta_0)\right)^{y_3} \left(\frac{1}{4}\theta_0\right)^{y_4}. \quad (59)$$

It is then supposed that the first of the original four cells can be split into two subcells, with probabilities $\frac{1}{2}$ and $\frac{1}{4}\theta_0$. We then write $y_1 = y_{11} + y_{12}$, and let

$$X = (Y_{11}, Y_{12}, Y_2, Y_3, Y_4), \quad (60)$$

where X has a multinomial distribution with five cells. Note that we do now have $Y = h(X)$.

This example is a popular one in the literature on the EM algorithm (see [11] for citations). It is never suggested that the splitting of the first group into two subgroups is motivated by the demands of the genetics theory itself. As stated in [1], the motivation for the splitting is to allow us to view the two random variables $Y_{12} + Y_4$ and $Y_2 + Y_3$ as governed by a binomial distribution; that is, we can view the value of $y_{12} + y_4$ as the number of heads and the value $y_2 + y_3$ as the number of tails that occur in the flipping of a biased coin $y_{12} + y_4 + y_2 + y_3$ times. This simplifies the calculation of the likelihood maximizer.

9 The Example of Finite Mixtures

We say that a random vector V taking values in \mathbb{R}^D is a *finite mixture* if, for $j = 1, \dots, J$, f_j is a probability density function or probability function, $\theta_j \geq 0$ is a weight, the θ_j sum to one, and the probability density function or probability function for V is

$$f_V(v|\theta) = \sum_{j=1}^J \theta_j f_j(v). \quad (61)$$

The value of D is unimportant, and for simplicity, we shall assume that $D = 1$.

We draw N independent samples of V , denoted v_n , and let y_n , the n th entry of the vector y , be the number v_n . To create the preferred data we assume that for each n , the number v_n is a sample of the random variable V_n whose pdf or pf is f_{j_n} , where the probability that $j_n = j$ is θ_j . We then let the N entries of the preferred data X be the indices j_n . The conditional distribution of Y , given X , is clearly independent of the parameter vector θ and is given by

$$f_{Y|X}(y|x, \theta) = \prod_{n=1}^N f_{j_n}(y_n);$$

therefore, X is acceptable. Note that we cannot recapture the entries of y from those of x , so the model $Y = h(X)$ does not hold here. Note also that although the vector y is taken originally to be a vector whose entries are independently drawn samples from V , when we create the preferred data X , we change our view of y . Now each entry of y is governed by a different distribution, so y is no longer viewed as a vector of independent sample values of a single random vector.

10 The EM and the Kullback-Leibler Distance

We illustrate the usefulness of acceptability and reformulate the M-step in terms of cross-entropy or Kullback-Leibler distance minimization.

Using Acceptable Data

The assumption that the data X is acceptable helps simplify the theoretical discussion of the EM algorithm.

For any preferred X the M-step of the EM algorithm, in the continuous case, is to maximize the function

$$\int f_{X|Y}(x|y, \theta^k) \log f_X(x|\theta) dx, \quad (62)$$

over $\theta \in \Theta$; the integral is replaced by a sum in the discrete case. For notational convenience we let

$$b(\theta^k) = f_{X|Y}(x|y, \theta^k), \quad (63)$$

and

$$f(\theta) = f_X(x|\theta); \quad (64)$$

both functions are functions of the vector variable x . Then the M-step is equivalent to minimizing the Kullback-Leibler or cross-entropy distance

$$\begin{aligned} KL(b(\theta^k), f(\theta)) &= \int f_{X|Y}(x|y, \theta^k) \log \left(\frac{f_{X|Y}(x|y, \theta^k)}{f_X(x|\theta)} \right) dx \\ &= \int f_{X|Y}(x|y, \theta^k) \log \left(\frac{f_{X|Y}(x|y, \theta^k)}{f_X(x|\theta)} \right) \\ &\quad + f_X(x|\theta) - f_{X|Y}(x|y, \theta^k) dx. \end{aligned} \quad (65)$$

This holds since both $f_X(x|\theta)$ and $f_{X|Y}(x|y, \theta^k)$ are probability density functions or probabilities.

For acceptable X we have

$$\begin{aligned} \log f_{X,Y}(x, y|\theta) &= \log f_{X|Y}(x|y, \theta) + \log f_Y(y|\theta) \\ &= \log f_{Y|X}(y|x) + \log f_X(x|\theta). \end{aligned} \quad (66)$$

Therefore,

$$\begin{aligned} \log f_Y(y|\theta^{k+1}) - \log f_Y(y|\theta^k) &= KL(b(\theta^k), f(\theta)) - KL(b(\theta^k), f(\theta^{k+1})) \\ &\quad + KL(b(\theta^k), b(\theta^{k+1})) - KL(b(\theta^k), b(\theta)). \end{aligned} \quad (67)$$

Since $\theta = \theta^{k+1}$ minimizes $KL(b(\theta^k), f(\theta))$, we have that

$$\begin{aligned} \log f_Y(y|\theta^{k+1}) - \log f_Y(y|\theta^k) &= KL(b(\theta^k), f(\theta^k)) \\ &\quad - KL(b(\theta^k), f(\theta^{k+1})) \\ &\quad + KL(b(\theta^k), b(\theta^{k+1})) \geq 0. \end{aligned} \quad (68)$$

This tells us, once again, that the sequence of likelihood values $\{\log f_Y(y|\theta^k)\}$ is increasing and that the sequence of its negatives, $\{-\log f_Y(y|\theta^k)\}$, is decreasing. Since we assume that there is a maximizer θ_{ML} of the likelihood, the sequence $\{-\log f_Y(y|\theta^k)\}$ is also bounded below and the sequences $\{KL(b(\theta^k), b(\theta^{k+1}))\}$ and $\{KL(b(\theta^k), f(\theta^k)) - KL(b(\theta^k), f(\theta^{k+1}))\}$ converge to zero.

Without some notion of convergence in the parameter space Θ , we cannot conclude that $\{\theta^k\}$ converges to a maximum likelihood estimate θ_{ML} . Without some additional assumptions, we cannot even conclude that the functions $f(\theta^k)$ converge to $f(\theta_{ML})$.

11 The Approach of Csiszár and Tusnády

For acceptable X the M-step of the EM algorithm is to minimize the function $KL(b(\theta^k), f(\theta))$ over $\theta \in \Theta$ to get θ^{k+1} . To put the EM algorithm into the framework of the *alternating-minimization* approach of Csiszár and Tusnády [12], we need to view the M-step in a slightly different way; the problem is that, for the continuous case, having found θ^{k+1} , we do not then minimize $KL(b(\theta), f(\theta^{k+1}))$ at the next step.

The Framework of Csiszár and Tusnády

Following [12], we take $\Psi(p, q)$ to be a real-valued function of the variables $p \in P$ and $q \in Q$, where P and Q are arbitrary sets. Minimizing $\Psi(p, q^n)$ gives p^n and minimizing $\Psi(p^n, q)$ gives q^{n+1} , so that

$$\Psi(p^n, q^n) \geq \Psi(p^n, q^{n+1}) \geq \Psi(p^{n+1}, q^{n+1}). \quad (69)$$

The objective is to find (\hat{p}, \hat{q}) such that

$$\Psi(p, q) \geq \Psi(\hat{p}, \hat{q}),$$

for all p and q . In order to show that $\{\Psi(p^n, q^n)\}$ converges to

$$d = \inf_{p \in P, q \in Q} \Psi(p, q)$$

the authors of [12] assume the three- and four-point properties.

If there is a nonnegative function $\Delta : P \times P \rightarrow \mathbb{R}$ such that

$$\Psi(p, q^{n+1}) - \Psi(p^{n+1}, q^{n+1}) \geq \Delta(p, p^{n+1}), \quad (70)$$

then the *three-point property* holds. If

$$\Delta(p, p^n) + \Psi(p, q) \geq \Psi(p, q^{n+1}), \quad (71)$$

for all p and q , then the *four-point property* holds. Combining these two inequalities, we have

$$\Delta(p, p^n) - \Delta(p, p^{n+1}) \geq \Psi(p^{n+1}, q^{n+1}) - \Psi(p, q). \quad (72)$$

From the inequality in (72) it follows easily that the sequence $\{\Psi(p^n, q^n)\}$ converges to d . Suppose this is not the case. Then there are p' , q' , and $D > d$ with

$$\Psi(p^n, q^n) \geq D > \Psi(p', q') \geq d.$$

From Eq. (72) we have

$$\Delta(p', p^n) - \Delta(p', p^{n+1}) \geq \Psi(p^{n+1}, q^{n+1}) - \Psi(p', q') \geq D - \Psi(p', q') > 0.$$

But since $\{\Delta(p', p^n)\}$ is a decreasing sequence of positive quantities, successive differences must converge to zero; that is, $\{\Psi(p^{n+1}, q^{n+1})\}$ must converge to $\Psi(p', q')$, which is a contradiction.

The *five-point property* of [12] is obtained by combining (70) and (71):

$$\Psi(p, q) + \Psi(p, q^{n-1}) \geq \Psi(p, q^n) + \Psi(p^n, q^{n-1}). \quad (73)$$

Note that the five-point property does not involve the second function $\Delta(p', p)$. However, assuming that the five-point property holds, it is possible to define $\Delta(p', p)$ so that both the three- and four-point properties hold. Assuming the five-point property, we have

$$\Psi(p, q^{n-1}) - \Psi(p, q^n) \geq \Psi(p^n, q^n) - \Psi(p, q), \quad (74)$$

from which we can show easily that $\{\Psi(p^n, q^n)\}$ converges to d .

Alternating Minimization for the EM Algorithm

Assume that X is acceptable. We define the function $F(\theta)$ to be

$$F(\theta) = \int f_{X|Y}(x|y, \theta) \log f_{Y|X}(y|x) dx, \quad (75)$$

for the continuous case, with a sum replacing the integral for the discrete case. Using the identities

$$\begin{aligned} f_{X,Y}(x, y|\theta) &= f_{X|Y}(x|y, \theta) f_Y(y|\theta) \\ &= f_{Y|X}(y|x, \theta) f_X(x|\theta) = f_{Y|X}(y|x) f_X(x|\theta), \end{aligned}$$

we then have

$$\log f_Y(y|\theta) = F(\theta') + KL(b(\theta'), b(\theta)) - KL(b(\theta'), f(\theta)), \quad (76)$$

for any parameter values θ and θ' . With the choice of $\theta' = \theta$, we have

$$\log f_Y(y|\theta) = F(\theta) - KL(b(\theta), f(\theta)). \quad (77)$$

Therefore, subtracting Eq. 77 from Eq. 76, we get

$$\begin{aligned} & (KL(b(\theta'), f(\theta)) - F(\theta')) - (KL(b(\theta), f(\theta)) - F(\theta)) \\ &= KL(b(\theta'), b(\theta)). \end{aligned} \quad (78)$$

Now we can put the EM algorithm into the alternating-minimization framework.

Define

$$\Psi(b(\theta'), f(\theta)) = KL(b(\theta'), f(\theta)) - F(\theta'). \quad (79)$$

We know from Eq. (78) that

$$\Psi(b(\theta'), f(\theta)) - \Psi(b(\theta), f(\theta)) = KL(b(\theta'), b(\theta)). \quad (80)$$

Therefore, we can say that the M-step of the EM algorithm is to minimize $\Psi(b(\theta^k), f(\theta))$ over $\theta \in \Theta$ to get θ^{k+1} and that minimizing $\Psi(b(\theta), f(\theta^{k+1}))$ gives us $\theta = \theta^{k+1}$ again. Because the EM algorithm can be viewed as an alternating minimization method, it is also a particular case of the sequential unconstrained minimization techniques [13] and of “optimization transfer,” [4].

With the choice of

$$\Delta(b(\theta'), b(\theta)) = KL(b(\theta'), b(\theta)),$$

Eq. (80) becomes

$$\Psi(b(\theta'), f(\theta)) - \Psi(b(\theta), f(\theta)) = \Delta(b(\theta'), b(\theta)), \quad (81)$$

which is the three-point property.

With $P = \mathcal{B}(\Theta)$ and $Q = \mathcal{F}(\Theta)$, the collections of all functions $b(\theta)$ and $f(\theta)$, respectively, we can view the EM algorithm as alternating minimization of the function $\Psi(p, q)$, over $p \in P$ and $q \in Q$. As we have seen, the three-point property holds. What about the four-point property?

The Kullback-Leibler distance is an example of a jointly convex Bregman distance. According to a lemma of Eggermont and LaRiccia [14, 15], the four-point property holds for alternating minimization of such distances, using $\Delta(p', p) = KL(p', p)$, provided that the sets P and Q are closed and convex subsets of \mathbb{R}^N . In the continuous case of the EM algorithm, we are not performing alternating minimization on the function $KL(b(\theta), f(\theta'))$, but on $KL(b(\theta), f(\theta')) + F(\theta)$. In the discrete case, whenever $Y = h(X)$, the function $F(\theta)$ is always zero, so we are performing alternating minimization on the KL distance $KL(b(\theta), f(\theta'))$. In [16] the authors consider the problem of minimizing a function of the form

$$\Lambda(p, q) = \phi(p) + \psi(q) + D_g(p, q), \quad (82)$$

where ϕ and ψ are convex and differentiable on \mathbb{R}^J , D_g is a Bregman distance, and $P = Q$ is the interior of the domain of g . In [13] it was shown that when D_g is jointly convex, the function $\Lambda(p, q)$ has the five-point property of [12], which is equivalent to the three- and four-point properties taken together. In some particular instances, the collection of the functions $f(\theta)$ is a convex subset of \mathbb{R}^J , as well, so the three- and four-point properties hold.

As we saw previously, to have $\Psi(p^n, q^n)$ converging to d , it is sufficient that the five-point property hold. It is conceivable, then, that the five-point property may hold for Bregman distances under somewhat more general conditions than those employed in the Eggermont-LaRiccia Lemma.

The five-point property for the EM case is the following:

$$\begin{aligned} & KL(b(\theta), f(\theta^k)) - KL(b(\theta), f(\theta^{k+1})) \\ & \geq \left(KL(b(\theta^k), f(\theta^k)) - F(\theta^k) \right) - \left(KL(b(\theta), f(\theta)) - F(\theta) \right). \end{aligned} \quad (83)$$

12 Sums of Independent Poisson Random Variables

The EM is often used with aggregated data. The case of sums of independent Poisson random variables is particularly important.

Poisson Sums

Let X_1, \dots, X_N be independent Poisson random variables with expected value $E(X_n) = \lambda_n$. Let X be the random vector with X_n as its entries, λ the vector whose entries are the λ_n , and $\lambda_+ = \sum_{n=1}^N \lambda_n$. Then the probability function for X is

$$f_X(x|\lambda) = \prod_{n=1}^N \lambda_n^{x_n} \exp(-\lambda_n)/x_n! = \exp(-\lambda_+) \prod_{n=1}^N \lambda_n^{x_n}/x_n!. \quad (84)$$

Now let $Y = \sum_{n=1}^N X_n$. Then, the probability function for Y is

$$\text{Prob}(Y = y) = \text{Prob}(X_1 + \dots + X_N = y) \quad (85)$$

$$= \sum_{x_1+\dots+x_N=y} \exp(-\lambda_+) \prod_{n=1}^N \lambda_n^{x_n}/x_n!. \quad (86)$$

As we shall see shortly, we have

$$\sum_{x_1+\dots+x_N=y} \exp(-\lambda_+) \prod_{n=1}^N \lambda_n^{x_n} / x_n! = \exp(-\lambda_+) \lambda_+^y / y!. \quad (87)$$

Therefore, Y is a Poisson random variable with $E(Y) = \lambda_+$.

When we observe an instance of Y , we can consider the conditional distribution $f_{X|Y}(x|y, \lambda)$ of $\{X_1, \dots, X_N\}$, subject to $y = X_1 + \dots + X_N$. We have

$$f_{X|Y}(x|y, \lambda) = \frac{y!}{x_1! \dots x_N!} \left(\frac{\lambda_1}{\lambda_+}\right)^{x_1} \dots \left(\frac{\lambda_N}{\lambda_+}\right)^{x_N}. \quad (88)$$

This is a *multinomial distribution*.

Given y and λ , the conditional expected value of X_n is then

$$E(X_n|y, \lambda) = y\lambda_n/\lambda_+.$$

To see why this is true, consider the marginal conditional distribution $f_{X_1|Y}(x_1|y, \lambda)$ of X_1 , conditioned on y and λ , which we obtain by holding x_1 fixed and summing over the remaining variables. We have

$$f_{X_1|Y}(x_1|y, \lambda) = \frac{y!}{x_1!(y-x_1)!} \left(\frac{\lambda_1}{\lambda_+}\right)^{x_1} \left(\frac{\lambda'_+}{\lambda_+}\right)^{y-x_1} \sum_{x_2+\dots+x_N=y-x_1} \frac{(y-x_1)!}{x_2! \dots x_N!} \prod_{n=2}^N \left(\frac{\lambda_n}{\lambda'_+}\right)^{x_n},$$

where

$$\lambda'_+ = \lambda_+ - \lambda_1.$$

As we shall show shortly,

$$\sum_{x_2+\dots+x_N=y-x_1} \frac{(y-x_1)!}{x_2! \dots x_N!} \prod_{n=2}^N \left(\frac{\lambda_n}{\lambda'_+}\right)^{x_n} = 1,$$

so that

$$f_{X_1|Y}(x_1|y, \lambda) = \frac{y!}{x_1!(y-x_1)!} \left(\frac{\lambda_1}{\lambda_+}\right)^{x_1} \left(\frac{\lambda'_+}{\lambda_+}\right)^{y-x_1}.$$

The random variable X_1 is equivalent to the random number of heads showing in y flips of a coin, with the probability of heads given by λ_1/λ_+ . Consequently, the conditional expected value of X_1 is $y\lambda_1/\lambda_+$, as claimed. In the next subsection we look more closely at the multinomial distribution.

The Multinomial Distribution

When we expand the quantity $(a_1 + \dots + a_N)^y$, we obtain a sum of terms, each having the form $a_1^{x_1} \dots a_N^{x_N}$, with $x_1 + \dots + x_N = y$. How many terms of the same form are there? There are N variables a_n . We are to use x_n of the a_n , for each $n = 1, \dots, N$, to get $y = x_1 + \dots + x_N$ factors. Imagine y blank spaces, each to be filled in by a variable as we do the selection. We select x_1 of these blanks and mark them a_1 . We can do that in $\binom{y}{x_1}$ ways. We then select x_2 of the remaining blank spaces and enter a_2 in them; we can do this in $\binom{y-x_1}{x_2}$ ways. Continuing in this way, we find that we can select the N factor types in

$$\binom{y}{x_1} \binom{y-x_1}{x_2} \dots \binom{y-(x_1+\dots+x_{N-2})}{x_{N-1}} \quad (89)$$

ways or in

$$\frac{y!}{x_1!(y-x_1)!} \dots \frac{(y-(x_1+\dots+x_{N-2}))!}{x_{N-1}!(y-(x_1+\dots+x_{N-1}))!} = \frac{y!}{x_1! \dots x_N!}. \quad (90)$$

This tells us in how many different sequences the factor variables can be selected. Applying this, we get the multinomial theorem:

$$(a_1 + \dots + a_N)^y = \sum_{x_1+\dots+x_N=y} \frac{y!}{x_1! \dots x_N!} a_1^{x_1} \dots a_N^{x_N}. \quad (91)$$

$$\text{Select } a_n = \lambda_n / \lambda_+. \text{ Then, } \frac{\lambda_1}{\lambda_+} + \dots + \frac{\lambda_N}{\lambda_+} = 1^y = \left(\frac{\lambda_1}{\lambda_+} + \dots + \frac{\lambda_N}{\lambda_+} \right)^y \quad (92)$$

$$= \sum_{x_1+\dots+x_N=y} \frac{y!}{x_1! \dots x_N!} \left(\frac{\lambda_1}{\lambda_+} \right)^{x_1} \dots \left(\frac{\lambda_N}{\lambda_+} \right)^{x_N}. \quad (93)$$

From this we get

$$\sum_{x_1+\dots+x_N=y} \exp(-\lambda_+) \prod_{n=1}^N \lambda_n^{x_n} / x_n! = \exp(-\lambda_+) \lambda_+^y / y!. \quad (94)$$

13 Poisson Sums in Emission Tomography

Sums of Poisson random variables and the problem of complete versus incomplete data arise in *single-photon computed emission tomography* (SPECT) [17].

The SPECT Reconstruction Problem

In their 1976 paper, Rockmore and Makovski [18] suggested that the problem of reconstructing a tomographic image be viewed as statistical parameter estimation. Shepp and Vardi [19] expanded on this idea and suggested that the EM algorithm discussed by Dempster, Laird, and Rubin [11] should be used for the reconstruction. The region of interest within the body of the patient is discretized into J pixels (or voxels), with $\lambda_j \geq 0$ the unknown amount of radionuclide within the j th pixel; we assume that λ_j is also the expected number of photons emitted from the j th pixel during the scanning time. Emitted photons are detected at any one of I detectors outside the body, with $y_i > 0$ the photon count at the i th detector. The probability that a photon emitted at the j th pixel will be detected at the i th detector is P_{ij} , which we assume is known; the overall probability of detecting a photon emitted from the j th pixel is $s_j = \sum_{i=1}^I P_{ij} > 0$.

The Preferred Data

For each i and j , the random variable X_{ij} is the number of photons emitted from the j th pixel and detected at the i th detector; the X_{ij} are assumed to be independent and $P_{ij}\lambda_j$ -Poisson. With x_{ij} a realization of X_{ij} , the vector x with components x_{ij} is our preferred data. The pdf for this preferred data is a probability vector, with

$$f_X(x|\lambda) = \prod_{i=1}^I \prod_{j=1}^J \exp^{-P_{ij}\lambda_j} (P_{ij}\lambda_j)^{x_{ij}} / x_{ij}! . \quad (95)$$

Given an estimate λ^k of the vector λ and the restriction that $Y_i = \sum_{j=1}^J X_{ij}$, the random variables X_{i1}, \dots, X_{iJ} have the multinomial distribution

$$\text{Prob}(x_{i1}, \dots, x_{iJ}) = \frac{y_i!}{x_{i1}! \cdots x_{iJ}!} \prod_{j=1}^J \left(\frac{P_{ij}\lambda_j}{(P\lambda)_i} \right)^{x_{ij}}.$$

Therefore, the conditional expected value of X_{ij} , given y and λ^k , is

$$E(X_{ij}|y, \lambda^k) = \lambda_j^k P_{ij} \left(\frac{y_i}{(P\lambda^k)_i} \right),$$

and the conditional expected value of the random variable

$$\log f_X(X|\lambda) = \sum_{i=1}^I \sum_{j=1}^J (-P_{ij}\lambda_j) + X_{ij} \log(P_{ij}\lambda_j) + \text{constants}$$

becomes

$$E(\log f_X(X|\lambda)|y, \lambda^k) = \sum_{i=1}^I \sum_{j=1}^J \left((-P_{ij}\lambda_j) + \lambda_j^k P_{ij} \left(\frac{y_i}{(P\lambda^k)_i} \right) \log(P_{ij}\lambda_j) \right),$$

omitting terms that do not involve the parameter vector λ . In the EM algorithm, we obtain the next estimate λ^{k+1} by maximizing $E(\log f_X(X|\lambda)|y, \lambda^k)$.

The log likelihood function for the preferred data X (omitting constants) is

$$LL_x(\lambda) = \sum_{i=1}^I \sum_{j=1}^J \left(-P_{ij} \lambda_j + X_{ij} \log(P_{ij} \lambda_j) \right). \quad (96)$$

Of course, we do not have the complete data.

The Incomplete Data

What we do have are the y_i , values of the random variables

$$Y_i = \sum_{j=1}^J X_{ij}; \quad (97)$$

this is the given data. These random variables are also independent and $(P\lambda)_i$ -Poisson, where

$$(P\lambda)_i = \sum_{j=1}^J P_{ij} \lambda_j.$$

The log likelihood function for the given data is

$$LL_y(\lambda) = \sum_{i=1}^I \left(-(P\lambda)_i + y_i \log((P\lambda)_i) \right). \quad (98)$$

Maximizing $LL_x(\lambda)$ in Eq. (96) is easy, while maximizing $LL_y(\lambda)$ in Eq. (98) is harder and requires an iterative method.

The EM algorithm involves two steps: in the E-step we compute the conditional expected value of $LL_x(\lambda)$, conditioned on the data vector y and the current estimate λ^k of λ ; in the M-step we maximize this conditional expected value to get the next λ^{k+1} . Putting these two steps together, we have the following EMML iteration:

$$\lambda_j^{k+1} = \lambda_j^k s_j^{-1} \sum_{i=1}^I P_{ij} \frac{y_i}{(P\lambda^k)_i}. \quad (99)$$

For any positive starting vector λ^0 , the sequence $\{\lambda^k\}$ converges to a maximizer of $LL_y(\lambda)$, over all nonnegative vectors λ .

Note that because we are dealing with finite probability vectors in this example, it is a simple matter to conclude that

$$f_Y(y|\lambda) = \sum_{x \in h^{-1}\{y\}} f_X(x|\lambda). \quad (100)$$

Using the KL Distance

In this subsection we assume, for notational convenience, that the system $y = P\lambda$ has been normalized so that $s_j = 1$ for each j . Maximizing $E(\log f_X(X|\lambda)|y, \lambda^k)$ is equivalent to minimizing $KL(r(\lambda^k), q(\lambda))$, where $r(\lambda)$ and $q(\lambda)$ are I by J arrays with entries

$$r(\lambda)_{ij} = \lambda_j P_{ij} \left(\frac{y_i}{(P\lambda)_i} \right),$$

and

$$q(\lambda)_{ij} = \lambda_j P_{ij}.$$

In terms of our previous notation, we identify $r(\lambda)$ with $b(\theta)$ and $q(\lambda)$ with $f(\theta)$. The set $\mathcal{F}(\Theta)$ of all $f(\theta)$ is now a convex set and the four-point property of [12] holds. The iterative step of the EMML algorithm is then

$$\lambda_j^{k+1} = \lambda_j^k \sum_{i=1}^I P_{i,j} \frac{y_i}{(P\lambda^k)_i}. \quad (101)$$

The sequence $\{\lambda^k\}$ converges to a maximizer λ_{ML} of the likelihood for any positive starting vector.

As we noted previously, before we can discuss the possible convergence of the sequence $\{\lambda^k\}$ of parameter vectors to a maximizer of the likelihood, it is necessary to have a notion of convergence in the parameter space. For the problem in this section, the parameter vectors λ are nonnegative. Proof of convergence of the sequence $\{\lambda^k\}$ depends heavily on the following [20]:

$$KL(y, P\lambda^k) - KL(y, P\lambda^{k+1}) = KL(r(\lambda^k), r(\lambda^{k+1})) + KL(\lambda^{k+1}, \lambda^k); \quad (102)$$

and

$$KL(\lambda_{ML}, \lambda^k) - KL(\lambda_{ML}, \lambda^{k+1}) \geq KL(y, P\lambda^k) - KL(y, P\lambda_{ML}). \quad (103)$$

14 Nonnegative Solutions for Linear Equations

Any likelihood maximizer λ_{ML} is also a nonnegative minimizer of the KL distance $KL(y, P\lambda)$, so the EMML algorithm can be thought of, more generally, as a method for finding a nonnegative solution (or approximate solution) for a system $y = P\lambda$ of linear equations in which $y_i > 0$ and $P_{ij} \geq 0$ for all indices. This will be helpful when we consider mixture problems.

The General Case

Suppose we want a nonnegative solution x for a system $Ax = b$ of real equations; unless b is positive and A has only nonnegative entries, we cannot use the EMML algorithm directly. We may, however, be able to transform $Ax = b$ to $P\lambda = y$.

Suppose that by rescaling the equations in $Ax = b$, we can make $c_j = \sum_{i=1}^I A_{ij} > 0$, for each $j = 1, \dots, J$, and $b_+ = \sum_{i=1}^I b_i > 0$. Now replace A_{ij} with $G_{ij} = A_{ij}/c_j$, and x_j with $z_j = c_j x_j$; then $Gz = Ax = b$ and $\sum_{i=1}^I G_{ij} = 1$, for all j . We also know now that $b_+ = z_+ > 0$, so z_+ is now known.

Let U and u be the matrix and column vector whose entries are all one, respectively, and let $t > 0$ be large enough so that all the entries of $B = G + tU$ and $(tz_+)u$ are positive. Now

$$Bz = Gz + (tz_+)u = b + (tz_+)u.$$

We then solve $Bz = b + (tz_+)u$ for z . It follows that $Ax = Gz = b$ and $x \geq 0$. Finally, we let $P = B$, $\lambda = z$, and $y = b + (tb_+)u$.

Regularization

It is often the case, as in tomography, that the entries of the vector y are obtained by measurements and are therefore noisy. Finding an exact solution of $y = P\lambda$ or even minimizing $KL(y, P\lambda)$ may not be advisable in such cases. To obtain an approximate solution that is relatively insensitive to the noise in y , we *regularize*. One way to do that is to minimize not $KL(y, P\lambda)$, but

$$F_\alpha(\lambda) = (1 - \alpha)KL(y, P\lambda) + \alpha KL(p, \lambda), \quad (104)$$

where $\alpha \in (0, 1)$ and $p > 0$ is a prior estimate of the desired λ . The iterative step of the regularized EMML algorithm is now

$$\lambda_j^{k+1} = (1 - \alpha) \left(\lambda_j^k s_j^{-1} \sum_{i=1}^I P_{ij} \frac{y_i}{(P\lambda^k)_i} \right) + \alpha p_j. \quad (105)$$

As was shown in [20], the sequence $\{\lambda^k\}$ converges to a minimizer of $F_\alpha(\lambda)$.

Acceleration

When the system $y = P\lambda$ is large, the EMML algorithm can be slow to converge. One method that has been used to accelerate convergence to a solution is the use of block iteration [21–23].

We begin by writing the index set $\{i = 1, 2, \dots, I\}$ as the (not necessarily disjoint) union of $B_n, n = 1, 2, \dots, N$. Of particular interest is the *row-action* EMML, obtained by letting each block be a singleton. At each step of the iteration, we employ only those equations whose index is a member of the current block. We then cycle through the blocks.

An obvious way to impose blocks would seem to be to modify the EMML iteration as follows:

$$\lambda_j^{k+1} = \lambda_j^k s_{n,j}^{-1} \sum_{i \in B_n} P_{ij} \frac{y_i}{(P\lambda^k)_i}, \quad (106)$$

where

$$s_{n,j} = \sum_{i \in B_n} P_{ij}.$$

This does not work, though.

Let $H_i = \{z \geq 0 | (Pz)_i = y_i\}$. Note that for a fixed $x > 0$, we cannot calculate in closed form the vector $z \in H_i$ that minimizes $KL(z, \lambda)$. However, the vector $z = z^i$ in H_i that minimizes the weighted KL distance

$$\sum_{j=1}^J P_{ij} KL(z_j, \lambda_j^k)$$

is given by

$$z_j^i = \lambda_j^k \frac{y_i}{(P\lambda^k)_i}. \quad (107)$$

The iterative step of the EMML algorithm can then be interpreted as saying that λ^{k+1} is a weighted arithmetic mean of the z^i ; that is,

$$\lambda_j^{k+1} = s_j^{-1} \sum_{i=1}^I P_{ij} z_j^i. \quad (108)$$

This suggests a different form for a block-iterative version of the EMML.

For $k = 0, 1, \dots$, and $n = n(k) = k(\text{mod } N) + 1$, let

$$\lambda_j^{k+1} = (1 - m_n^{-1} s_{nj}) \lambda_j^k + m_n^{-1} \lambda_j^k \sum_{i \in B_n} P_{ij} \frac{y_i}{(P\lambda^k)_i}, \quad (109)$$

where $m_n = \max_j s_{nj}$. This is the *rescaled* block-iterative EMML (RBI-EMML) algorithm. The sequence $\{\lambda^k\}$ converges to a nonnegative solution of the system $y = P\lambda$, for any choice of blocks, whenever the system has a nonnegative solution [21].

When each block is a singleton, that is, $B_n = B_i = \{i\}$, for $i = 1, 2, \dots, I = N$, the RBI-EMML becomes the EMART algorithm, with the iterative step

$$\lambda_j^{k+1} = (1 - m_i^{-1} P_{ij}) \lambda_j^k + \lambda_j^k m_i^{-1} P_{ij} \frac{y_i}{(P\lambda^k)_i}, \quad (110)$$

where $m_i = \max_j P_{ij} > 0$. It is interesting to compare the EMART algorithm with the *multiplicative algebraic reconstruction technique* (MART) [24], which has the iterative step

$$\lambda_j^{k+1} = \lambda_j^k \left(\frac{y_i}{(P\lambda^k)_i} \right)^{P_{ij}/m_i}, \quad (111)$$

so that

$$\lambda_j^{k+1} = \left(\lambda_j^k \right)^{1-P_{ij}/m_i} \left(\lambda_j^k \frac{y_i}{(P\lambda^k)_i} \right)^{P_{ij}/m_i}, \quad (112)$$

or

$$\log \lambda_j^{k+1} = (1 - m_i^{-1} P_{ij}) \log \lambda_j^k + m_i^{-1} P_{ij} \log \left(\lambda_j^k \frac{y_i}{(P\lambda^k)_i} \right). \quad (113)$$

The difference between the MART and the EMART is then the difference between a geometric mean and an arithmetic mean.

The simultaneous MART (SMART) is analogous to the EMML and uses all the equations at each step [20, 25, 26]. The iterative step for the SMART is

$$\lambda_j^{k+1} = \lambda_j^k \exp \left(s_j^{-1} \sum_{i=1}^I P_{ij} \log \frac{y_i}{(P\lambda^k)_i} \right). \quad (114)$$

Block-iterative versions of the MART (RBI-SMART) have been considered by [27] and [21]. When $y = P\lambda$ has nonnegative solutions, the RBI-SMART sequence converges to the nonnegative solution of $y = P\lambda$ for which the cross-entropy $KL(\lambda, \lambda^0)$ is minimized. When there are no nonnegative solutions of $y = P\lambda$, the SMART converges to the nonnegative minimizer of $KL(P\lambda, y)$ for which $KL(\lambda, \lambda^0)$ is minimized [28].

Using Prior Bounds on λ

The EMML algorithm finds an approximate nonnegative solution of $y = P\lambda$. In some applications it is helpful to be able to incorporate upper and lower bounds on the λ [29].

The SMART, EMML, MART, and EMART methods are based on the Kullback-Leibler distance between nonnegative vectors. To impose more general constraints

on the entries of λ , we derive algorithms based on shifted KL distances, also called *Fermi-Dirac generalized entropies*.

For a fixed real vector u , the shifted KL distance $KL(x - u, z - u)$ is defined for vectors x and z having $x_j \geq u_j$ and $z_j \geq u_j$. Similarly, the shifted distance $KL(v - x, v - z)$ applies only to those vectors x and z for which $x_j \leq v_j$ and $z_j \leq v_j$. For $u_j \leq v_j$, the combined distance

$$KL(x - u, z - u) + KL(v - x, v - z)$$

is restricted to those x and z whose entries x_j and z_j lie in the interval $[u_j, v_j]$. Our objective is to mimic the derivation of the SMART and EMML methods, replacing KL distances with shifted KL distances, to obtain algorithms that enforce the constraints $u_j \leq \lambda_j \leq v_j$, for each j . The algorithms that result are the ABMART and ABEMML block-iterative methods. These algorithms were originally presented in [30], in which the vectors u and v were called a and b , hence the names of the algorithms. We shall assume that the entries of the matrix P are nonnegative. We shall denote by B_n , $n = 1, \dots, N$ a partition of the index set $\{i = 1, \dots, I\}$ into blocks. For $k = 0, 1, \dots$ let $n = n(k) = k(\bmod N) + 1$.

The ABMART Algorithm

We assume that $(Pu)_i \leq y_i \leq (Pv)_i$ and seek a solution of $P\lambda = y$ with $u_j \leq \lambda_j \leq v_j$, for each j . The algorithm begins with an initial vector λ^0 satisfying $u_j \leq \lambda_j^0 \leq v_j$, for each j . Having calculated λ^k , we take

$$\lambda_j^{k+1} = \alpha_j^k v_j + (1 - \alpha_j^k) u_j, \quad (115)$$

with $n = n(k)$,

$$\alpha_j^k = \frac{c_j^k \prod^n (d_i^k)^{P_{ij}}}{1 + c_j^k \prod^n (d_i^k)^{A_{ij}}}, \quad (116)$$

$$c_j^k = \frac{(\lambda_j^k - u_j)}{(v_j - \lambda_j^k)}, \quad (117)$$

and

$$d_j^k = \frac{(y_i - (Pu)_i)((Pv)_i - (P\lambda^k)_i)}{((Pv)_i - y_i)((P\lambda^k)_i - (Pu)_i)}, \quad (118)$$

where \prod^n denotes the product over those indices i in $B_{n(k)}$. Notice that at each step of the iteration, λ_j^k is a convex combination of the endpoints u_j and v_j , so that λ_j^k always lies in the interval $[u_j, v_j]$.

We have the following theorem concerning the convergence of the ABMART algorithm:

Theorem 1. *If there is a solution of the system $P\lambda = y$ that satisfies the constraints $u_j \leq \lambda_j \leq v_j$ for each j , then, for any N and any choice of the blocks B_n , the ABMART sequence converges to that constrained solution of $P\lambda = y$ for which the Fermi-Dirac generalized entropic distance from λ to λ^0 , given by*

$$KL(\lambda - u, \lambda^0 - u) + KL(v - \lambda, v - \lambda^0),$$

is minimized. If there is no constrained solution of $P\lambda = y$, then, for $N = 1$, the ABMART sequence converges to the minimizer of

$$KL(P\lambda - Pu, y - Pu) + KL(Pv - P\lambda, Pv - y)$$

for which

$$KL(\lambda - u, \lambda^0 - u) + KL(v - \lambda, v - \lambda^0)$$

is minimized.

The proof is in [30].

The ABEMML Algorithm

We make the same assumptions as previously. The iterative step of the ABEMML algorithm is

$$\lambda_j^{k+1} = \alpha_j^k v_j + (1 - \alpha_j^k) u_j, \quad (119)$$

where

$$\alpha_j^k = \gamma_j^k / d_j^k, \quad (120)$$

$$\gamma_j^k = (\lambda_j^k - u_j) e_j^k, \quad (121)$$

$$\beta_j^k = (v_j - \lambda_j^k) f_j^k, \quad (122)$$

$$d_j^k = \gamma_j^k + \beta_j^k, \quad (123)$$

$$e_j^k = \left(1 - \sum_{i \in B_n} P_{ij} \right) + \sum_{i \in B_n} P_{ij} \left(\frac{y_i - (Pu)_i}{(P\lambda^k)_i - (Pu)_i} \right), \quad (124)$$

and

$$f_j^k = \left(1 - \sum_{i \in B_n} P_{ij} \right) + \sum_{i \in B_n} P_{ij} \left(\frac{(Pv)_i - y_i}{(Pv)_i - (P\lambda^k)_i} \right). \quad (125)$$

The following theorem concerns the convergence of the ABEMML algorithm:

Theorem 2. *If there is a solution of the system $P\lambda = y$ that satisfies the constraints $u_j \leq \lambda_j \leq v_j$ for each j , then, for any N and any choice of the blocks B_n , the ABEMML sequence converges to such a constrained solution of $P\lambda = y$. If there is no constrained solution of $P\lambda = y$, then, for $N = 1$, the ABEMML sequence converges to a constrained minimizer of*

$$KL(y - Pu, P\lambda - Pu) + KL(Pv - y, Pv - P\lambda).$$

The proof is found in [30]. In contrast to the ABMART theorem, this is all we can say about the limits of the ABEMML sequences.

15 Finite Mixture Problems

Estimating the combining proportions in probabilistic mixture problems shows that there are meaningful examples of our acceptable-data model, and provides important applications of likelihood maximization.

Mixtures

We say that a random vector V taking values in \mathbb{R}^D is a *finite mixture* [31, 32] if there are probability density functions or probabilities f_j and numbers $\theta_j \geq 0$, for $j = 1, \dots, J$, such that the probability density function or probability function for V has the form

$$f_V(v|\theta) = \sum_{j=1}^J \theta_j f_j(v), \quad (126)$$

for some choice of the $\theta_j \geq 0$ with $\sum_{j=1}^J \theta_j = 1$. As previously, we shall assume, without loss of generality, that $D = 1$.

The Likelihood Function

The data are N realizations of the random variable V , denoted v_n , for $n = 1, \dots, N$, and the given data is the vector $y = (v_1, \dots, v_N)$. The column vector $\theta = (\theta_1, \dots, \theta_J)^T$ is the generic parameter vector of mixture combining proportions. The likelihood function is

$$L_y(\theta) = \prod_{n=1}^N \left(\theta_1 f_1(v_n) + \dots + \theta_J f_J(v_n) \right). \quad (127)$$

Then the log likelihood function is

$$LL_y(\theta) = \sum_{n=1}^N \log \left(\theta_1 f_1(v_n) + \dots + \theta_J f_J(v_n) \right).$$

With u the column vector with entries $u_n = 1/N$, and P the matrix with entries $P_{nj} = f_j(v_n)$, we define

$$s_j = \sum_{n=1}^N P_{nj} = \sum_{n=1}^N f_j(v_n).$$

Maximizing $LL_y(\theta)$ is equivalent to minimizing

$$F(\theta) = KL(u, P\theta) + \sum_{j=1}^J (1 - s_j)\theta_j. \quad (128)$$

A Motivating Illustration

To motivate such mixture problems, we imagine that each data value is generated by first selecting one value of j , with probability θ_j , and then selecting a realization of a random variable governed by $f_j(v)$. For example, there could be J bowls of colored marbles, and we randomly select a bowl, and then randomly select a marble within the selected bowl. For each n the number v_n is the numerical code for the color of the n th marble drawn. In this illustration we are using a mixture of probability functions, but we could have used probability density functions.

The Acceptable Data

We approach the mixture problem by creating acceptable data. We imagine that we could have obtained $x_n = j_n$, for $n = 1, \dots, N$, where the selection of v_n is governed by the function $f_{j_n}(v)$. In the bowls example, j_n is the number of the bowl from which the n th marble is drawn. The acceptable-data random vector is $X = (X_1, \dots, X_N)$, where the X_n are independent random variables taking values in the set $\{j = 1, \dots, J\}$. The value j_n is one realization of X_n . Since our objective is to estimate the true θ_j , the values v_n are now irrelevant. Our ML estimate of the true θ_j is simply the proportion of times $j = j_n$. Given a realization x of X , the conditional pdf or pf of Y does not involve the mixing proportions, so X is acceptable. Notice also that it is not possible to calculate the entries of y from those of x ; the model $Y = h(X)$ does not hold.

The Mix-EM Algorithm

Using this acceptable data, we derive the EM algorithm, which we call the Mix-EM algorithm.

With N_j denoting the number of times the value j occurs as an entry of x , the likelihood function for X is

$$L_x(\theta) = f_X(x|\theta) = \prod_{j=1}^J \theta_j^{N_j}, \quad (129)$$

and the log likelihood is

$$LL_x(\theta) = \log L_x(\theta) = \sum_{j=1}^J N_j \log \theta_j. \quad (130)$$

Then

$$E(\log L_x(\theta)|y, \theta^k) = \sum_{j=1}^J E(N_j|y, \theta^k) \log \theta_j. \quad (131)$$

To simplify the calculations in the E-step, we rewrite $LL_x(\theta)$ as

$$LL_x(\theta) = \sum_{n=1}^N \sum_{j=1}^J X_{nj} \log \theta_j, \quad (132)$$

where $X_{nj} = 1$ if $j = j_n$ and zero otherwise. Then we have

$$E(X_{nj}|y, \theta^k) = \text{prob}(X_{nj} = 1|y, \theta^k) = \frac{\theta_j^k f_j(v_n)}{f(v_n|\theta^k)}. \quad (133)$$

The function $E(LL_x(\theta)|y, \theta^k)$ becomes

$$E(LL_x(\theta)|y, \theta^k) = \sum_{n=1}^N \sum_{j=1}^J \frac{\theta_j^k f_j(v_n)}{f(v_n|\theta^k)} \log \theta_j. \quad (134)$$

Maximizing with respect to θ , we get the iterative step of the Mix-EM algorithm:

$$\theta_j^{k+1} = \frac{1}{N} \theta_j^k \sum_{n=1}^N \frac{f_j(v_n)}{f(v_n|\theta^k)}. \quad (135)$$

We know from our previous discussions that since the preferred data X is acceptable, likelihood is non-decreasing for this algorithm. We shall go further now and show that the sequence of probability vectors $\{\theta^k\}$ converges to a maximizer of the likelihood.

Convergence of the Mix-EM Algorithm

As we noted earlier, maximizing the likelihood in the mixture case is equivalent to minimizing

$$F(\theta) = KL(u, P\theta) + \sum_{j=1}^J (1 - s_j)\theta_j,$$

over probability vectors θ . It is easily shown that if $\hat{\theta}$ minimizes $F(\theta)$ over all nonnegative vectors θ , then $\hat{\theta}$ is a probability vector. Therefore, we can obtain the maximum likelihood estimate of θ by minimizing $F(\theta)$ over nonnegative vectors θ .

The following theorem is found in [33].

Theorem 3. *Let u be any positive vector, P any nonnegative matrix with $s_j > 0$ for each j , and*

$$F(\theta) = KL(u, P\theta) + \sum_{j=1}^J \beta_j KL(\gamma_j, \theta_j).$$

If $s_j + \beta_j > 0$, $\alpha_j = s_j/(s_j + \beta_j)$, and $\beta_j \gamma_j \geq 0$, for all j , then the iterative sequence given by

$$\theta_j^{k+1} = \alpha_j s_j^{-1} \theta_j^k \left(\sum_{n=1}^N P_{n,j} \frac{u_n}{(P\theta^k)_n} \right) + (1 - \alpha_j) \gamma_j \quad (136)$$

converges to a nonnegative minimizer of $F(\theta)$.

With the choices $u_n = 1/N$, $\gamma_j = 0$, and $\beta_j = 1 - s_j$, the iteration in Eq. (136) becomes that of the Mix-EM algorithm. Therefore, the sequence $\{\theta^k\}$ converges to the maximum likelihood estimate of the mixing proportions.

16 More on Convergence

There is a mistake in the proof of convergence given in [11]. Wu [34] and Boyles [35] attempted to repair the error but also gave examples in which the EM algorithm failed to converge to a global maximizer of likelihood. In Chap. 3 of the book

by McLachlan and Krishnan [1], we find the basic theory of the EM algorithm, including available results on convergence and the rate of convergence. Because many authors rely on Eq. (14), it is not clear that these results are valid in the generality in which they are presented. There appears to be no single convergence theorem that is relied on universally; each application seems to require its own proof of convergence. When the use of the EM algorithm was suggested for SPECT and PET, it was necessary to prove convergence of the resulting iterative algorithm in Eq. (99), as was eventually achieved in a sequence of papers [19, 36–38], and [20]. When the EM algorithm was applied to list-mode data in SPECT and PET [39–41], the resulting algorithm differed slightly from that in Eq. (99) and a proof of convergence was provided in [33]. The convergence theorem in [33] also establishes the convergence of the iteration in Eq. (135) to the maximum-likelihood estimate of the mixing proportions.

17 Open Questions

As we have seen, the conventional formulation of the EM algorithm presents difficulties when probability density functions are involved. We have shown here that the use of acceptable preferred data can be helpful in resolving this issue, but other ways may also be useful.

Proving convergence of the sequence $\{\theta^k\}$ appears to involve the selection of an appropriate topology for the parameter space Θ . While it is common to assume that Θ is a subset of Euclidean space and that the usual norm should be used to define distance, it may be helpful to tailor the metric to the nature of the parameters. In the case of Poisson sums, for example, the parameters are nonnegative vectors, and we found that the cross-entropy distance is more appropriate. Even so, additional assumptions appear necessary before convergence of the $\{\theta^k\}$ can be established. To simplify the analysis, it is often assumed that cluster points of the sequence lie in the interior of the set Θ , which is not a realistic assumption in some applications.

It may be wise to consider, instead, convergence of the functions $f_X(x|\theta^k)$ or maybe even to identify the parameters θ with the functions $f_X(x|\theta)$. Proving convergence to $L_y(\theta_{ML})$ of the likelihood values $L_y(\theta^k)$ is also an option.

18 Conclusion

Difficulties with the conventional formulation of the EM algorithm in the continuous case of probability density functions (pdf) have prompted us to adopt a new definition, that of acceptable data. As we have shown, this model can be helpful in generating EM algorithms in a variety of situations. For the discrete case of probability functions (pf), the conventional approach remains satisfactory. In both cases, the two steps of the EM algorithm can be viewed as alternating minimization of the Kullback-Leibler distance between two sets of parameterized pf or pdf, along

the lines investigated by Csiszár and Tusnády [12]. In order to use the full power of their theory, however, we need the sets to be closed and convex. This does occur in the important special case of sums of independent Poisson random variables, but is not generally the case.

Acknowledgments I wish to thank Professor Paul Eggermont of the University of Delaware for helpful discussions on these matters.

Abstract

This chapter deals with iterative methods for nonlinear ill-posed problems. We present gradient and Newton type methods as well as nonstandard iterative algorithms such as Kaczmarz, expectation maximization, and Bregman iterations.

Our intention here is to cite convergence results in the sense of regularization and to provide further references to the literature.

1 Introduction

This chapter will be devoted to the iterative solution of inverse problems formulated as nonlinear operator equations

$$F(x) = y, \quad (1)$$

where $F : \mathcal{D}(F) \rightarrow \mathcal{Y}$ with domain $\mathcal{D}(F) \subseteq \mathcal{X}$. The exposition will be mainly restricted to the case of \mathcal{X} and \mathcal{Y} being Hilbert spaces with inner products $\langle \cdot, \cdot \rangle$ and norms $\|\cdot\|$. Some references for the Banach space case will be given.

We will assume attainability of the exact data y in a ball $\mathcal{B}_\rho(x_0)$, i.e., the equation $F(x) = y$ is solvable in $\mathcal{B}_\rho(x_0)$. The element x_0 is an initial guess which may incorporate a-priori knowledge of an exact solution.

The actually available data y^δ will in practice usually be contaminated with noise for which we here use a deterministic model, i.e.,

$$\|y^\delta - y\| \leq \delta, \quad (2)$$

where the noise level δ is assumed to be known. For a convergence analysis with stochastic noise, see the references in section “Further Literature on Gauss–Newton Type Methods”.

2 Preliminaries

Conditions on F

For the proofs of well-definedness and local convergence of the iterative methods considered here we need several conditions on the operator F . Basically, we inductively show that the iterates remain in a neighborhood of the initial guess. Hence, to guarantee applicability of the forward operator to these iterates, we assume that

$$\mathcal{B}_{2\rho}(x_0) \subseteq \mathcal{D}(F) \quad (3)$$

for some $\rho > 0$.

Moreover, we need that F is continuously Fréchet-differentiable, that $\|F'(x)\|$ is uniformly bounded with respect to $x \in \mathcal{B}_{2\rho}(x_0)$, and that problem (1) is properly scaled, i.e., certain parameters occurring in the iterative methods have to be chosen appropriately in dependence of this uniform bound.

The assumption that F' is Lipschitz continuous,

$$\|F'(\tilde{x}) - F'(x)\| \leq L \|\tilde{x} - x\|, \quad x, \tilde{x} \in \mathcal{B}_{2\rho}(x_0), \quad (4)$$

that is often used to show convergence of iterative methods for well-posed problems, implies that

$$\|F(\tilde{x}) - F(x) - F'(x)(\tilde{x} - x)\| \leq c \|\tilde{x} - x\|^2, \quad x, \tilde{x} \in \mathcal{B}_{2\rho}(x_0). \quad (5)$$

However, this Taylor remainder estimate is too weak for the ill-posed situation unless the solution is sufficiently smooth (see, e.g., case (ii) in Theorem 9 below). An assumption on F that can often be found in the literature on nonlinear ill-posed problems is the *tangential cone condition*

$$\begin{aligned} \|F(x) - F(\tilde{x}) - F'(x)(x - \tilde{x})\| &\leq \eta \\ \|F(x) - F(\tilde{x})\|, \quad \eta < \frac{1}{2}, \quad x, \tilde{x} \in \mathcal{B}_{2\rho}(x_0) &\subseteq \mathcal{D}(F), \end{aligned} \quad (6)$$

which implies that

$$\frac{1}{1 + \eta} \|F'(x)(\tilde{x} - x)\| \leq \|F(\tilde{x}) - F(x)\| \leq \frac{1}{1 - \eta} \|F'(x)(\tilde{x} - x)\|$$

for all $x, \tilde{x} \in \mathcal{B}_{2\rho}(x_0)$. One can even prove (see [70, Proposition 2.1]).

Proposition 1. *Let $\rho, \varepsilon > 0$ be such that*

$$\begin{aligned} \|F(x) - F(\tilde{x}) - F'(x)(x - \tilde{x})\| &\leq c(x, \tilde{x}) \\ \|F(x) - F(\tilde{x})\|, \quad x, \tilde{x} \in \mathcal{B}_\rho(x_0) &\subseteq \mathcal{D}(F), \end{aligned}$$

for some $c(x, \tilde{x}) \geq 0$, where $c(x, \tilde{x}) < 1$ if $\|x - \tilde{x}\| \leq \varepsilon$.

(i) Then for all $x \in \mathcal{B}_\rho(x_0)$

$$M_x := \{\tilde{x} \in \mathcal{B}_\rho(x_0) : F(\tilde{x}) = F(x)\} = x + \mathcal{N}(F'(x)) \cap \mathcal{B}_\rho(x_0)$$

and $\mathcal{N}(F'(x)) = \mathcal{N}(F'(\tilde{x}))$ for all $\tilde{x} \in M_x$. Moreover,

$$\mathcal{N}(F'(x)) \supseteq \{t(\tilde{x} - x) : \tilde{x} \in M_x, t \in \mathbb{R}\},$$

where instead of \supseteq equality holds if $x \in \overset{\circ}{\mathcal{B}}_\rho(x_0)$.

(ii) If $F(x) = y$ is solvable in $\mathcal{B}_\rho(x_0)$, then a unique x_0 -minimum-norm solution exists. It is characterized as the solution x^\dagger of $F(x) = y$ in $\mathcal{B}_\rho(x_0)$ satisfying the condition

$$x^\dagger - x_0 \in \mathcal{N}(F'(x^\dagger))^\perp \subseteq \mathcal{X}. \quad (7)$$

If $F(x) = y$ is solvable in $\mathcal{B}_\rho(x_0)$ but a condition like (6) is not satisfied, then at least existence (but no uniqueness) of an x_0 -minimum-norm solution is guaranteed provided that F is weakly sequentially closed (see [36, Chapter 10]).

For the proofs of convergence rates one even needs stronger conditions on F' than condition (6).

Source Conditions

It is well known by now that the convergence of regularized solutions can be arbitrarily slow. Rates can only be proven if the exact solution x^\dagger satisfies some regularity assumptions, so-called source conditions. They are usually of Hölder-type, i.e.,

$$x^\dagger - x_0 = (F'(x^\dagger)^* F'(x^\dagger))^\mu v, \quad v \in \mathcal{N}(F'(x^\dagger))^\perp \quad (8)$$

for some exponent $\mu > 0$. Due to typical smoothing properties of the linearized forward operator $F'(x^\dagger)$, they can be interpreted as smoothness assumptions on the initial error $x^\dagger - x_0$.

Since (8) is usually too strong for severely ill-posed problems, logarithmic source conditions, i.e.,

$$\begin{aligned} x^\dagger - x_0 &= f_\mu^L(F'(x^\dagger)^* F'(x^\dagger))v, \quad \mu > 0, \quad v \in \mathcal{N}(F'(x^\dagger))^\perp, \\ f_\mu^L(\lambda) &:= (-\ln(\lambda c_L^{-1}))^{-\mu}, \quad c_L > c_s^2, \end{aligned} \quad (9)$$

have been considered by Hohage [56] (cf. [30, Theorem 2.7] for Landweber iteration, [54] for the iteratively regularized Gauss–Newton method IRGNM, and [55] for generalized IRGNM).

Stopping Rules

In the context of ill-posed problems it is essential to stop iterative solution methods according to an appropriate rule to avoid an unbounded growth of the propagated noise. There are two possibilities, either a-priori rules or a-posteriori rules. A-priori rules [see, e.g., (58)] are computationally very effective. However, the disadvantage is that one has to know the smoothness index μ in (8) or (9) explicitly.

This is avoided in a-posteriori stopping rules. The most well-known a-posteriori criterion is the so-called *discrepancy principle*, i.e., the iteration is stopped after $k_* = k_*(\delta, y^\delta)$ steps with

$$\|y^\delta - F(x_{k_*}^\delta)\| \leq \tau\delta < \|y^\delta - F(x_k^\delta)\|, \quad 0 \leq k < k_*, \quad (10)$$

where $\tau > 1$.

The Lepskii type balancing principle is an interesting alternative a-posteriori rule, see [6, 8] and (62) below in the context of iterative methods.

If the noise level δ in (2) is unknown, heuristic stopping rules such as the quasioptimality principle, the Hanke–Raus rule, or the L-curve criterion still lead to convergence under certain structural assumptions on the noise, see [7, 74, 75, 89].

3 Gradient Methods

One way to derive iterative regularization methods is to apply gradient methods to the minimization problem

$$\min \frac{1}{2} \|F(x) - y\|^2 \quad \text{over } \mathcal{D}(F).$$

Since the negative gradient of this functional is given by $F'(x)^*(y - F(x))$ and taking into account that only noisy data y^δ are available, this yields methods of the form

$$x_{k+1}^\delta = x_k^\delta + \omega_k^\delta F'(x_k^\delta)^*(y^\delta - F(x_k^\delta)), \quad (11)$$

where $x_0^\delta = x_0$ is an initial guess of the exact solution. Choosing the factor ω_k^δ in a special way we obtain well-known methods like Landweber iteration, the steepest descent method, and the minimal error method.

Nonlinear Landweber Iteration

If one chooses $\omega_k^\delta = \omega$ to be constant, one obtains Landweber iteration. As already mentioned in the introduction of this chapter, well-definedness and convergence can only be proven if problem (1) is properly scaled. Without loss of generality we may assume that $\omega_k^\delta \equiv 1$ and that

$$\|F'(x)\| \leq 1, \quad x \in \mathcal{B}_{2\rho}(x_0) \subset \mathcal{D}(F). \quad (12)$$

The nonlinear Landweber iteration is then given as the method

$$x_{k+1}^\delta = x_k^\delta + F'(x_k^\delta)^*(y^\delta - F(x_k^\delta)), \quad k \in \mathbb{N}_0. \quad (13)$$

We want to emphasize that for fixed iteration index k the iterate x_k^δ depends continuously on the data y^δ , since x_k^δ is the result of a combination of continuous operations.

The results on convergence and convergence rates for this method presented here were established in [49] (see also [70]). To begin with, we formulate the following monotonicity property that gives us a clue how to choose the number τ in the stopping rule (10) (see [70, Proposition 2.2]).

Proposition 2. *Assume that the conditions (12) and (6) hold and that the equation $F(x) = y$ has a solution $x_* \in \mathcal{B}_\rho(x_0)$. If $x_k^\delta \in \mathcal{B}_\rho(x_*)$, a sufficient condition for x_{k+1}^δ to be a better approximation of x_* than x_k^δ is that*

$$\|y^\delta - F(x_k^\delta)\| > 2 \frac{1 + \eta}{1 - 2\eta} \delta.$$

Moreover, it then holds that $x_k^\delta, x_{k+1}^\delta \in \mathcal{B}_\rho(x_*) \subset \mathcal{B}_{2\rho}(x_0)$.

In view of this proposition, the number τ in the stopping rule (10) should be chosen as

$$\tau = 2 \frac{1 + \eta}{1 - 2\eta}$$

with η as in (6). To be able to prove that the stopping index k_* in (10) is finite and hence well defined it turns out that τ has to be chosen slightly larger (see [70, Corollary 2.3]), i.e.,

$$\tau > 2 \frac{1 + \eta}{1 - 2\eta} > 2. \quad (14)$$

Corollary 1. *Let the assumptions of Proposition 2 hold and let k_* be chosen according to the stopping rule (10), (14). Then*

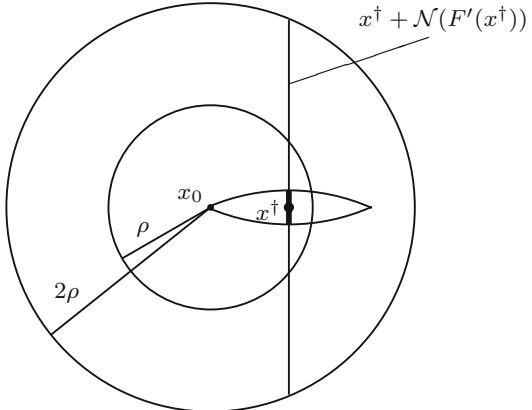

$$k_*(\tau\delta)^2 < \sum_{k=0}^{k_*-1} \|y^\delta - F(x_k^\delta)\|^2 \leq \frac{\tau}{(1 - 2\eta)\tau - 2(1 + \eta)} \|x_0 - x_*\|^2.$$

In particular, if $y^\delta = y$ (i.e., if $\delta = 0$), then

$$\sum_{k=0}^{\infty} \|y - F(x_k)\|^2 < \infty. \quad (15)$$

Note that (15) implies that if Landweber iteration is run with precise data $y = y^\delta$, then the residual norms of the iterates tend to zero as $k \rightarrow \infty$. That is, if the iteration converges, then the limit is necessarily a solution of $F(x) = y$. The following convergence result holds (see [70, Theorem 2.4]):

Fig. 1 The sketch shows the initial element x_0 , the x_0 -minimum-norm solution x^\dagger , the subset $x^\dagger + \mathcal{N}(F'(x^\dagger))$ and in bold the region, where the limit of the iterates x_k can be

Theorem 1. Assume that the conditions (12) and (6) hold and that the equation $F(x) = y$ is solvable in $\mathcal{B}_\rho(x_0)$. Then the nonlinear Landweber iteration applied to exact data y converges to a solution of $F(x) = y$. If $\mathcal{N}(F'(x^\dagger)) \subset \mathcal{N}(F'(x))$ for all $x \in \mathcal{B}_\rho(x^\dagger)$, then x_k converges to x^\dagger as $k \rightarrow \infty$.

We emphasize that, in general, the limit of the Landweber iterates is no x_0 -minimum-norm solution. However, since the monotonicity result of Proposition 2 holds for every solution, the limit of x_k has to be at least close to x^\dagger . As can be seen below, it has to be the closer the larger ρ can be chosen (Fig. 1).

It is well known that, if y^δ does not belong to the range of F , then the iterates x_k^δ of (13) cannot converge but still allow a stable approximation of a solution of $F(x) = y$ provided the iteration is stopped after k_* steps. The next result shows that the stopping rule (10), (14) renders the Landweber iteration a regularization method (see [70, Theorem 2.6]):

Theorem 2. Let the assumptions of Theorem 1 hold and let $k_* = k_*(\delta, y^\delta)$ be chosen according to the stopping rule (10), (14). Then the Landweber iterates $x_{k_*}^\delta$ converge to a solution of $F(x) = y$. If $\mathcal{N}(F'(x^\dagger)) \subset \mathcal{N}(F'(x))$ for all $x \in \mathcal{B}_\rho(x^\dagger)$, then $x_{k_*}^\delta$ converges to x^\dagger as $\delta \rightarrow 0$.

To obtain convergence rates the exact solution has to satisfy some source conditions. Moreover, one has to guarantee that the iterates remain in $\mathcal{R}(F'(x^\dagger)^*)$. In [49] rates were proven under the additional assumption that F satisfies

$$F'(x) = R_x F'(x^\dagger) \quad \text{and} \quad \|R_x - I\| \leq c \|x - x^\dagger\|, \quad x \in \mathcal{B}_{2\rho}(x_0),$$

where $\{R_x : x \in \mathcal{B}_{2\rho}(x_0)\}$ is a family of bounded linear operators $R_x : \mathcal{Y} \rightarrow \mathcal{Y}$ and c is a positive constant.

Unfortunately, these conditions are not always satisfied (see [49, Example 4.3]). Therefore, we consider instead of (13) the following slightly modified iteration method,

$$x_{k+1}^\delta = x_k^\delta + \omega G^\delta(x_k^\delta)^*(y^\delta - F(x_k^\delta)), \quad k \in \mathbb{N}_0, \quad (16)$$

where, as above, $x_0^\delta = x_0$ is an initial guess, $G^\delta(x) := G(x, y^\delta)$, and G is a continuous operator mapping $\mathcal{D}(F) \times \mathcal{Y}$ into $\mathcal{L}(\mathcal{X}, \mathcal{Y})$. The iteration will again be stopped according to the discrepancy principle (10).

To obtain local convergence and convergence rates for this modification we need the following assumptions:

Assumption 9. Let ρ be a positive number such that $\mathcal{B}_{2\rho}(x_0) \subset \mathcal{D}(F)$.

- (i) The equation $F(x) = y$ has an x_0 -minimum-norm solution x^\dagger in $\mathcal{B}_\rho(x_0)$.
- (ii) There exist positive constants c_1, c_2, c_3 and linear operators R_x^δ such that for all $x \in \mathcal{B}_\rho(x^\dagger)$ the following estimates hold:

$$\|F(x) - F(x^\dagger) - F'(x^\dagger)(x - x^\dagger)\| \leq c_1 \|F(x) - F(x^\dagger)\| \|x - x^\dagger\|, \quad (17)$$

$$G^\delta(x) = R_x^\delta G^\delta(x^\dagger), \quad (18)$$

$$\|R_x^\delta - I\| \leq c_2 \|x - x^\dagger\|, \quad (19)$$

$$\|F'(x^\dagger) - G^\delta(x^\dagger)\| \leq c_3 \delta. \quad (20)$$

- (iii) The scaling parameter ω in (16) satisfies the condition

$$\omega \|F'(x^\dagger)\|^2 \leq 1.$$

Note that, if instead of (17) the slightly stronger condition

$$\begin{aligned} \|F(x) - F(\tilde{x}) - F'(x)(x - \tilde{x})\| &\leq c \|x - \tilde{x}\| \\ \|F(x) - F(\tilde{x})\|, x, \tilde{x} &\in \mathcal{B}_{2\rho}(x_0) \subseteq \mathcal{D}(F), \end{aligned} \quad (21)$$

holds in $\mathcal{B}_{2\rho}(x_0)$ for some $c > 0$, then the unique existence of the x_0 -minimum-norm solution x^\dagger follows from Proposition 1 if $F(x) = y$ is solvable in $\mathcal{B}_\rho(x_0)$.

Convergence and convergence rates for the modification above are obtained as follows (see [70, Theorems 2.8 and 2.13]):

Theorem 3. Let Assumption 9 hold and let $k_* = k_*(\delta, y^\delta)$ be chosen according to the stopping rule (10).

- (i) If $\|x_0 - x^\dagger\|$ is so small and if the parameter τ in (10) is so large that

$$2\eta_1 + \eta_2^2 \eta_3^2 < 2$$

and

$$\tau > \frac{2(1 + \eta_1 + c_3\eta_2 \|x_0 - x^\dagger\|)}{2 - 2\eta_1 - \eta_2^2\eta_3^2},$$

where

$$\begin{aligned}\eta_1 &:= \|x_0 - x^\dagger\| (c_1 + c_2(1 + c_1 \|x_0 - x^\dagger\|)), \\ \eta_2 &:= 1 + c_2 \|x_0 - x^\dagger\|, \\ \eta_3 &:= 1 + 2c_3 \|x_0 - x^\dagger\|,\end{aligned}$$

then the modified Landweber iterates $x_{k_*}^\delta$ converge to x^\dagger as $\delta \rightarrow 0$.

- (ii) If $\tau > 2$ and if $x^\dagger - x_0$ satisfies (8) with some $0 < \mu \leq 1/2$ and $\|v\|$ sufficiently small, then it holds that

$$k_* = O\left(\|v\|^{\frac{2}{2\mu+1}} \delta^{-\frac{2}{2\mu+1}}\right)$$

and

$$\|x_{k_*}^\delta - x^\dagger\| = \begin{cases} O\left(\|v\|^{\frac{1}{2\mu+1}} \delta^{\frac{2\mu}{2\mu+1}}\right), & \mu < \frac{1}{2}, \\ O\left(\sqrt{\|v\| \delta}\right), & \mu = \frac{1}{2}. \end{cases}$$

Note that for the modified Landweber iteration we obtain the same convergence rates and the same asymptotical estimate for k_* as for linear ill-posed problems (compare [36, Theorem 6.5]) if $\mu \leq 1/2$ in (8).

Under the Assumption 9 and according to the theorem above the best possible convergence rate is

$$\|x_{k_*}^\delta - x^\dagger\| = O(\sqrt{\delta})$$

provided that $\mu = 1/2$. Even if $\mu > 1/2$ we cannot improve this rate without an additional restriction of the nonlinearity of F .

We will show for the following parameter estimation problem that the conditions of Assumption 9 are satisfied if $F'(x)$ is replaced by a certain operator $G^\delta(x)$.

Example 1. We treat the problem of estimating the diffusion coefficient a in

$$-(a(s)u(s)_s)_s = f(s), \quad s \in (0, 1), \quad u(0) = 0 = u(1), \quad (22)$$

where $f \in L^2$; the subscript s denotes derivative with respect to s .

In this example, F is defined as the parameter-to-solution mapping

$$\begin{aligned} F : \mathcal{D}(F) &:= \{a \in H^1[0, 1] : a(s) \geq \underline{a} > 0\} \rightarrow L^2[0, 1] \\ a &\mapsto F(a) := u(a), \end{aligned}$$

where $u(a)$ is the solution of (22). One can prove that F is Fréchet-differentiable (see, e.g., [24]) with

$$\begin{aligned} F'(a)h &= A(a)^{-1}[(hu_s(a))_s], \\ F'(a)^*w &= -B^{-1}[u_s(a)(A(a)^{-1}w)_s], \end{aligned}$$

where

$$\begin{aligned} A(a) : H^2[0, 1] \cap H_0^1[0, 1] &\rightarrow L^2[0, 1] \\ u &\mapsto A(a)u := -(au_s)_s \end{aligned}$$

and

$$\begin{aligned} B : \mathcal{D}(B) &:= \{\psi \in H^2[0, 1] : \psi'(0) = \psi'(1) = 0\} \rightarrow L^2[0, 1] \\ \psi &\mapsto B\psi := -\psi'' + \psi; \end{aligned}$$

note that B^{-1} is the adjoint of the embedding operator from $H^1[0, 1]$ in $L^2[0, 1]$.

First of all, we show that F satisfies condition (17): let $F(a) = u$, $F(\tilde{a}) = \tilde{u}$, and $w \in L^2$. Noting that $(\tilde{u} - u) \in H^2 \cap H_0^1$ and that $A(a)$ is one-to-one and onto for $a, \tilde{a} \in \mathcal{D}(F)$ we obtain that

$$\begin{aligned} &\langle F(\tilde{a}) - F(a) - F'(a)(\tilde{a} - a), w \rangle_{L^2} \\ &= \langle (\tilde{u} - u) - A(a)^{-1}[(\tilde{a} - a)u_s]_s, w \rangle_{L^2} \\ &= \langle A(a)(\tilde{u} - u) - ((\tilde{a} - a)u_s)_s, A(a)^{-1}w \rangle_{L^2} \\ &= \langle ((\tilde{a} - a)(\tilde{u}_s - u_s))_s, A(a)^{-1}w \rangle_{L^2} \\ &= -\langle (\tilde{a} - a)(\tilde{u} - u)_s, (A(a)^{-1}w)_s \rangle_{L^2} \\ &= \langle F(\tilde{a}) - F(a), ((\tilde{a} - a)(A(a)^{-1}w)_s)_s \rangle_{L^2}. \end{aligned}$$

This together with the fact that $\|g\|_{L^\infty} \leq \sqrt{2}\|g\|_{H^1}$ and that $\|g\|_{L^\infty} \leq \|g'\|_{L^2}$ if $g \in H^1$ is such that $g(\xi) = 0$ for some $\xi \in [0, 1]$ yields the estimate

$$\begin{aligned} &\|F(\tilde{a}) - F(a) - F'(a)(\tilde{a} - a)\|_{L^2} \\ &\leq \sup_{\|w\|_{L^2}=1} \langle F(\tilde{a}) - F(a), ((\tilde{a} - a)(A(a)^{-1}w)_s)_s \rangle_{L^2} \end{aligned}$$

$$\begin{aligned}
&\leq \|F(\tilde{a}) - F(a)\|_{L^2} \sup_{\|w\|_{L^2}=1} \left[\left\| \left(\frac{\tilde{a}-a}{a} \right)_s \right\|_{L^2} \|a(A(a)^{-1}w)_s\|_{L^\infty} \right. \\
&\quad \left. + \left\| \frac{\tilde{a}-a}{a} \right\|_{L^\infty} \|w\|_{L^2} \right] \\
&\leq \underline{a}^{-1}(1 + \sqrt{2} + \underline{a}^{-1}\sqrt{2}\|a\|_{H^1}) \|F(\tilde{a}) - F(a)\|_{L^2} \|\tilde{a} - a\|_{H^1}. \tag{23}
\end{aligned}$$

This implies (17).

The conditions (18) and (19) are not fulfilled with $G^\delta(x) = F'(x)$. Noting that $F'(a)^*w$ is the unique solution of the variational problem: for all $v \in H^1$

$$\langle (F'(a)^*w)_s, v_s \rangle_{L^2} + \langle F'(a)^*w, v \rangle_{L^2} = \langle u(a), ((A(a)^{-1}w)_s v)_s \rangle_{L^2}, \tag{24}$$

we propose to choose G^δ in (16) as follows: $G^\delta(a)^*w = G(a, u^\delta)^*w$ is the unique solution g of the variational problem

$$\langle g_s, v_s \rangle_{L^2} + \langle g, v \rangle_{L^2} = \langle u^\delta, ((A(a)^{-1}w)_s v)_s \rangle_{L^2}, \quad v \in H^1. \tag{25}$$

This operator G^δ obviously satisfies (18), since

$$G(\tilde{a}, u^\delta)^* = G(a, u^\delta)^* R(\tilde{a}, a)^*$$

with

$$R(\tilde{a}, a)^* = A(a)A(\tilde{a})^{-1}.$$

The condition (19) is satisfied, since one can estimate as in (23) that

$$\|R(\tilde{a}, a)^* - I\| = \|A(a)A(\tilde{a})^{-1} - I\| \leq \underline{a}^{-1}(1 + \sqrt{2} + \underline{a}^{-1}\sqrt{2}\|\tilde{a}\|_{H^1}) \|\tilde{a} - a\|_{H^1}.$$

Note that a constant c_2 independent from \tilde{a} can be found, since it is assumed that $\tilde{a} \in \mathcal{B}_\rho(a)$. Now we turn to condition (20): using (24) and (25) we obtain similarly to (23) the estimate

$$\begin{aligned}
\|(F'(a)^* - G(a, u^\delta)^*)w\|_{H^1} &= \sup_{\|v\|_{H^1}=1} \langle u(a) - u^\delta, ((A(a)^{-1}w)_s v)_s \rangle_{L^2} \\
&\leq \underline{a}^{-1}(1 + \sqrt{2} + \underline{a}^{-1}\sqrt{2}\|a\|_{H^1}) \|u(a) - u^\delta\|_{L^2} \|w\|_{L^2}.
\end{aligned}$$

This together with $F(a^\dagger) = u(a^\dagger)$ and $\|u^\delta - u(a^\dagger)\|_{L^2} \leq \delta$ implies that

$$\|F'(a^\dagger) - G(a^\dagger, u^\delta)\| \leq \underline{a}^{-1}(1 + \sqrt{2} + \underline{a}^{-1}\sqrt{2}\|a^\dagger\|_{H^1}) \delta$$

and hence (20) holds.

Thus, Theorem 3 is applicable, i.e., if ω and τ are chosen appropriately, then the modified Landweber iterates $a_{k_*}^\delta$ (cf. (16)) where k_* is chosen according to the stopping rule (10) converge to the exact solution a^\dagger with the rate $O(\sqrt{\delta})$ provided that

$$a^\dagger - a_0 = -B^{-1}[u_s(a^\dagger)(A(a^\dagger)^{-1}w)_s]$$

with $\|w\|$ sufficiently small. Note that this means that

$$\begin{aligned} a^\dagger - a_0 &\in H^3, & (a^\dagger - a_0)_s(0) &= 0 = (a^\dagger - a_0)_s(1), \\ z := \frac{(a^\dagger - a_0)_{ss} - (a^\dagger - a_0)}{u_s(a)} &\in H^1, & \int_0^1 z(s) ds &= 0. \end{aligned}$$

Basically this means that one has to know all rough parts of a^\dagger up to H^3 . But without this knowledge one cannot expect to get the rate $O(\sqrt{\delta})$.

In [49] two other nonlinear problems were treated where conditions (18) and (19) are satisfied with $G^\delta(x) = F'(x)$.

Landweber Iteration in Hilbert Scales

We have mentioned in the last subsection that for classical Landweber iteration the rates cannot be better than $O(\sqrt{\delta})$ under the given assumptions. However, better rates may be obtained for solutions that satisfy stronger smoothness conditions if the iteration is performed in a subspace of \mathcal{X} with a stronger norm. This leads us directly to regularization in Hilbert scales. On the other hand for solutions with poor smoothness properties the number of iterations may be reduced if the iteration is performed in a space with a weaker norm.

First of all, we shortly repeat the definition of a Hilbert scale: let L be a densely defined unbounded self-adjoint strictly positive operator in \mathcal{X} . Then $(\mathcal{X}_s)_{s \in \mathbb{R}}$ denotes the Hilbert scale induced by L if \mathcal{X}_s is the completion of $\bigcap_{k=0}^{\infty} D(L^k)$ with respect to the Hilbert space norm $\|x\|_s := \|L^s x\|_{\mathcal{X}}$; obviously, $\|x\|_0 = \|x\|_{\mathcal{X}}$ (see [78] or [36, Section 8.4] for details).

The operator $F'(x_k^\delta)^*$ in (13) will now be replaced by the adjoint of $F'(x_k^\delta)$ considered as an operator from \mathcal{X}_s into \mathcal{Y} . Usually $s \geq 0$, but we will see below that there are special cases where a negative choice of s can be advantageous. Since by definition of \mathcal{X}_s this adjoint is given by $L^{-2s} F'(x_k^\delta)^*$, (13) is replaced by the iteration process

$$x_{k+1}^\delta = x_k^\delta + L^{-2s} F'(x_k^\delta)^*(y^\delta - F(x_k^\delta)), \quad k \in \mathbb{N}_0. \quad (26)$$

As in the previous chapter the iteration process is stopped according to the discrepancy principle (10).

Proofs of convergence and convergence rates for this method can be found in [34, 70, 88]. For an approach, where the Hilbert scale is chosen in the space Y , see [33].

The following basic conditions are needed.

Assumption 10.

- (i) $F : \mathcal{D}(F)(\subset \mathcal{X}) \rightarrow \mathcal{Y}$ is continuous and Fréchet-differentiable in \mathcal{X} .
- (ii) $F(x) = y$ has a solution x^\dagger .
- (iii) $\|F'(x^\dagger)x\| \leq \bar{m}\|x\|_{-a}$ for all $x \in \mathcal{X}$ and some $a > 0$, $\bar{m} > 0$. Moreover, the extension of $F'(x^\dagger)$ to \mathcal{X}_{-a} is injective.
- (iv) $B := F'(x^\dagger)L^{-s}$ is such that $\|B\|_{\mathcal{X}, \mathcal{Y}} \leq 1$, where $-a < s$. If $s < 0$, $F'(x^\dagger)$ has to be replaced by its extension to \mathcal{X}_s .

Usually, for the analysis of regularization methods in Hilbert scales a stronger condition than (iii) is used, namely (cf., e.g., [88])

$$\|F'(x^\dagger)x\| \sim \|x\|_{-a} \quad \text{for all } x \in \mathcal{X}, \quad (27)$$

where the number a can be interpreted as a *degree of ill-posedness* of the linearized problem in x^\dagger . However, this condition is not always fulfilled. Sometimes one can only prove that condition (iii) in Assumption 10 holds. It might also be possible that one can prove an estimate from below in a slightly weaker norm (see examples in [34]), i.e.,

$$\|F'(x^\dagger)x\| \geq \underline{m}\|x\|_{-\tilde{a}} \quad \text{for all } x \in \mathcal{X} \text{ and some } \tilde{a} \geq a, \underline{m} > 0. \quad (28)$$

The next proposition sheds more light onto condition (iii) in Assumption 10 and (28). The proof follows the lines of [36, Corollary 8.22] noting that the results there not only hold for $s \geq 0$ but also for $s > -a$.

Proposition 3. *Let Assumption 10 hold. Then for all $v \in [0, 1]$ it holds that*

$$\begin{aligned} \mathcal{D}((B^*B)^{-\frac{v}{2}}) &= \mathcal{R}((B^*B)^{\frac{v}{2}}) \subset \mathcal{X}_{v(a+s)}, \\ \|(B^*B)^{\frac{v}{2}}x\| &\leq \bar{m}^v\|x\|_{-v(a+s)} \quad \text{for all } x \in \mathcal{X}, \\ \|(B^*B)^{-\frac{v}{2}}x\| &\geq \bar{m}^{-v}\|x\|_{v(a+s)} \quad \text{for all } x \in \mathcal{D}((B^*B)^{-\frac{v}{2}}). \end{aligned}$$

Note that condition (iii) is equivalent to

$$\mathcal{R}(F'(x^\dagger)^*) \subset \mathcal{X}_a \quad \text{and} \quad \|F'(x^\dagger)^*w\|_a \leq \bar{m}\|w\| \quad \text{for all } w \in \mathcal{Y}.$$

If in addition condition (28) holds, then for all $v \in [0, 1]$ it holds that

$$\begin{aligned} \mathcal{X}_{v(\tilde{a}+s)} &\subset \mathcal{R}((B^*B)^{\frac{v}{2}}) = \mathcal{D}((B^*B)^{-\frac{v}{2}}), \\ \|(B^*B)^{\frac{v}{2}}x\| &\geq \underline{m}^v \|x\|_{-\nu(\tilde{a}+s)} \quad \text{for all } x \in \mathcal{X}, \\ \|(B^*B)^{-\frac{v}{2}}x\| &\leq \underline{m}^{-v} \|x\|_{\nu(\tilde{a}+s)} \quad \text{for all } x \in \mathcal{X}_{v(\tilde{a}+s)}. \end{aligned}$$

Note that condition (28) is equivalent to

$$\begin{aligned} \mathcal{X}_{\tilde{a}} &\subset \mathcal{R}(F'(x^\dagger)^*) \text{ and } \|F'(x^\dagger)^*w\|_{\tilde{a}} \geq \underline{m}\|w\| \\ \text{for all } w &\in \mathcal{N}(F'(x^\dagger)^*)^\perp \text{ with } F'(x^\dagger)^*w \in \mathcal{X}_{\tilde{a}}. \end{aligned}$$

In our convergence analysis the following *shifted* Hilbert scale will play an important role

$$\begin{aligned} \tilde{\mathcal{X}}_r &:= \mathcal{D}((B^*B)^{\frac{s-r}{2(a+s)}}L^s) \quad \text{equipped with the norm} \\ \|x\|_r &:= \|(B^*B)^{\frac{s-r}{2(a+s)}}L^sx\|_{\mathcal{X}}, \end{aligned}$$

where a , s , and B are as in Assumption 10. Some properties of this shifted Hilbert scale can be found in [70, Proposition 3.3].

For the convergence rates analysis we need the following smoothness conditions on the solution x^\dagger and the Fréchet-derivative of F .

Assumption 11.

- (i) $x_0 \in \tilde{\mathcal{B}}_\rho(x^\dagger) := \{x \in \mathcal{X} : x - x^\dagger \in \tilde{\mathcal{X}}_0 \wedge \|x - x^\dagger\|_0 \leq \rho\} \subset \mathcal{D}(F)$ for some $\rho > 0$.
- (ii) $\|F'(x^\dagger) - F'(x)\|_{\tilde{\mathcal{X}}_{-b}, \mathcal{Y}} \leq c \|x^\dagger - x\|_0^\beta$ for all $x \in \tilde{\mathcal{B}}_\rho(x^\dagger)$ and some $b \in [0, a]$, $\beta \in (0, 1]$, and $c > 0$.
- (iii) $x^\dagger - x_0 \in \tilde{\mathcal{X}}_u$ for some $(a - b)/\beta < u \leq b + 2s$, i.e., there is an element $v \in \mathcal{X}$ so that

$$L^s(x^\dagger - x_0) = (B^*B)^{\frac{u-s}{2(a+s)}}v \quad \text{and} \quad \|v\|_0 = \|x_0 - x^\dagger\|_u.$$

Condition (iii) is a smoothness condition for the exact solution comparable to (8). Usually \mathcal{X}_u is used instead of $\tilde{\mathcal{X}}_u$. However, these conditions are equivalent if (27) holds.

For the proof of the next convergence rates result see [70, Theorem 3.8].

Theorem 4. *Let Assumptions 10 and 11 hold. Moreover, let $k_* = k_*(\delta, y^\delta)$ be chosen according to the stopping rule (10) with $\tau > 2$ and let $\|x_0 - x^\dagger\|_u$ be sufficiently small. Then the following estimates are valid for $\delta > 0$ and some positive constants c_r :*

$$k_* \leq \left(\frac{2\tau}{\tau-2} \|x_0 - x^\dagger\|_u \delta^{-1} \right)^{\frac{2(a+s)}{a+u}} \quad (29)$$

and for $-a \leq r < u$

$$\|x_{k_*}^\delta - x^\dagger\|_r \leq c_r \|x_0 - x^\dagger\|_u^{\frac{a+r}{a+u}} \delta^{\frac{u-r}{a+u}}.$$

As usual for regularization in Hilbert scales, we are interested in obtaining convergence rates with respect to the norm in $\mathcal{X} = \mathcal{X}_0$.

Corollary 2. *Under the assumptions of Theorem 4 the following estimates hold:*

$$\|x_{k_*}^\delta - x^\dagger\| = O\left(\delta^{\frac{u}{a+u}}\right) \quad \text{if } s \leq 0, \quad (30)$$

$$\|x_{k_*}^\delta - x^\dagger\| = O\left(\|x_{k_*}^\delta - x^\dagger\|_s\right) = O\left(\delta^{\frac{u-s}{a+u}}\right) \quad \text{if } 0 < s < u.$$

If in addition (28) holds, then for $s > 0$ the rate can be improved to

$$\|x_{k_*}^\delta - x^\dagger\| = O\left(\|x_{k_*}^\delta - x^\dagger\|_r\right) = O\left(\delta^{\frac{u-r}{a+u}}\right) \quad \text{if } r := \frac{s(\tilde{a}-a)}{\tilde{a}+s} \leq u.$$

Note that (29) implies that k_* is finite for $\delta > 0$ and hence $x_{k_*}^\delta$ is a stable approximation of x^\dagger .

Moreover, it can be seen from (29) that the larger s the faster k_* possibly grows if $\delta \rightarrow 0$. As a consequence, s should be kept as small as possible to reduce the number of iterations and hence to reduce the numerical effort. If u is close to 0, it might be possible to choose a negative s . According to (30), we would still get the optimal rate, but, due to (29), k_* would not grow so fast. Choosing a negative s could be interpreted as a preconditioned Landweber method (cf. [34]).

We will now comment on the rates in Corollary 2: if only Assumption 10 (iii) is satisfied, i.e., if $\|F'(x^\dagger)x\|$ may be estimated through the norm in \mathcal{X}_{-a} only from above, convergence rates in \mathcal{X} can only be given if $s < u$, i.e., only for the case of undersmoothing. If $s > 0$, the rates will not be optimal in general. To obtain rates also for $s > u$, i.e., for the case of oversmoothing, condition (28) has to be additionally satisfied. From what we said on the choice of s above, the case of oversmoothing is not desirable. However, note that the rates for $\|x_{k_*}^\delta - x^\dagger\|_0$ can be improved if (28) holds also for $0 < s < u$. Moreover, if $\tilde{a} = a$, i.e., if the usual equivalence condition (27) is satisfied, then we always obtain the usual optimal rates $O(\delta^{\frac{u}{a+u}})$ (see [87]).

For numerical computations one has to approximate the infinite-dimensional spaces by finite-dimensional ones. Also the operators F and $F'(x)^\ast$ have to be approximated by suitable finite-dimensional realizations. An appropriate convergence rates analysis has been carried out in [88]. This analysis also shows that a modification, where $F'(x_k^\delta)^\ast$ in (26) is replaced by $G^\delta(x_k^\delta)$ similar as in (16), is possible.

Steepest Descent and Minimal Error Method

These two methods are again of the form (11), where the coefficients ω_k^δ are chosen as

$$\omega_k^\delta := \frac{\|s_k^\delta\|^2}{\|F'(x_k^\delta)s_k^\delta\|^2} \quad \text{and} \quad \omega_k^\delta := \frac{\|y^\delta - F(x_k^\delta)\|^2}{\|s_k^\delta\|^2}$$

for the *steepest descent method* and for the *minimal error method*, respectively.

In [35] it has been shown that even for the solution of *linear* ill-posed problems the steepest descent method is only a regularization method when stopped via a discrepancy principle and not via an a-priori parameter choice strategy. Therefore, we will use (10), (14) as stopping rule.

Again one can show the monotonicity of the errors and well-definedness of the steepest descent and minimal error method (see [70, Proposition 3.20]). Convergence can be shown for perturbed data (see, e.g., [70, Theorem 3.22]). However, so far, convergence rates were proved only in the case of exact data (see [90]).

Further Literature on Gradient Methods

Iteratively Regularized Landweber Iteration

By adding an additional penalty term to the iteration scheme of classical Landweber iteration, i.e.,

$$x_{k+1}^\delta = x_k^\delta + F'(x_k^\delta)^*(y^\delta - F(x_k^\delta)) + \beta_k(x_0 - x_k^\delta) \quad \text{with} \quad 0 < \beta_k \leq \beta_{\max} < \frac{1}{2}.$$

one can obtain convergence rates results under weaker restrictions on the nonlinearity of F (see [70, Section 3.2], [98]). The additional term is motivated by the iteratively regularized Gauss–Newton method, see section “Iteratively Regularized Gauss–Newton Method”.

A Derivative Free Approach

Based on an idea by Engl and Zou [37], Kügler, in his thesis [80] (see also [79]), developed a modification of Landweber iteration for parameter identification problems where it is not needed that F is Fréchet-differentiable.

Generalization to Banach Spaces

A generalization of Landweber iteration to the case where \mathcal{X} and \mathcal{Y} are Banach spaces was considered in the papers [71, 99, 100], see also the book [101]. The basic version (in case of reflexive preimage space X) reads as

$$x_{k+1}^\delta = j_{q^*}^{X^*} \left(j_q^X(x_k^\delta) + \omega_k^\delta F'(x_k^\delta)^* j_p^Y(y^\delta - F(x_k^\delta)) \right),$$

where $p, q \in (1, \infty)$, $q^* = \frac{q}{q-1}$, X^* is the dual of X , j_q^X denotes a single valued selection from the set valued duality mapping $J_q^X = \partial\left(\frac{1}{q}\|\cdot\|^q\right)$, $J_q^X : X \rightarrow 2^{X^*}$, and ω_k^δ is an appropriately chosen step size. Banach space versions of the iteratively regularized Landweber iteration can be found in [51, 64].

4 Newton Type Methods

Newton's method for the nonlinear operator equation (1) reads as

$$F'(x_k^\delta)(x_{k+1}^\delta - x_k^\delta) = y^\delta - F(x_k^\delta). \quad (31)$$

Since ill-posedness of the nonlinear problem (1) is usually inherited by its linearization (31), regularization has to be applied in each Newton step. Formulating (31) as a least squares problem

$$\min_{x \in \mathcal{D}(F)} \|y^\delta - F(x_k^\delta) - F'(x_k^\delta)(x - x_k^\delta)\|^2$$

and applying Tikhonov regularization leads to either the Levenberg–Marquardt method

$$x_{k+1}^\delta = \arg \min_{x \in \mathcal{D}(F)} \|y^\delta - F(x_k^\delta) - F'(x_k^\delta)(x - x_k^\delta)\|^2 + \alpha_k \|x - x_k^\delta\|^2, \quad (32)$$

where the regularization term $\|x - x_k^\delta\|^2$ is updated in each Newton step, or the iteratively regularized Gauss–Newton method (IRGNM)

$$x_{k+1}^\delta = \arg \min_{x \in \mathcal{D}(F)} \|y^\delta - F(x_k^\delta) - F'(x_k^\delta)(x - x_k^\delta)\|^2 + \alpha_k \|x - x_0\|^2 \quad (33)$$

with a fixed a-priori guess $x_0 \in \mathcal{X}$. The choice of the sequence of regularization parameters α_k and the main ideas of the convergence analysis are quite different for both methods as will be outlined in the following subsections.

Levenberg–Marquardt and Inexact Newton Methods

In the Hilbert space setting with an open set $\mathcal{D}(F)$, the minimizer of the quadratic functional in (32) can be written as the solution of a linear system which leads to the formulation

$$x_{k+1}^\delta = x_k^\delta + (F'(x_k^\delta)^* F'(x_k^\delta) + \alpha_k I)^{-1} F'(x_k^\delta)^* (y^\delta - F(x_k^\delta)), \quad (34)$$

of the Levenberg–Marquardt method that can as well be motivated by a trust region approach.

Our exposition follows the seminal paper by Hanke [46], in which the first convergence analysis for this class of Newton type methods was given. According to this paper, α_k should be chosen such that

$$\|y^\delta - F(x_k^\delta) - F'(x_k^\delta)(x_{k+1}^\delta(\alpha_k) - x_k^\delta)\| = q \|y^\delta - F(x_k^\delta)\| \quad (35)$$

for some $q \in (0, 1)$, where $x_{k+1}^\delta(\alpha)$ is defined as in (34) with α_k replaced by α . This means that the Newton equation (31) is only solved up to a residual of magnitude $q \|y^\delta - F(x_k^\delta)\|$ which corresponds to the concept of inexact Newton methods as they were first considered for well-posed problems in [28]. It can be shown (see [46]) that (35) has a unique solution α_k provided that

$$\|y^\delta - F(x_k^\delta) - F'(x_k^\delta)(x^\dagger - x_k^\delta)\| \leq \frac{q}{\gamma} \|y^\delta - F(x_k^\delta)\| \quad (36)$$

for some $\gamma > 1$ which in its turn can be guaranteed by (21).

The key step in the convergence analysis of the Levenberg–Marquardt method is to show monotonicity of the error norms $\|x_k^\delta - x^\dagger\|$. To sketch this monotonicity proof we assume that (36) holds and therewith the parameter choice (35) is feasible. Using the notation $K_k = F'(x_k^\delta)$ as well as Cauchy–Schwarz inequality and the identity

$$\alpha_k(K_k K_k^* + \alpha_k I)^{-1}(y^\delta - F(x_k^\delta)) = y^\delta - F(x_k^\delta) - K_k(x_{k+1}^\delta - x_k^\delta),$$

we get

$$\begin{aligned} & \|x_{k+1}^\delta - x^\dagger\|^2 - \|x_k^\delta - x^\dagger\|^2 \\ &= 2 \langle x_{k+1}^\delta - x_k^\delta, x_k^\delta - x^\dagger \rangle + \|x_{k+1}^\delta - x_k^\delta\|^2 \\ &= \langle (K_k K_k^* + \alpha_k I)^{-1}(y^\delta - F(x_k^\delta)), \\ &\quad 2K_k(x_k^\delta - x^\dagger) + (K_k K_k^* + \alpha_k I)^{-1}K_k K_k^*(y^\delta - F(x_k^\delta)) \rangle \\ &= -2\alpha_k \|(K_k K_k^* + \alpha_k I)^{-1}(y^\delta - F(x_k^\delta))\|^2 \\ &\quad - \|(K_k^* K_k + \alpha_k I)^{-1}K_k^*(y^\delta - F(x_k^\delta))\|^2 \\ &\quad + 2 \langle (K_k K_k^* + \alpha_k I)^{-1}(y^\delta - F(x_k^\delta)), y^\delta - F(x_k^\delta) - K_k(x^\dagger - x_k^\delta) \rangle \\ &\leq -\|x_{k+1}^\delta - x_k^\delta\|^2 - 2\alpha_k^{-1} \|y^\delta - F(x_k^\delta) - K_k(x_{k+1}^\delta - x_k^\delta)\|. \end{aligned} \quad (37)$$

$$\left(\|y^\delta - F(x_k^\delta) - K_k(x_{k+1}^\delta - x_k^\delta)\| - \|y^\delta - F(x_k^\delta) - K_k(x^\dagger - x_k^\delta)\| \right).$$

By (36) and the parameter choice (35), we have

$$\|y^\delta - F(x_k^\delta) - K_k(x^\dagger - x_k^\delta)\| \leq \gamma^{-1} \|y^\delta - F(x_k^\delta) - K_k(x_{k+1}^\delta - x_k^\delta)\|.$$

Thus, (37) and $\gamma > 1$ imply estimates (38) and (39) in the following proposition (see [70, Proposition 4.1]):

Proposition 4. Let $0 < q < 1 < \gamma$ and assume that (1) has a solution and that (36) holds so that α_k can be defined via (35). Then, the following estimates hold:

$$\|x_k^\delta - x^\dagger\|^2 - \|x_{k+1}^\delta - x^\dagger\|^2 \geq \|x_{k+1}^\delta - x_k^\delta\|^2, \quad (38)$$

$$\begin{aligned} & \|x_k^\delta - x^\dagger\|^2 - \|x_{k+1}^\delta - x^\dagger\|^2 \\ & \geq \frac{2(\gamma-1)}{\gamma\alpha_k} \|y^\delta - F(x_k^\delta) - F'(x_k^\delta)(x_{k+1}^\delta - x_k^\delta)\|^2 \end{aligned} \quad (39)$$

$$\geq \frac{2(\gamma-1)(1-q)q}{\gamma \|F'(x_k^\delta)\|^2} \|y^\delta - F(x_k^\delta)\|^2. \quad (40)$$

Based on the resulting weak convergence of a subsequence of x_k^δ as well as on quadratic summability of the (linearized) residuals, which can be easily obtained by summing up both sides of (39) and (40), one obtains convergence as $k \rightarrow \infty$ in case of exact data [70, Theorem 4.2]:

Theorem 5. Let $0 < q < 1$ and assume that (1) is solvable in $\mathcal{B}_\rho(x_0)$, that F' is uniformly bounded in $\mathcal{B}_\rho(x^\dagger)$, and that the Taylor remainder of F satisfies (21) for some $c > 0$. Then the Levenberg–Marquardt method with exact data $y^\delta = y$, $\|x_0 - x^\dagger\| < q/c$ and α_k determined from (35), converges to a solution of $F(x) = y$ as $k \rightarrow \infty$.

In case of noisy data, Hanke [46] proposes to stop the iteration according to the discrepancy principle (10) and proves convergence as $\delta \rightarrow 0$ (see, e.g., [70, Theorem 4.3]):

Theorem 6. Let the assumptions of Theorem 5 hold. Additionally let $k_* = k_*(\delta, y^\delta)$ be chosen according to the stopping rule (10) with $\tau > 1/q$. Then for $\|x_0 - x^\dagger\|$ sufficiently small, the discrepancy principle (10) terminates the Levenberg–Marquardt method with α_k determined from (35) after finitely many iterations k_* , and

$$k_*(\delta, y^\delta) = O(1 + |\ln \delta|).$$

Moreover, the Levenberg–Marquardt iterates $x_{k_*}^\delta$ converge to a solution of $F(x) = y$ as $\delta \rightarrow 0$.

Convergence rates seem to be much harder to prove for the Levenberg–Marquardt method than for the iteratively regularized Gauss–Newton method (see section “Iteratively Regularized Gauss–Newton Method”). Suboptimal rates under source conditions (8) have been proven by Rieder [94, 95] under the nonlinearity assumption

$$F'(x) = R_x F'(x^\dagger) \quad \text{and} \quad \|I - R_x\| \leq c_R \|x - x^\dagger\|, \quad x \in \mathcal{B}_\rho(x_0) \subseteq \mathcal{D}(F), \quad (41)$$

where c_R is a positive constant. Only quite recently, Hanke [48, Theorem 2.1] proved the following optimal rates result:

Theorem 7. *Let a solution x^\dagger of (1) exist and let (41) as well as (8) hold with some $0 < \mu \leq 1/2$ and $\|v\|$ sufficiently small. Moreover, let α_k and k_* be chosen according to (35) and (10), respectively with $\tau > 2$ and $1 > q > 1/\tau$. Then the Levenberg–Marquardt iterates defined by (34) remain in $\mathcal{B}_\rho(x_0)$ and converge with the rate*

$$\|x_{k_*}^\delta - x^\dagger\| = O\left(\delta^{\frac{2\mu}{2\mu+1}}\right).$$

Finally, we quote the rates result [70, Theorem 4.7] that is almost optimal and instead of the a-posteriori choices of α_k and k_* , presumes a geometrically decreasing sequence of regularization parameters, i.e.,

$$\alpha_k = \alpha_0 q^k, \quad \text{for some } \alpha_0 > 0, \quad q \in (0, 1), \quad (42)$$

and the following a-priori stopping rule

$$\eta_{k_*} \alpha_{k_*}^{\mu+\frac{1}{2}} \leq \delta < \eta_k \alpha_k^{\mu+\frac{1}{2}}, \quad 0 \leq k < k_*, \quad \eta_k := \eta(k+1)^{-(1+\varepsilon)}, \\ \text{for some } \eta > 0, \quad \varepsilon > 0. \quad (43)$$

Theorem 8. *Let a solution x^\dagger of (1) exist and let (41) as well as (8) hold with some $0 < \mu \leq 1/2$ and $\|v\|$ sufficiently small. Moreover, let α_k and k_* be chosen according to (42) and (43) with η sufficiently small, respectively. Then the Levenberg–Marquardt iterates defined by (34) remain in $\mathcal{B}_\rho(x_0)$ and converge with the rate*

$$\|x_{k_*}^\delta - x^\dagger\| = O\left(\delta(1 + |\ln \delta|)^{(1+\varepsilon)})^{\frac{2\mu}{2\mu+1}}\right).$$

Moreover,

$$\|F(x_{k_*}^\delta) - y\| = O\left(\delta(1 + |\ln \delta|)^{(1+\varepsilon)}\right)$$

and

$$k_* = O(1 + |\ln \delta|).$$

For the noise free case ($\delta = 0, \eta = 0$) we obtain that

$$\|x_k - x^\dagger\| = O(\alpha_k^\mu),$$

and that

$$\|F(x_k) - y\| = O\left(\alpha_k^{\mu+\frac{1}{2}}\right).$$

Further Literature on Inexact Newton Methods

Hanke [47] and Rieder [94–96] have extended the Levenberg–Marquardt method by proposing regularization methods other than Tikhonov in the inexact solution of the Newton equation

$$x_{k+1}^\delta = x_k^\delta + \Phi(F'(x_k^\delta), y^\delta - F(x_k^\delta)),$$

with $\Phi(F'(x_k^\delta), y^\delta - F(x_k^\delta))$, e.g., defined by the conjugate gradient method.

Recently, Hochbruck et al. [53] proposed the application of an exponential Euler scheme to the Showalter differential equation

$$x'(t) = F'(x(t))^*(y^\delta - F(x_k^\delta)),$$

which leads to a Newton type iterative method of the form

$$x_{k+1}^\delta = x_k^\delta + h_k \phi(-h_k F'(x_k^\delta)^* F'(x_k^\delta)) F'(x_k^\delta)^*(y^\delta - F(x_k^\delta)),$$

with

$$\phi(z) = \frac{e^z - 1}{z}.$$

In [52] they show convergence using the discrepancy principle (10) as a stopping rule under condition (6), as well as optimal convergence rates under the condition that

$$F'(x) = R_x F'(x^\dagger) \quad \text{and} \quad \|I - R_x\| \leq c_R, \quad x \in \mathcal{B}_\rho(x^\dagger) \subseteq \mathcal{D}(F), \quad (44)$$

for some $c_R \in (0, 1)$, and under the source condition (8) with $\mu \leq 1/2$ for an appropriate choice of the pseudo time step size h_k .

Iteratively Regularized Gauss–Newton Method

In the Hilbert space setting, the variational formulation (33) of the iteratively regularized Gauss–Newton method can be equivalently written as

$$x_{k+1}^\delta = x_k^\delta + (F'(x_k^\delta)^* F'(x_k^\delta) + \alpha_k I)^{-1} (F'(x_k^\delta)^*(y^\delta - F(x_k^\delta)) + \alpha_k (x_0 - x_k^\delta)). \quad (45)$$

Here the sequence of regularization parameters is a-priori chosen such that

$$\alpha_k > 0, \quad 1 \leq \frac{\alpha_k}{\alpha_{k+1}} \leq r, \quad \lim_{k \rightarrow \infty} \alpha_k = 0, \quad (46)$$

for some $r > 1$.

This method was first proposed and analyzed by Bakushinskii [3], see also [5] and the references therein, as well as [15, 54, 66, 69, 70]. The results presented here and in section ‘‘Generalizations of the IRGNM’’ together with proofs and further details can be found in [70].

The key point in the convergence analysis of the iteratively regularized Gauss–Newton method is the fact that under a source condition (8) the error $\|x_{k+1}^\delta - x^\dagger\|$ is up to some *small* additional terms equal to $\alpha_k^\mu w_k(\mu)$ with $w_k(s)$ defined as in the following lemma that is easy to prove.

Lemma 1. *Let $K \in \mathcal{L}(\mathcal{X}, \mathcal{Y})$, $s \in [0, 1]$, and let $\{\alpha_k\}$ be a sequence satisfying $\alpha_k > 0$ and $\alpha_k \rightarrow 0$ as $k \rightarrow \infty$. Then it holds that*

$$w_k(s) := \alpha_k^{1-s} \|(K^* K + \alpha_k I)^{-1}(K^* K)^s v\| \leq s^s (1-s)^{1-s} \|v\| \leq \|v\| \quad (47)$$

and that

$$\lim_{k \rightarrow \infty} w_k(s) = \begin{cases} 0, & 0 \leq s < 1, \\ \|v\|, & s = 1, \end{cases}$$

for any $v \in \mathcal{N}(A)^\perp$.

Indeed, in the linear and noiseless case ($F(x) = Kx$, $\delta = 0$) we get from (45) using $Kx^\dagger = y$ and (8)

$$\begin{aligned} x_{k+1} - x^\dagger &= x_k - x^\dagger + (K^* K + \alpha_k I)^{-1}(K^* K(x^\dagger - x_k) + \alpha_k(x_0 - x^\dagger + x^\dagger - x_k)) \\ &= -\alpha_k(K^* K + \alpha_k I)^{-1}(K^* K)^\mu v \end{aligned}$$

To take into account noisy data and nonlinearity, we rewrite (45) as

$$\begin{aligned} x_{k+1}^\delta - x^\dagger &= -\alpha_k(K^* K + \alpha_k I)^{-1}(K^* K)^\mu v \\ &\quad - \alpha_k(K_k^* K_k + \alpha_k I)^{-1}(K^* K - K_k^* K_k) \\ &\quad (K^* K + \alpha_k I)^{-1}(K^* K)^\mu v \\ &\quad + (K_k^* K_k + \alpha_k I)^{-1} K_k^*(y^\delta - F(x_k^\delta) + K_k(x_k^\delta - x^\dagger)), \end{aligned} \quad (48)$$

where we set $K_k := F'(x_k^\delta)$, $K := F'(x^\dagger)$.

Let us consider the case that $0 \leq \mu < 1/2$ in (8) and assume that the nonlinearity condition (44) as well as $x_k^\delta \in \mathcal{B}_\rho(x^\dagger) \subseteq \mathcal{B}_{2\rho}(x_0)$ hold. Therewith, for the Taylor remainder we obtain that

$$\|F(x_k^\delta) - F(x^\dagger) - K_k(x_k^\delta - x^\dagger)\| \leq 2c_R \|K(x_k^\delta - x^\dagger)\|. \quad (49)$$

The estimates [see (47)]

$$\|(K_k^* K_k + \alpha_k I)^{-1}\| \leq \alpha_k^{-1}, \quad \|(K_k^* K_k + \alpha_k I)^{-1} K_k^*\| \leq \frac{1}{2} \alpha_k^{-\frac{1}{2}},$$

and the identity

$$K^* K - K_k^* K_k = K_k^* (R_{x_k^\delta}^{-1*} - R_{x_k^\delta}) K$$

imply that

$$\begin{aligned} & \|\alpha_k(K_k^* K_k + \alpha_k I)^{-1}(K^* K - K_k^* K_k)(K^* K + \alpha_k I)^{-1}(K^* K)^\mu v\| \\ & \leq \frac{1}{2} \alpha_k^{-\frac{1}{2}} \|R_{x_k^\delta}^{-1*} - R_{x_k^\delta}\| \|K(K^* K + \alpha_k I)^{-1}(K^* K)^\mu v\| \end{aligned}$$

This together with (2), (47), (48), and $F(x^\dagger) = y$ yields the estimate (50) in Lemma 2 below. Inserting the identity $K = R_{x_k^\delta}^{-1} K_k$ into (48) we obtain

$$\begin{aligned} K e_{k+1}^\delta &= -\alpha_k K(K^* K + \alpha_k I)^{-1}(K^* K)^\mu v \\ &\quad - \alpha_k R_{x_k^\delta}^{-1} K_k (K_k^* K_k + \alpha_k I)^{-1} K_k^* (R_{x_k^\delta}^{-1*} - R_{x_k^\delta}) K \\ &\quad (K^* K + \alpha_k I)^{-1}(K^* K)^\mu v \\ &\quad - R_{x_k^\delta}^{-1} K_k (K_k^* K_k + \alpha_k I)^{-1} K_k^* \\ &\quad (F(x_k^\delta) - F(x^\dagger) - K_k(x_k^\delta - x^\dagger) + y - y^\delta). \end{aligned}$$

Now the estimate (51) in Lemma 2 below follows together with (2), (44), (47), and (49).

Similarly one can derive estimates (52), (53) in case of $1/2 \leq \mu \leq 1$ under the Lipschitz condition (4), by using (5) and the decomposition

$$K^* K - K_k^* K_k = K_k^*(K - K_k) + (K^* - K_k^*)K.$$

Lemma 2. *Let (3), (8), (46) hold and assume that $x_k^\delta \in \mathcal{B}_\rho(x^\dagger)$. Moreover, set $K := F'(x^\dagger)$, $e_k^\delta := x_k^\delta - x^\dagger$, and let $w_k(\cdot)$ be defined as in (47).*

(i) *If $0 \leq \mu < 1/2$ and (44) hold, we obtain the estimates*

$$\|e_{k+1}^\delta\| \leq \alpha_k^\mu w_k(\mu) + c_R \alpha_k^\mu w_k(\mu + \tfrac{1}{2}) + \alpha_k^{-\frac{1}{2}} (c_R \|Ke_k^\delta\| + \tfrac{1}{2}\delta), \quad (50)$$

$$\begin{aligned} \|Ke_{k+1}^\delta\| &\leq (1 + 2c_R(1 + c_R)) \alpha_k^{\mu+\frac{1}{2}} w_k(\mu + \tfrac{1}{2}) \\ &\quad + (1 + c_R) (2c_R \|Ke_k^\delta\| + \delta). \end{aligned} \quad (51)$$

(ii) If $1/2 \leq \mu \leq 1$ and (4) hold, we obtain the estimates

$$\begin{aligned} \|e_{k+1}^\delta\| &\leq \alpha_k^\mu w_k(\mu) + L \|e_k^\delta\| (\tfrac{1}{2} \alpha_k^{\mu-\frac{1}{2}} w_k(\mu) + \|(K^* K)^{\mu-\frac{1}{2}} v\|) \\ &\quad + \tfrac{1}{2} \alpha_k^{-\frac{1}{2}} (\tfrac{1}{2} L \|e_k^\delta\|^2 + \delta), \end{aligned} \quad (52)$$

$$\begin{aligned} \|Ke_{k+1}^\delta\| &\leq \alpha_k \|(K^* K)^{\mu-\frac{1}{2}} v\| + L^2 \|e_k^\delta\|^2 (\tfrac{1}{2} \alpha_k^{\mu-\frac{1}{2}} w_k(\mu) + \|(K^* K)^{\mu-\frac{1}{2}} v\|) \\ &\quad + L \alpha_k^{\frac{1}{2}} \|e_k^\delta\| (\alpha_k^{\mu-\frac{1}{2}} w_k(\mu) + \tfrac{1}{2} \|(K^* K)^{\mu-\frac{1}{2}} v\|) \\ &\quad + (\tfrac{1}{2} L \alpha_k^{-\frac{1}{2}} \|e_k^\delta\| + 1) (\tfrac{1}{2} L \|e_k^\delta\|^2 + \delta). \end{aligned} \quad (53)$$

It is readily checked that the nonlinearity condition (44) used in Lemma 2 can be extended to

$$F'(\tilde{x}) = R(\tilde{x}, x) F'(x) + Q(\tilde{x}, x) \quad (54)$$

$$\|I - R(\tilde{x}, x)\| \leq c_R \quad (55)$$

$$\|Q(\tilde{x}, x)\| \leq c_Q \|F'(x^\dagger)(\tilde{x} - x)\| \quad (56)$$

for $x, \tilde{x} \in \mathcal{B}_{2\rho}(x_0)$, where c_R and c_Q are nonnegative constants.

With the a-priori stopping rule

$$k_* \rightarrow \infty \quad \text{and} \quad \eta \geq \delta \alpha_{k_*}^{-\frac{1}{2}} \rightarrow 0 \quad \text{as } \delta \rightarrow 0. \quad (57)$$

for $\mu = 0$ and

$$\eta \alpha_{k_*}^{\mu+\frac{1}{2}} \leq \delta < \eta \alpha_k^{\mu+\frac{1}{2}}, \quad 0 \leq k < k_*, \quad (58)$$

for $0 < \mu \leq 1$ one obtains optimal convergence rates as follows (see [70, Theorem 4.12]):

Theorem 9. Let (3), (8), (46) hold and let $k_* = k_*(\delta)$ be chosen according to (57) for $\mu = 0$ and (58) for $0 < \mu \leq 1$, respectively.

(i) If $0 \leq \mu < 1/2$, we assume that (54)–(56) hold and that $\|x_0 - x^\dagger\|$, $\|v\|$, η , ρ , c_R are sufficiently small.

(ii) If $1/2 \leq \mu \leq 1$, we assume that (4) and $\|x_0 - x^\dagger\|$, $\|v\|$, η , ρ are sufficiently small.

Then we obtain that

$$\|x_{k_*}^\delta - x^\dagger\| = \begin{cases} o(1), & \mu = 0, \\ O(\delta^{\frac{2\mu}{2\mu+1}}), & 0 < \mu \leq 1. \end{cases}$$

For the noise free case ($\delta = 0$, $\eta = 0$) we obtain that

$$\|x_k - x^\dagger\| = \begin{cases} o(\alpha_k^\mu), & 0 \leq \mu < 1, \\ O(\alpha_k), & \mu = 1, \end{cases}$$

and that

$$\|F(x_k) - y\| = \begin{cases} o(\alpha_k^{\mu+\frac{1}{2}}), & 0 \leq \mu < \frac{1}{2}, \\ O(\alpha_k), & \frac{1}{2} \leq \mu \leq 1. \end{cases}$$

With the discrepancy principle (10) as an a-posteriori stopping rule in place of the a-priori stopping rule (57), (58), optimal rates can be obtained under a Hölder type source condition (8) with $\mu \leq \frac{1}{2}$ (see [70, Theorem 4.13]):

Theorem 10. Let (3), (8), (46), and (54)–(56) hold for some $0 \leq \mu \leq 1/2$, and let $k_* = k_*(\delta)$ be chosen according to (10) with $\tau > 1$. Moreover, we assume that $\|x_0 - x^\dagger\|$, $\|v\|$, $1/\tau$, ρ , and c_R are sufficiently small. Then we obtain the rates

$$\|x_{k_*}^\delta - x^\dagger\| = \begin{cases} o(\delta^{\frac{2\mu}{2\mu+1}}), & 0 \leq \mu < \frac{1}{2}, \\ O(\sqrt{\delta}), & \mu = \frac{1}{2}. \end{cases}$$

In case $\mu = 0$, and with an a-posteriori choice of α_k similar to (35), the nonlinearity condition can be relaxed to (6), see [71].

Further Literature on Gauss–Newton Type Methods

Generalizations of the IRGNM

Already Bakushinskii in [4] proposed to replace Tikonov regularization in (45) by a more general method defined via functional calculus by a filter function g with $g(\lambda) \approx \frac{1}{\lambda}$:

$$x_{k+1}^\delta = x_0 + g(F'(x_k^\delta)^* F'(x_k^\delta)) F'(x_k^\delta)^* (y^\delta - F(x_k^\delta) - F'(x_k^\delta)(x_0 - x_k^\delta)), \quad (59)$$

with $\alpha_k \searrow 0$.

Still more general, one can replace the operator $g(F'(x_k^\delta)^* F'(x_k^\delta))F'(x_k^\delta)^*$ by some regularization operator $R_\alpha(F'(x))$ with

$$R_\alpha(F'(x)) \approx F'(x)^\dagger,$$

satisfying certain structural conditions so that the convergence analysis for the resulting Newton type method

$$x_{k+1}^\delta = x_0 + R_{\alpha_k}(F'(x_k^\delta))(y^\delta - F(x_k^\delta) - F'(x_k^\delta)(x_0 - x_k^\delta)). \quad (60)$$

(see [30, 55, 59, 61, 62, 70]) applies not only to methods defined via functional calculus such as iterated Tikhonov regularization, Landweber iteration, and Lardy's method but also to regularization by discretization.

An additional augmentation of the analysis concerns the type of nonlinearity condition. Alternatively to range invariance of the adjoint of $F'(x)$ (41), which is closely related to (6), one can consider range invariance of $F'(x)$ itself

$$F'(\tilde{x}) = F'(x)R(\tilde{x}, x) \quad \text{and} \quad \|I - R(\tilde{x}, x)\| \leq c_R \|\tilde{x} - x\| \quad (61)$$

for $x, \tilde{x} \in \mathcal{B}_{2\rho}(x_0)$ and some positive constant c_R .

Incorporation of convex constraints is considered in [66, 102].

Generalized Source Conditions

Convergence and optimal rates for the iteratively regularized Gauss–Newton method were established in [82] under a general source condition of the form

$$x^\dagger - x_0 = f(F'(x^\dagger)^* F'(x^\dagger))v, \quad v \in \mathcal{N}(F'(x^\dagger))^\perp,$$

with an index function $f : [0, \|F'(x^\dagger)\|^2] \rightarrow [0, \infty]$ that is increasing and continuous with $f(0) = 0$. These include logarithmic source conditions (9) that are appropriate for severely ill-posed problems. For this purpose, it is assumed that conditions (54)–(56) hold and the iteration is stopped according to the discrepancy principle (10).

Other A-posteriori Stopping Rules

Bauer and Hohage in [6] carry out a convergence analysis with the Lepskii balancing principle, i.e.,

$$\begin{aligned} k_* = \min \left\{ k \in \{0, \dots, k_{\max}\} : \|x_k^\delta - x_m^\delta\| \leq 8c_\Phi \alpha_m^{-1/2} \delta \right. \\ \left. \forall m \in \{k+1, \dots, k_{\max}\} \right\} \end{aligned} \quad (62)$$

(with $k_{\max} = k_{\max}(\delta)$ an a-priori determined index up to which the iterates are well defined) in place of the discrepancy principle as an a-posteriori stopping rule.

Optimal convergence rates are shown for (60) with R_α defined by Landweber iteration or (iterated) Tikhonov regularization under a condition similar to (54)–(56) if (8) with $\mu \leq 1/2$ or (9) holds, and under condition (4) if $\mu \geq 1/2$ in (8). The advantage of this stopping rule is that saturation at $\mu = 1/2$ is avoided.

Stochastic Noise Models

In many practical applications (e.g., in weather forecast), the data noise is not only of deterministic nature as assumed in our exposition, but also random noise has to be taken into account. In [8] Bauer, Hohage, and Munk consider the noise model

$$y^{\delta,\sigma} = F(x^\dagger) + \delta\eta + \sigma\xi$$

where $\eta \in \mathcal{Y}$, $\|\eta\| \leq 1$ describes the deterministic part of the noise with noise level δ , ξ is a normalized Hilbert space process in \mathcal{Y} (see, e.g., [13]) and σ^2 is the variance of the stochastic noise. Under a Hölder source condition (8) with $\mu > 1/2$ and assuming a Lipschitz condition (4), they show almost optimal convergence rates (i.e., with an additional factor that is logarithmic in σ) of (60) with R_α defined by iterated Tikhonov regularization and with the Lepskii balancing principle (62) as a stopping rule. The setting of Hohage and Werner [57] allows for an even much more general setting with regard to the stochastic noise.

Generalization to Banach Space

Bakushinski and Kokurin in [5] consider the setting $\mathcal{Y} = \mathcal{X}$ with \mathcal{X} Banach space. Using the Riesz–Dunford formula, they prove optimal convergence rates for the generalized Newton method (59) under the Lipschitz condition (4), provided a sufficiently strong source condition, namely (8) with $\mu \geq 1/2$ holds.

In [71], based on the variational formulation of the iteratively regularized Gauss–Newton method,

$$x_{k+1}^\delta = \arg \min_{x \in \mathcal{D}(F)} \|y^\delta - F(x_k^\delta) - F'(x_k^\delta)(x - x_k^\delta)\|^p + \alpha_k \|x - x_0\|^q$$

with $p, q \in (1, \infty)$ and Banach space norms, convergence in the general situation of possibly different Banach spaces \mathcal{X} , \mathcal{Y} without source condition under the nonlinearity assumption (6) is proved. Convergence rates under variational and approximate source conditions generalizing (8) to the Banach space setting are provided in the paper [65].

The convergence rates results in [57] even hold for more general data misfit as well as regularization functionals in place of Banach space norms. Results on Gauss–Newton methods with other regularization than Tikhonov (similarly to section “Generalizations of the IRGNM”) can be found, e.g., in [58, 68].

Efficient Implementation

To speed up convergence and save computational effort, it is essential to use preconditioning when applying an iterative regularization method R_α in (60).

Egger in [32] defines preconditioners for these iterations (Landweber iteration, CG, or the v -methods, see, e.g., [36]) via Hilbert scales (see, e.g., [36]), which leads to an iterative scheme of the form

$$x_{k+1}^\delta = x_0 + g(\mathcal{L}^{-2s} F'(x_k^\delta)^* F'(x_k^\delta)) \mathcal{L}^{-2s} F'(x_k^\delta)^* (y^\delta - F(x_k^\delta) - F'(x_k^\delta)(x_0 - x_k^\delta)),$$

where \mathcal{L} is typically a differential operator and s an appropriately chosen exponent. It is shown in [32] that this leads to a reduction of the number of iterations to about the square root.

In his thesis [81], Langer makes use of the close connection between the CG iteration and Lanczos' method in order to construct a spectral preconditioner that is especially effective for severely ill-posed problems.

Further strategies for saving computational effort are, e.g., multigrid [1, 42, 63, 67, 76], quasi Newton [41, 60], and adaptive discretization [72, 73] methods.

5 Nonstandard Iterative Methods

The methods presented above were based on the standard ideas of minimizing a least-squares functional, namely gradient descent and Newton methods. In the following we shall discuss further iterative methods, either not based on descent of the objective functional or based on descent for a different functional than least-squares.

Kaczmarz and Splitting Methods

Kaczmarz-type methods are used as splitting algorithms for large operators. They are usually applied if \mathcal{Y} and F can be split into

$$\mathcal{Y} = \mathcal{Y}_1 \times \mathcal{Y}_2 \times \cdots \times \mathcal{Y}_M$$

and

$$F = (F_1, F_2, \dots, F_M),$$

with continuous operators $F_j : \mathcal{X} \rightarrow \mathcal{Y}_j$. The corresponding least-squares problem is the minimization of the functional

$$J(x) = \frac{1}{2} \sum_{j=1}^M \|F_j(x) - y_j^\delta\|_{\mathcal{Y}_j}^2.$$

The basic idea of a Kaczmarz-type method is to apply an iterative scheme to each of the least-squares terms $\frac{1}{2} \|F_j(x) - y_j^\delta\|_{\mathcal{Y}_j}^2$ separately in substeps of the iteration. The three most commonly used approaches are the *Landweber–Kaczmarz method* (cf. [77])

$$x_{k+j/M}^\delta = x_{k+(j-1)/M}^\delta - \omega_k F'_j(x_{k+(j-1)/M}^\delta)^*(F_j(x_{k+(j-1)/M}^\delta) - y_j^\delta), \\ j = 1, \dots, M$$

the *nonlinear Kaczmarz method*

$$x_{k+j/M}^\delta = x_{k+(j-1)/M}^\delta - \omega_k F'_j(x_{k+j/M}^\delta)^*(F_j(x_{k+j/M}^\delta) - y_j^\delta), \quad j = 1, \dots, M$$

and the *Gauss–Newton–Kaczmarz method*

$$x_{k+j/M}^\delta = x_{k+(j-1)/M}^\delta - (F'_j(x_{k+(j-1)/M}^\delta)^* F'_j(x_{k+(j-1)/M}^\delta) + \alpha_{k,j} I)^{-1} \\ F'_j(x_{k+(j-1)/M}^\delta)^*(F_j(x_{k+(j-1)/M}^\delta) - y_j^\delta).$$

Further Newton–Kaczmarz methods can be constructed in the same way as iteratively regularized and inexact Newton methods (cf. [19]).

The Landweber–Kaczmarz and the nonlinear Kaczmarz method can be interpreted as time discretization by operator splitting for the minimizing flow

$$x'(t) = - \sum_{j=1}^M F'_j(x(t))^*(F_j(x(t)) - y_j^\delta),$$

with forward, respectively, backward Euler operator splitting (cf. [38, 92]). The nonlinear Kaczmarz method is actually a special case of the *Douglas–Rachford splitting algorithm* applied to the above least-squares problem, the iterate $x_{k+j/M}^\delta$ can be computed as a minimizer of the Tikhonov-type functional

$$J_{k,j}(x) = \frac{1}{2} \|F_j(x) - y_j^\delta\|_{\mathcal{Y}_j}^2 + \frac{1}{2\tau} \|x - x_{k+(j-1)/M}^\delta\|^2.$$

The convergence analysis of Kaczmarz methods is very similar to the analysis of the iterative methods mentioned above, if nonlinearity conditions on each single operator F_j are posed (cf. [43, 44, 77] for the Landweber–Kaczmarz, [10, 19, 83] for Newton–Kaczmarz, [9, 27] for nonlinear Kaczmarz and further variants). The verification of those conditions is usually an even harder task than for the collection of operators $F = (F_1, \dots, F_M)$, also due to the usually large nullspace of their linearizations. The analysis can however provide at least a good idea on the convergence behavior of the algorithms. A nontrivial point in Kaczmarz methods is an a-posteriori stopping criterion, since in general the overall residual is not decreasing, which rules out standard approaches such as the discrepancy principles. Some discussions of this issue can be found in [43], where criteria based on the sequence of residuals $(\|F(x_{k+j/M}^\delta) - y_j^\delta\|)_{j=1,\dots,M}$ have been introduced, supplemented by additional skipping strategies.

Kaczmarz methods have particular advantages in inverse problems for partial differential equations, when many state equations for different parameters (e.g., different boundary values or different sources) need to be solved. Then the operators

F_j can be set up such that a problem for one state equation can be solved after the other, which is memory efficient. We mention that in this case also the Landweber iteration can be carried out in the same memory-efficient way, since

$$F'(x)^*(F(x) - y^\delta) = \sum_{j=1}^M F'_j(x)^*(F_j(x) - y_j^\delta).$$

But in most cases one observes faster convergence for the Kaczmarz-type variant, which is similar as comparing classical Jacobi and Gauss–Seidel methods.

Splitting methods are frequently used for the iterative solution of problems with variational regularization of the form

$$x_\alpha^\delta \in \arg \min_x \left[\frac{1}{2} \|F(x) - y^\delta\|^2 + \alpha R(x) \right],$$

where $R : \mathcal{X} \rightarrow \mathbb{R} \cup \{+\infty\}$ is an appropriate convex regularization functional. It is then natural to apply operator splitting to the least-squares part and the regularization part, if R is not quadratic. The most important approaches are the *Douglas–Rachford splitting* (in particular for linear operators F , cf. [31])

$$\begin{aligned} x_{k+1/2}^\delta &\in \arg \min_x \left[\frac{1}{2} \|F(x) - y\|^2 + \frac{1}{2\omega_k} \|x - x_k^\delta\|^2 \right] \\ x_{k+1}^\delta &\in \arg \min_x \left[R(x) + \frac{1}{2\omega_k} \|x - x_{k+1/2}^\delta\|^2 \right] \end{aligned}$$

and the *forward–backward splitting algorithm* (cf. [84])

$$\begin{aligned} x_{k+1/2}^\delta &= x_k^\delta - \omega_k F'(x_k^\delta)^*(F(x_k^\delta) - y^\delta) \\ x_{k+1}^\delta &\in \arg \min_x \left[R(x) + \frac{1}{2\omega_k} \|x - x_{k+1/2}^\delta\|^2 \right] \end{aligned}$$

Such algorithms are particularly popular for nonsmooth regularization (cf. [25]), in the case of sparsity enforcing penalties (ℓ^1 -norms) the second step in both algorithms can be computed explicitly via shrinkage (thresholding) formulas, such schemes are hence also called *iterative shrinkage* (cf. [26]).

EM Algorithms

A very popular algorithm in the case of image reconstruction with nonnegativity constraints is the *expectation maximization (EM) method*, also called *Richardson–Lucy algorithm* (cf. [12, 86]). In the case of $F : L^1(\Omega) \rightarrow L^1(\Sigma)$ being a linear operator, it is given by the multiplicative fixed-point scheme

$$x_{k+1}^\delta = x_k^\delta F^* \left(\frac{y^\delta}{Fx_k^\delta} \right). \quad (63)$$

For F and F^* being positivity preserving operators (such as the Radon transform or convolutions with positive kernels), the algorithm preserves the positivity of an initial value x_0^δ if the data y^δ are positive, too. Positivity of data is a too strong restriction in the case of an additive noise model, like stochastic Gaussian models or bounds in squared L^2 -distances. It is however well suited for multiplicative models such as Poisson models used for imaging techniques based on counting emitted particles (photons or positrons). The log-likelihood functional of a Poisson model, respectively its asymptotic for large count rates, can also be used to derive a variational interpretation of the EM-algorithm. More precisely (63) is a descent method for the functional

$$J(x) := \int_{\Sigma} \left[y^\delta \log \left(\frac{y^\delta}{Fx} \right) - y^\delta + Fx \right] d\sigma,$$

which corresponds to the *Kullback–Leibler divergence* (relative entropy) between the output Fx and the data y^δ . Minimizing J over nonnegative functions leads to the optimality condition

$$x \left(-F^* \left(\frac{y^\delta}{Fx} \right) + F^* 1 \right) = 0.$$

With appropriate operator scaling $F^* 1 = 1$ this yields the fixed-point equation

$$x = x F^* \left(\frac{y^\delta}{Fx} \right),$$

which is the basis of the EM-algorithm:

$$x_{k+1}^\delta = \frac{x_k^\delta}{F^* 1} F^* \left(\frac{y^\delta}{Fx_k^\delta} \right).$$

The EM-algorithm or Richardson–Lucy algorithm (cf. [103]) is a special case of the general EM framework by Dempster, Laird, and Rubin (cf. [29]).

Performing an analogous analysis for a nonlinear operator $F : L^1(\Omega) \rightarrow L^1(\Sigma)$ we are led to the fixed-point equation

$$xF'(x)^* 1 = xF'(x)^* \left(\frac{y^\delta}{Fx} \right).$$

Since it seems unrealistic to scale $F'(x)^*$ for arbitrary x it is more suitable to keep the term and divide by $F'(x)^* 1$. The corresponding fixed-point iteration is the *nonlinear EM algorithm*

$$x_{k+1}^\delta = \frac{x_k^\delta}{F'(x_k^\delta)^* 1} F'(x_k^\delta)^* \left(\frac{y^\delta}{F(x_k^\delta)} \right).$$

The convergence analysis in the nonlinear case is still widely open. Therefore, we only comment on the case of linear operators F here (cf. also [85, 86] for details). In order to avoid technical difficulties the scaling condition $F^*1 = 1$ will be assumed in the following. The major ingredients are reminiscent of the convergence analysis of the Landweber iteration, but they replace the norm distance by the Kullback–Leibler divergence

$$KL(x, \tilde{x}) = \int_{\Omega} \left[x \log \frac{x}{\tilde{x}} - x + \tilde{x} \right] d\omega,$$

which is a nonnegative distance, but obviously not a metric. First of all, x_k^δ can be characterized as a minimizer of the (convex) functional

$$J_k(x) := -J(x) + KL(x_{k+1}^\delta, x)$$

over all nonnegative L^1 -functions, given x_{k+1}^δ . Thus, comparing with the functional value at x_{k+1}^δ we find that the likelihood functional J decreases during the iteration, more precisely

$$J(x_{k+1}^\delta) \leq J(x_k^\delta) - KL(x_{k+1}^\delta, x_k^\delta).$$

This part of the analysis holds also in the case of exact data. The second inequality directly concerns the dissipation of the Kullback–Leibler divergence between the iterates and a solution, hence assumes the existence of x^\dagger with $Fx^\dagger = y$. Using convexity arguments one obtains

$$KL(x^\dagger, x_{k+1}) + J(x_k) \leq KL(x^\dagger, x_k).$$

Hence, together with the monotonicity of $(J(x_j))_{j \in \mathbb{N}}$

$$KL(x^\dagger, x_k) + kJ(x_k) \leq KL(x^\dagger, x_k) + \sum_{j=0}^{k-1} J(x_j) \leq KL(x^\dagger, x_0),$$

which implies boundedness of the Kullback–Leibler divergence (hence a weak compactness of x_k in L^1) and convergence $J(x_k) \rightarrow 0$ analogous to the arguments for the Landweber iteration.

The noisy case is less clear, apparently also due to the difficulties in defining a reasonable noise level for Poisson noise. An analysis defining the noise level in terms of the likelihood of the noisy data has been given in [93]. Further analysis in the case of noisy data seems to be necessary, however. This also concerns stopping rules for noisy data, which are usually based on the noise level. A promising multiscale stopping criterion based on the stochastic modeling of Poisson noise has been introduced and tested recently (cf. [14]). For a combination of EM with Kaczmarz ideas, see [45].

Iterative methods are also used for Penalized EM-Reconstruction (equivalently Bayesian MAP estimation), i.e., for minimizing

$$J(x) + \alpha R(x)$$

over nonnegative L^1 -functions, where $\alpha > 0$ is a regularization parameter and R is an appropriate regularization functional, e.g., total variation or negative entropy.

A frequently used modification of the EM algorithm in this case is Green's One-Step-Late (OSL) method (see [39, 40]).

$$x_{k+1}^\delta = \frac{x_k^\delta}{F^* 1 + \alpha R'(x_k)} F^* \left(\frac{y^\delta}{F x_k^\delta} \right),$$

which seems efficient if the pointwise sign of $R'(x_k)$ can be controlled, e.g., for entropy-type regularization functionals

$$R(x) = \int_{\Omega} E(x)$$

with convex $E : \Omega \rightarrow \mathbb{R}^+$ and $E'(0) = 0$. The additional effort compared to EM is negligible and the method converges reasonably fast to a minimizer of $J + \alpha R$. For other important variational regularization methods, in particular gradient-based functionals, the OSL method is less successful, since $R'(x_k)$ does not necessarily have the same sign as x_k , thus $F^* 1 + \alpha R'(x_k)$ can be negative or zero, in which case the iteration has to be stopped or some ad-hoc fixes have to be introduced. Another obvious disadvantage of the OSL method is the fact that it cannot handle nonsmooth regularizations such as total variation and ℓ^1 -norms, which are often used to incorporate structural prior knowledge. As a more robust alternative, splitting methods have been introduced also in this case. In [97] a positivity-preserving forward–backward splitting algorithm with particular focus on total variation regularization has been introduced. The two-step algorithm alternates the classical EM-step with a weighted denoising problem

$$\begin{aligned} x_{k+1/2}^\delta &= x_k^\delta F^* \left(\frac{y^\delta}{F x_k^\delta} \right) \\ x_{k+1}^\delta &\in \arg \min_x \left[\int_{\Omega} \frac{(x - x_{k+1/2}^\delta)^2}{x_k^\delta} + \alpha R(x) \right]. \end{aligned}$$

Convergence can be ensured with further damping, i.e., if the second half step is replaced by

$$x_{k+1}^\delta \in \arg \min_x \left[\int_{\Omega} \frac{(x - \omega_k x_{k+1/2}^\delta - (1 - \omega_k)x_k^\delta)^2}{x_k^\delta} + \alpha R(x) \right]$$

with $\omega_k \in (0, 1)$ sufficiently small. This algorithm is a semi-implicit approximation of the optimality condition

$$-F^* \left(\frac{y^\delta}{F_x} \right) + 1 + \alpha p = 0, \quad p \in \partial R(x),$$

where the operator-dependent first part is approximated explicitly and the regularization part p implicitly. What seems surprising is that the constant 1 is approximated by $x_{k+1}^\delta/x_k^\delta$, which however turns out to be crucial for preserving positivity.

Bregman Iterations

A very general way of constructing iterative methods in Banach spaces are iterations using so-called *Bregman distances*. For a convex functional R , the Bregman distance is defined by

$$D_R^p(\tilde{x}, x) = R(\tilde{x}) - R(x) - \langle p, \tilde{x} - x \rangle, \quad p \in \partial R(x).$$

Note that for nonsmooth R the subgradient is not single-valued, hence the distance depends on the choice of the specific subgradient. Bregman distances are a very general class of distances in general, the main properties are $D_R^p(\tilde{x}, x) \geq 0$ and $D_R^p(x, x) = 0$. Particular cases are

$$D_R^p(\tilde{x}, x) = \frac{1}{2} \|\tilde{x} - x\|^2 \quad \text{for } R(x) = \frac{1}{2} \|x\|^2$$

and the Kullback–Leibler divergence for R being a logarithmic entropy functional.

If some data similarity measure $H(F(x), y^\delta)$ and a regularization functional R is given, the Bregman iteration (cf. [16, 91] in its original, different context) consists of

$$x_{k+1}^\delta \in \arg \min_x [H(F(x), y^\delta) + D_R^{p_k}(x, x_k^\delta)]$$

with the dual update

$$p_{k+1} = p_k - \partial_x H(F(x_{k+1}^\delta), y^\delta) \in \partial R(x_{k+1}^\delta).$$

The Bregman iteration is a primal–dual method in the sense that it computes an update for the primal variable x as well as for the dual variable $p \in \partial R(x)$. Consequently one also needs to specify an initial value for the subgradient $p_0 \in \partial R(x_0^\delta)$.

Most investigations of the Bregman iteration have been carried out for H being a squared norm, i.e., the least-squares case discussed above

$$H(F(x), y^\delta) = \frac{1}{2} \|F(x) - y^\delta\|^2.$$

Under appropriate nonlinearity conditions a full convergence analysis can be carried out (cf. [2]), in general only leading to some weak convergence and convergence in the Bregman distance. If F is a nonlinear operator, further approximations in the Bregman iterations by linearization are possible leading to the Landweber-type method (also called linearized Bregman iteration)

$$x_{k+1}^\delta \in \arg \min_x \left[\langle F'(x_k^\delta)(x - x_k^\delta), F(x_k^\delta) - y^\delta \rangle + D_R^{p_k}(x, x_k^\delta) \right]$$

and Levenberg–Marquardt type method

$$x_{k+1}^\delta \in \arg \min_x \left[\frac{1}{2} \|F(x_k^\delta) + F'(x_k^\delta)(x - x_k^\delta) - y^\delta\|^2 + D_R^{p_k}(x, x_k^\delta) \right].$$

Both schemes have been analyzed in [2], see also [21–23] for the linearized Bregman iteration in compressed sensing. We mention that in particular the linearized Bregman method does not work with an arbitrary convex regularization functional. In order to guarantee that the functional to be minimized in each step of the iteration is bounded from below so that the iterates are well defined, a quadratic part in the regularization term is needed.

A discussion of Bregman iterations in the case of nonquadratic term H can be found in [17, 18, 50] with particular focus on F being a linear operator. In this case also a dual Bregman iteration can be constructed, which coincides with the original one in the case of quadratic H , but differs in general. For this dual Bregman iterations also convergence rates under appropriate source conditions can be shown (cf. [18]), which seems out of reach for the original Bregman iteration for general H . A systematic analysis of Bregman iterations in image restoration can be found in [20]. In [11], Bregman iterations are used to enhance generalized total variation and infimal convolution regularization.

6 Conclusion

Iterative methods offer an attractive alternative to variational regularization but are also closely linked to them via iterative optimization. In this chapter we aimed at giving a broad overview on the main classical (gradient and Newton type) as well as nonstandard (Kaczmarz, expectation maximization, Bregman) iterations. We put an emphasis on their regularizing properties for nonlinear ill-posed problems in Hilbert spaces and provided outlooks on further aspects such as efficient implementation, stochastic noise models, or formulations in Banach spaces.

Abstract

In this chapter, an introduction is given into the use of level set techniques for inverse problems and image reconstruction. Several approaches are presented which have been developed and proposed in the literature since the publication of the original (and seminal) paper by F. Santosa in 1996 on this topic. The emphasis of this chapter, however, is not so much on providing an exhaustive overview of all ideas developed so far but on the goal of outlining the general idea of structural inversion by level sets, which means the reconstruction of complicated images with interfaces from indirectly measured data. As case studies, recent results (in 2D) from microwave breast screening, history matching in reservoir engineering, and crack detection are presented in order to demonstrate the general ideas outlined in this chapter on practically relevant and instructive examples. Various references and suggestions for further research are given as well.

1 Introduction

Level Set Methods for Inverse Problems and Image Reconstruction

The level set technique has been introduced for the solution of inverse problems in the seminal paper of Santosa [82]. Since then, it has developed significantly and appears to become now a standard technique for solving inverse problems with interfaces. However, there are still a large number of unresolved problems and open questions related to this method, which keeps fuelling active research on it worldwide. This chapter can only give a rough overview of some techniques which have been discussed so far in the literature. For more details which go beyond the material covered here, the reader is referred to the recent review articles [20, 31–

[33, 92], each of them providing a slightly different view on the topic and making available a rich set of additional references which the interested reader can follow for further consultation.

Images and Inverse Problems

An *image*, as referred to in this chapter, is a (possibly vector-valued) function which assigns to each point of a given domain in 2D or in 3D one or more physical parameter values which are characteristic for that point. An image often contains *interfaces*, across which one or more of these physical parameters change value in a discontinuous manner. In many applications, these interfaces coincide with physical interfaces between different materials or regions. These interfaces divide the domain Ω in subdomains Ω_k , $k = 1, \dots, K$ of different region-specific internal *parameter profiles*. Often, due to the different physical structures of each of these regions, quite different mathematical models might be most appropriate for describing them in the given context.

Since the image represents physical parameters, it can be tested by physical inspection. Here, the physical parameters typically appear in partial differential equations (PDEs) or in integral equations (IEs) as space-dependent coefficients, and various probing fields are created for measuring the response of the image to these inputs. Due to physical restrictions, these measurements are typically only possible at few discrete locations, often situated at the boundary of the domain Ω , but sometimes also at a small number of points inside Ω . If the underlying PDE is time dependent, then these measurements can be time-dependent functions. The corresponding measured *data* give information on the spatial distribution of the subdomains and on the corresponding internal model parameters.

Sometimes the physical interpretation of the image is that of a source distribution rather than a parameter distribution. Then, the image itself creates the probing field and needs to be determined from just one set of measured data. Also combinations are possible where some components of the (vector-valued) image describe source distributions and other components describe parameter distributions. Initial conditions or boundary conditions can also often be interpreted as images in this spirit, which need to be determined from indirect data. It is clear that this concept of an image can be generalized even further, which leads to interesting mathematical problems and concepts.

There is often a large variety of additional *prior information* available for determining the image, whose character depends on the given application. For example, it might be known or assumed that all parameter profiles inside the individual subregions of a domain Ω are constant with known or unknown region-specific values. In this particular case, only the interfaces between the different regions, and possibly the unknown parameter values, need to be reconstructed from the gathered data, which, as a mathematical problem, is much better posed [37, 71] than the task of estimating independent values at each individual pixel or voxel from the same data set without additional prior information on the image. However, in many realistic applications, the image to be found is more complicated, and even

the combined available information is not sufficient or adequate for completely and uniquely determining the underlying image. This becomes even worse due to typically noisy or incomplete data, or due to model inaccuracies. Then, it needs to be determined which information on the image is desired and which information can reasonably be expected from the data, taking into account the available additional prior information. Depending on the specific application, different viewpoints are typically taken which yield different strategies for obtaining images which agree (in an application-specific sense) with the given information. We will give some instructive examples further below.

Determining an image (or a set of possible images) from the measured data, in the above-described sense and by taking into account the available additional prior information, is called here *imaging* or *image reconstruction*. In practice, images are often represented in a computer and thereby need to be discretized somehow. The most popular discretization model uses 2D pixels or 3D voxels for representing an image, even though alternative models are possible. Often the underlying PDE also needs to be discretized on some grid, which could be done by finite differences, finite volumes, finite elements, and other techniques. The discretization for the image does not necessarily need to be identical to the discretization used for solving the PDE, and sometimes different models are used for discretizing the image and the PDE. However, in these cases, some method needs to be provided to map from one representation to the other. In a level set representation of an image, also the level set functions need to be discretized for being represented in a computer. The above said then holds true also for the discretizations of the level set functions, which could either follow the same model as the PDE and/or a pixel model for the image or follow a different pattern.

The Forward and the Inverse Problem

In this chapter, it is supposed that data \tilde{g} are given in the form

$$\tilde{g} = \mathcal{M}\tilde{\mathbf{u}}, \quad (1)$$

where \mathcal{M} denotes a linear measurement operator, and $\tilde{\mathbf{u}}$ are the physical states created by the sources \mathbf{q} for probing the image. It is assumed that a physical model $\Lambda(b)$ is given, which incorporates the (possibly vector-valued) model parameter b and which is able to (roughly) predict the probing physical states when being plugged into an appropriate numerical simulator, provided the correct sources and physical parameters during the measurement process were known. The forward operator \mathcal{A} is defined as

$$\mathcal{A}(b, \mathbf{q}) = \mathcal{M}\Lambda(b)^{-1}\mathbf{q}. \quad (2)$$

As mentioned, $\Lambda(b)$ is often described in a form of some partial differential equation (PDE) or, alternatively, an integral equation (IE), and the individual coefficients of the model parameter b appear at one or several places in this model

as space-dependent coefficients. In most applications, measurements are taken only at few locations of the domain, for example, at the boundary of the area of interest, from which the physical parameters b or the source \mathbf{q} (or both) need to be inferred in the whole domain. It is said that with respect to these unknowns, the measurements are indirect: They are taken not at the locations where the unknowns need to be determined but indirectly by their overall impact on the states (modeled by the underlying PDE or IE) probing the image, which are measured only at few locations. The behavior of the states is modeled by the operator \mathcal{A} in (2). If in \mathcal{A} only b (but not \mathbf{q}) is unknown, then the problem is an inverse parameter or inverse scattering problem. If in \mathcal{A} only \mathbf{q} (but not b) is unknown, then the problem is an inverse source problem. Given measured data \tilde{g} , the “residual operators” \mathcal{R} are correspondingly given by

$$\mathcal{R}(b, \mathbf{q}) = \mathcal{A}(b, \mathbf{q}) - \tilde{g}. \quad (3)$$

Given the above definitions, an *image* is defined here as a mapping

$$a : \Omega \rightarrow \mathbb{R}^n,$$

where Ω is a bounded or unbounded region in \mathbb{R}^2 or in \mathbb{R}^3 and n is the number of components of the (vector-valued) image. Each component function a_k , $k = 1, \dots, n$, represents a space-dependent physical characteristic of the domain Ω which can be probed by physical inspection. If it appears as a coefficient of a PDE (or IE), it is denoted $a_k = b_k$, and if it appears as a source, it is denoted $a_k = q_k$. The exposition given in this chapter mainly focuses on the recovery of parameter distributions $a_k = b_k$ and addresses several peculiarities related to those cases. However, the main concepts carry over without major changes to inverse source problems and also to some related formulations as, for example, the reconstruction of boundary or initial conditions of PDEs.

2 Examples and Case Studies

Some illustrative examples and case studies are presented in the following, which will be used further on in this chapter for demonstrating basic ideas and concepts on realistic and practical situations.

Example 1: Microwave Breast Screening

Figure 1 shows two-dimensional images from the application of microwave breast screening. The images of size 160×160 pixels have been constructed synthetically based on MRI images of the female breast. Three representative breast structures are displayed in the three images of the left column, where the value at each pixel of the images represents the physical parameter “static relative permittivity.”

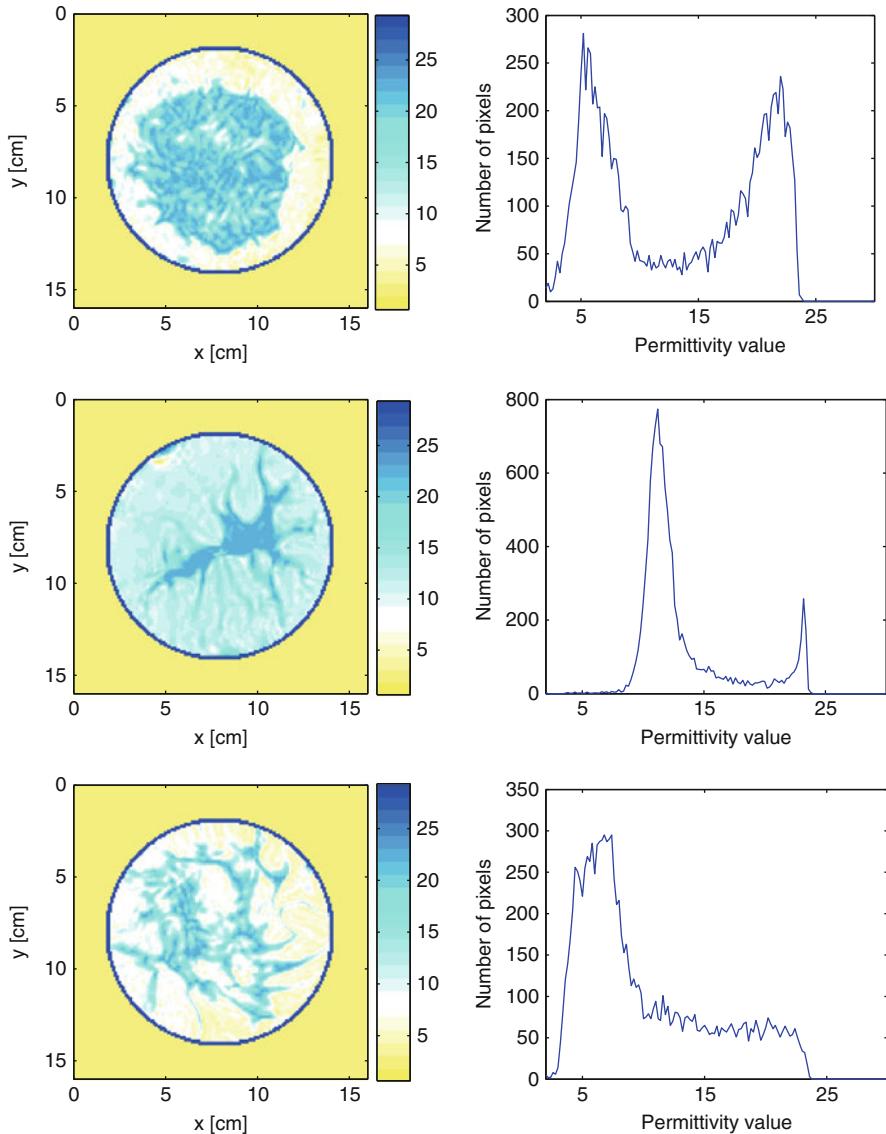

Fig. 1 Three images from microwave breast screening. The three images are synthetically generated from MRI breast models. *Left column:* two-dimensional maps of the distribution of the static permittivity ε_{st} inside the three breast models. *Right column:* the corresponding histograms of values of ε_{st} in each map

A commonly accepted model for breast tissue is to roughly distinguish between skin, fatty tissue and fibroglandular tissue. In the images also a matching liquid is shown in which the breast is immersed. Inside the breast, regions can be identified easily which correspond to fibroglandular tissue (high static relative permittivity

values) and fatty tissue (low static relative permittivity values), separated by a more or less complicated interface. On the right column, histograms are shown for the distributions of static relative permittivity values inside the breast. In these histograms, it becomes apparent that values for fatty and fibroglandular tissue are clustered around two typical values, but with a broader range of distribution. However, a clear identification of fatty and fibroglandular tissue cannot be made easily for each pixel of the image based on just these values.

Nevertheless, during a reconstruction, and from anatomical reasoning, it does make sense to assume a model where fatty and fibroglandular tissue occupy some subregions of the breast where a sharp interface exists between these subregions. Finding these subregions provides valuable information for the physician. Furthermore, it might be sufficient for an overall evaluation of the situation to have a smoothly varying profile of tissue parameters reconstructed inside each of these subregions, allowing for the choice of a smoothly varying profile of static relative permittivity values inside each region. In the same spirit, from anatomical reasoning, it makes sense to assume a sharp interface (now of less complicated behavior) separating the skin region from the fatty/fibroglandular tissue on the one side and from the matching liquid on the other side. It might also be reasonable to assume that the skin and the matching liquid have constant static permittivity values, which might be known or not. If a tumor in its early stage of development is sought in this breast model, it will occupy an additional region of small size (and either simple or complicated shape and topology) and might have constant but unknown static relative permittivity value inside this region.

During a reconstruction for breast screening, this set of plausible assumptions provides us with a complex mathematical breast model which incorporates this prior information and might yield an improved and more realistic image for the reconstructed breast (including a better estimate of the tumor characteristics) than a regular pixel-based inversion would be able to provide. This is so because it is assumed that the real breast follows roughly the complicated model constructed above and that this additional information is taken into account in the inversion.

In this application, the underlying PDE is the system of time-harmonic Maxwell's equations, or its 2D representative (describing so-called TM-waves), a Helmholtz equation. The "static relative permittivity," as mapped in Fig. 1, represents one parameter entering in the wavenumber of the Debye dispersion model. The electromagnetic fields are created by specifically developed microwave antennas surrounding the breast, and the data are gathered at different microwave antennas also located around the breast. For more details, see [52].

Example 2: History Matching in Petroleum Engineering

Figure 2 shows a synthetically created 2D image of a hydrocarbon reservoir during the production process. Circles indicate injection wells, and crosses indicate production wells. The physical parameter displayed in the image is the permeability, which affects fluid flow in the reservoir. Physically, two lithofacies can be distinguished in this image, namely, sandstone and shaly sandstone (further on simply

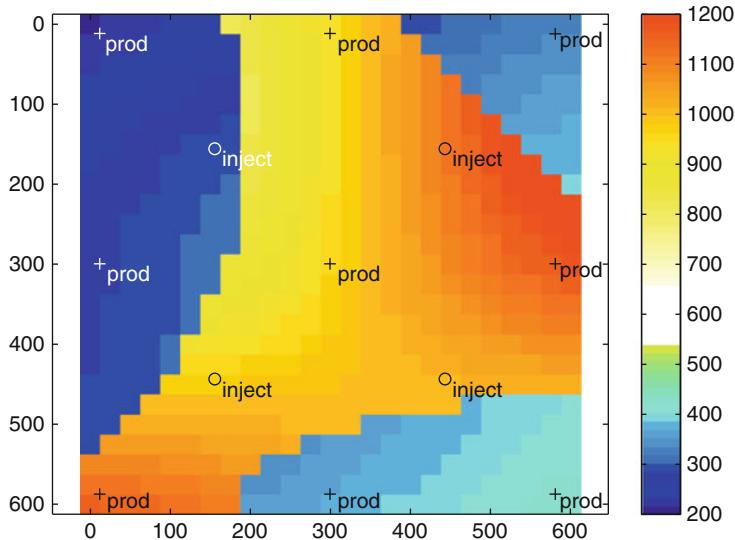

Fig. 2 An image from reservoir engineering. Shown is the permeability distribution of a fluid flow model in a reservoir which consists of a sandstone lithofacie (values in the range of 150–500 mDarcy) and a shaly sandstone lithofacie (values in the range 900–1,300 mDarcy), separated by a sharp interface. The sandstone region shows an overall linear trend in the permeability distribution, whereas the shaly sandstone region does not show any clear trend

called “shale”). The sandstone region has permeability values roughly in the range 150–500 mDarcy, whereas shale has permeability values more in the range 900–1,300 mDarcy. In petroleum engineering applications, the parameters inside a given lithofacie sometimes follow an overall linear trend, which is the case here inside the sandstone region. This information is often available from geological evaluation of the terrain. As a rough approximation, inside this region, the permeability distribution can be modeled mathematically as a smooth perturbation of a bilinear model. Inside the shale region, no trend is observed or expected, and therefore the permeability distribution is described as a smooth perturbation of a constant distribution (i.e., an overall smoothly varying profile).

During a reconstruction, a possible model would be to reconstruct a reservoir image from production data which consists of three different quantities: (1) the interface between the sandstone and shale lithofacies, (2) the smooth perturbation of the constant profile inside the shale region, and (3) the overall trend (i.e., the bilinear profile) inside the sandstone region, assuming that inside this sandstone region the smooth perturbation is small compared to this dominant overall trend. In this application, the PDE is a system of equations modeling two-phase or three-phase fluid flow in a porous medium, of which the relative permeability is one model parameter.

The “fields” (in a slightly generalized sense) are represented in this application by pressure values and water/oil saturation values at each point inside the reservoir

during production and are generated by injecting (under high pressure) water in the injection wells and extracting (imposing lower pressure) water and oil from the production wells. The data are the injection and production rates of water and oil, respectively, and sometimes pressure values measured at injection and production wells over production time. For more details, see [35].

Example 3: Crack Detection

Figure 3 shows an image of a disconnected crack embedded in a homogeneous material. The cracks are represented in this simplified model as very thin regions of fixed thickness. The physical parameter represented by the image is the conductivity distribution in the domain. Only two values can be assumed by this conductivity, one inside the thin region (crack) and another one in the background. The background value is typically known, and the value inside the crack might either be approximately known or it might be an unknown of the inverse problem. The same holds true for the thickness of the crack, which is assumed constant along the cracks, even though the correct thickness (the constant) might become an unknown of the inverse problem as well. Here insulating cracks are considered, where the conductivity is significantly lower than in the background. The probing fields inside the domain are the electrostatic potentials which are produced by applying voltages at various locations along the boundary of the domain, and the data are the corresponding currents across the boundary at discrete positions.

This model can be considered as a special case of a binary medium where volumetric inclusions are embedded in a homogeneous background. However, the fact that these structures are very thin with fixed thickness requires some special treatment during the shape evolution, which will be commented on further below. In this application, the underlying PDE is a second-order elliptic equation modeling the distribution of electric potentials in the domain for a set of given applied voltage patterns. For more details, see [4].

3 Level Set Representation of Images with Interfaces

A complex image in the above sense needs a convenient mathematical representation in order to be dealt with in a computational and mathematical framework. In this section, several different approaches are listed which have been proposed in the literature for describing images with interfaces by a level set technique. First, the most basic representation is given, which only considers binary media. Afterwards, various representations are described which represent more complicated situations.

The Basic Level Set Formulation for Binary Media

In the shape inverse problem in its simplest form, the parameter distribution is described by

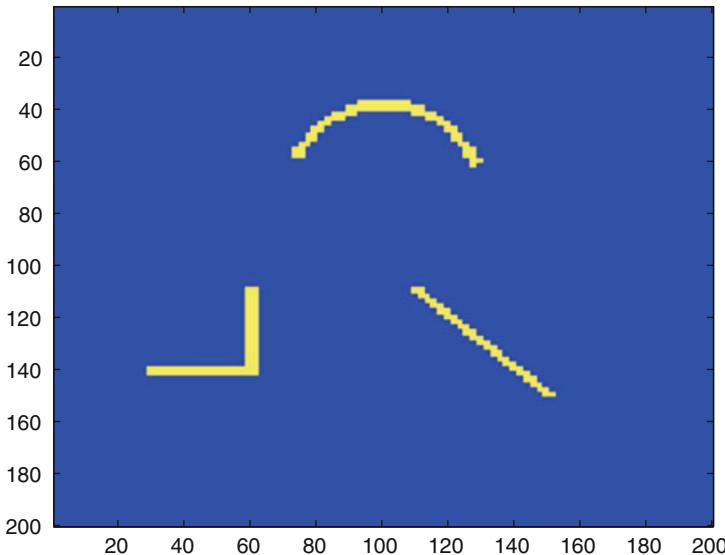

Fig. 3 An image from the application of crack detection. Three disconnected crack components are embedded in a homogeneous background medium and need to be reconstructed from electrostatic measurements at the region boundary. In the considered case of insulating cracks, these components are modeled as thin shapes of fixed thickness with a conductivity value much lower than the background conductivity

$$b(\mathbf{x}) = \begin{cases} b^{(i)}(\mathbf{x}) & \text{in } D \\ b^{(e)}(\mathbf{x}) & \text{in } \Omega \setminus D \end{cases}, \quad (4)$$

where $D \subset \Omega$ is a subregion of Ω and where usually discontinuities in the parameters b occur at the interface ∂D . In the *basic level set representation for the shape* D , a (sufficiently smooth, i.e., Lipschitz continuous) level set function $\phi : \Omega \rightarrow \mathbb{R}$ is introduced and the shape D is described by

$$\begin{cases} \phi(\mathbf{x}) \leq 0 & \text{for all } \mathbf{x} \in D, \\ \phi(\mathbf{x}) > 0 & \text{for all } \mathbf{x} \in \Omega \setminus D. \end{cases} \quad (5)$$

In other words, the parameter function b has the form

$$b(\mathbf{x}) = \begin{cases} b^{(i)}(\mathbf{x}) & \text{where } \phi(\mathbf{x}) \leq 0 \\ b^{(e)}(\mathbf{x}) & \text{where } \phi(\mathbf{x}) > 0. \end{cases} \quad (6)$$

Certainly, a unique representation of the image is possible by just knowing those points where $\phi(\mathbf{x})$ has a change of sign (the so-called zero level set) and additionally knowing the two interior profiles $b^{(i)}(\mathbf{x})$ and $b^{(e)}(\mathbf{x})$ inside those areas of Ω where they are active (which are D and $\Omega \setminus D$, respectively). Often, however, it is more

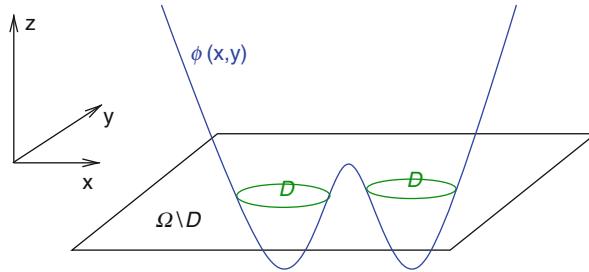

Fig. 4 The basic level set representation of a shape D . Those points of the domain where the describing level set function assumes negative values are “inside” the shape D described by the level set function ϕ , while those with positive values are “outside” it. The zero level set where $\phi = 0$ represents the shape boundary

convenient to assume that these functions are defined on larger sets which include the minimal sets mentioned above. In this chapter, it is assumed that all functions are defined on the entire domain Ω , by employing any convenient extensions from the abovementioned sets to the rest of Ω . Again, it is clear that the above extensions are not unique and that many possible representations can then be found for a given image. Which one to choose depends on details of the algorithm for constructing the image, on the available prior information, and possibly on other criteria (Fig. 4).

For a sufficiently smooth level set function, the boundary of the shape D permits the characterization

$$\partial D = \{\mathbf{x} \in \Omega, \quad \phi(\mathbf{x}) = 0\}. \quad (7)$$

This representation motivates the name *zero level set* for the boundary of the shape. In some representations listed further below, however, level set functions are preferred which are discontinuous across those sets where they change sign. Then, the boundary of the different regions can be defined alternatively as

$$\begin{aligned} \partial D = \{\mathbf{x} \in \Omega : \text{for all } \rho > 0 \text{ we can find } \mathbf{x}_1, \mathbf{x}_2 \in B_\rho(\mathbf{x}) \\ \text{with } \phi(\mathbf{x}_1) > 0 \text{ and } \phi(\mathbf{x}_2) \leq 0\} \end{aligned} \quad (8)$$

where $B_\rho(\mathbf{x}_0) = \{\mathbf{x} \in \Omega : |\mathbf{x} - \mathbf{x}_0| < \rho\}$.

Level Set Formulations for Multivalued and Structured Media

As mentioned already above, in many applications the binary model described in section “The Basic Level Set Formulation for Binary Media” is not sufficient and more complex image models need to be employed. Several means have been discussed in the literature for generalizing the basic model to more complex situations, some of them being listed in the following.

Different Levels of a Single Smooth Level Set Function

A straightforward generalization of the technique described in section “The Basic Level Set Formulation for Binary Media” consists in using, in addition to the level set zero, additional level sets of a given smooth (e.g., Lipschitz continuous) level set function in order to describe different regions of a given domain [99]. For example, define

$$\Gamma_i = \{\mathbf{x} \in \Omega, \quad \phi(\mathbf{x}) = c_i\} \quad (9)$$

$$D_i = \{\mathbf{x} \in \Omega, \quad c_{i+1} < \phi(\mathbf{x}) < c_i\}, \quad (10)$$

where c_i are prespecified values with $c_{i+1} > c_i$ for $i = 0, \dots, \underline{i} - 1$ and with $c_0 = +\infty$, $c_{\underline{i}} = -\infty$. Then,

$$\Omega = \bigcup_{i=0}^{\underline{i}} D_i, \quad \text{with } D_i \cap D_{i'} = \emptyset \quad \text{for } i \neq i'. \quad (11)$$

A *level set representation for the image b* is then given as a tupel $(b_0, \dots, b_{\underline{i}}, \phi)$ which satisfies

$$b(\mathbf{x}) = b_i(\mathbf{x}) \text{ for } c_{i+1} < \phi(\mathbf{x}) < c_i. \quad (12)$$

It is clear that certain topological restrictions are imposed on the distribution of the regions D_i by this formulation. In particular, it favors certain nested structures. For more details, see [63].

Piecewise Constant Level Set Function

This model describes piecewise constant multiple phases of a domain by only one level set function and has its origins in the application of image segmentation. A single level set function is used which is only allowed to take a small number of different values, e.g.,

$$\phi(\mathbf{x}) = i \quad \text{in } D_i, \quad \text{for } i = 0, \dots, \underline{i}, \quad (13)$$

$$\Omega = \bigcup_{i=0}^{\underline{i}} D_i, \quad \text{with } D_i \cap D_{i'} = \emptyset \quad \text{for } i \neq i'.$$

Introducing the set of basis functions γ_i

$$\gamma_i = \frac{1}{\alpha_i} \prod_{\substack{j=1 \\ j \neq i}}^{\underline{i}} (\phi - j) \quad \text{with } \alpha_i = \prod_{\substack{j=1 \\ j \neq i}}^{\underline{i}} (i - j), \quad (14)$$

the parameter distribution $b(\mathbf{x})$ is defined as

$$b = \sum_{i=1}^{\underline{i}} b_i \gamma_i. \quad (15)$$

A *level set representation for the image* b is then given as a tupel $(b_1, \dots, b_{\underline{i}}, \phi)$ with

$$b(\mathbf{x}) = b_i \quad \text{where } \phi(\mathbf{x}) = i. \quad (16)$$

Numerical results using this model can be found, among others, in [61, 65, 67, 97].

Vector Level Set

In [99] multiple phases are described by using one individual level set function for each of these phases, i.e.,

$$\Gamma_i = \{\mathbf{x} \in \Omega, \quad \phi_i(\mathbf{x}) = 0\} \quad (17)$$

$$D_i = \{\mathbf{x} \in \Omega, \quad \phi_i(\mathbf{x}) \leq 0\}, \quad (18)$$

for sufficiently smooth level set functions ϕ_i , $i = 0, \dots, \underline{i}$. In this model, the *level set representation for the image* b is given by a tupel $(b_1, \dots, b_{\underline{i}}, \phi_1, \dots, \phi_{\underline{i}})$ which satisfies

$$b(x) = b_k(x) \text{ where } \phi_k(\mathbf{x}) \leq 0. \quad (19)$$

Care needs to be taken here that different phases do not overlap, which is not automatically incorporated in the model. For more details on how to address this and other related issues, see [99].

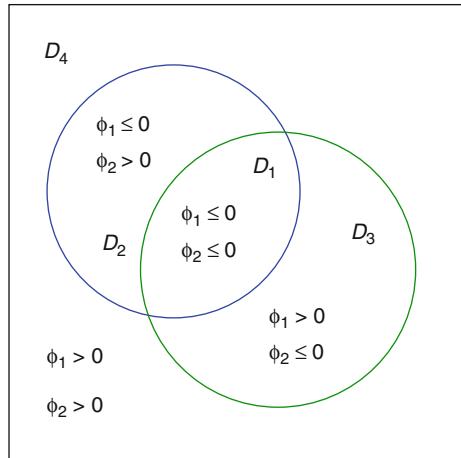

Color Level Set

An alternative way of describing different phases by more than one level set functions has been introduced in [95] in the framework of image segmentation and further investigated by [14, 25, 38, 63, 92] in the framework of inverse problems. In this model (which also is known as the Chan–Vese model), up to 2^n different phases can be represented by n different level set functions by distinguishing all possible sign combinations for these functions. For example, a *level set representation for an image* b containing up to four different phases is given by the tupel $(b_1, b_2, b_3, b_4, \phi_1, \phi_2)$ which satisfies

$$\begin{aligned} b(\mathbf{x}) = & b_1(1 - H(\phi_1))(1 - H(\phi_2)) + b_2(1 - H(\phi_1))H(\phi_2) \\ & + b_3H(\phi_1)(1 - H(\phi_2)) + b_4H(\phi_1)H(\phi_2). \end{aligned} \quad (20)$$

Also here, the contrast values b_v , $v = 1, \dots, 4$ are allowed to be smoothly varying functions inside each region. The four different regions are then given by

Fig. 5 Color level set representation of multiple shapes. Each region is characterized by a different sign combination of the two describing level set functions

$$D_1 = \{\mathbf{x}, \phi_1 \leq 0 \text{ and } \phi_2 \leq 0\} \quad (21)$$

$$D_2 = \{\mathbf{x}, \phi_1 \leq 0 \text{ and } \phi_2 > 0\}$$

$$D_3 = \{\mathbf{x}, \phi_1 > 0 \text{ and } \phi_2 \leq 0\}$$

$$D_4 = \{\mathbf{x}, \phi_1 > 0 \text{ and } \phi_2 > 0\}.$$

This yields a complete covering of the domain Ω by the four regions, each point $\mathbf{x} \in \Omega$ being part of exactly one of the four shapes D_v ; see Fig. 5.

Binary Color Level Set

An alternative technique for using more than one level set function for describing multiple phases, which is, in a certain sense, a combination of the piecewise constant level set model described in section ‘‘Piecewise Constant Level Set Function’’ and the color level set technique described in section ‘‘Color Level Set,’’ has been proposed in [62] for the application of Mumford–Shah image segmentation. For the description of up to four phases by two (now piecewise constant) level set functions ϕ_1 and ϕ_2 , in this binary level set model, the two level set functions are required to satisfy

$$\phi_i \in \{-1, 1\}, \text{ or } \phi_i^2 = 1, i \in \{1, 2\}. \quad (22)$$

The parameter function $b(\mathbf{x})$ is given by

$$b(\mathbf{x}) = \frac{1}{4} \left(b_1(\phi_1 - 1)(\phi_2 - 1) - b_2(\phi_1 - 1)(\phi_2 + 1) - b_3(\phi_1 + 1)(\phi_2 - 1) + b_4(\phi_1 + 1)(\phi_2 + 1) \right), \quad (23)$$

and the four different regions are encoded as

$$\begin{aligned} D_1 &= \{\mathbf{x}, \phi_1 = -1 \text{ and } \phi_2 = -1\} \\ D_2 &= \{\mathbf{x}, \phi_1 = -1 \text{ and } \phi_2 = +1\} \\ D_3 &= \{\mathbf{x}, \phi_1 = +1 \text{ and } \phi_2 = -1\} \\ D_4 &= \{\mathbf{x}, \phi_1 = +1 \text{ and } \phi_2 = +1\}. \end{aligned} \quad (24)$$

A *level set representation* for an image b containing up to four different phases is given by the tuple $(b_1, b_2, b_3, b_4, \phi_1, \phi_2)$ which satisfies (23). For more details, we refer to [62].

Level Set Formulations for Specific Applications

Often, for specific applications, it is convenient to develop particular modifications or generalizations of the above-described general approaches for describing multiple regions by taking into account assumptions and prior information which are very specific to the particular application. A few examples are given below.

A Modification of Color Level Set for Tumor Detection

In the application of tumor detection from microwave data for breast screening (see section “Example 1: Microwave Breast Screening”), the following situation needs to be modeled. The breast consists of four possible tissue types, namely, the skin, fibroglandular tissue, fatty tissue, and a possible tumor. Each of these tissue types might have an internal structure, which is (together with the mutual interfaces) one unknown of the inverse problem. In principle, the color level set description using two level set functions for describing four different phases would be sufficient for modeling this situation. However, the reconstruction algorithm as presented in [52] requires some flexibility with handling these four regions separately, which is difficult in this minimal representation of four regions. Therefore, in [52], the following modified version of the general representation of color level sets is proposed for modeling this situation. In this modified version, m different phases (here $m = 4$) are described by $n = m - 1$ level set functions in the following form

$$\begin{aligned} b(\mathbf{x}) &= b_1(1 - H(\phi_1)) + H(\phi_1) \left[b_2(1 - H(\phi_2)) \right. \\ &\quad \left. + H(\phi_2) \{b_3(1 - H(\phi_3)) + b_4 H(\phi_3)\} \right] \end{aligned} \quad (25)$$

or

$$\begin{aligned} D_1 &= \{\mathbf{x}, \phi_1 \leq 0\} \\ D_2 &= \{\mathbf{x}, \phi_1 > 0 \text{ and } \phi_2 \leq 0\} \\ D_3 &= \{\mathbf{x}, \phi_1 > 0 \text{ and } \phi_2 > 0 \text{ and } \phi_3 \leq 0\} \\ D_4 &= \{\mathbf{x}, \phi_1 > 0 \text{ and } \phi_2 > 0 \text{ and } \phi_3 > 0\}, \end{aligned} \quad (26)$$

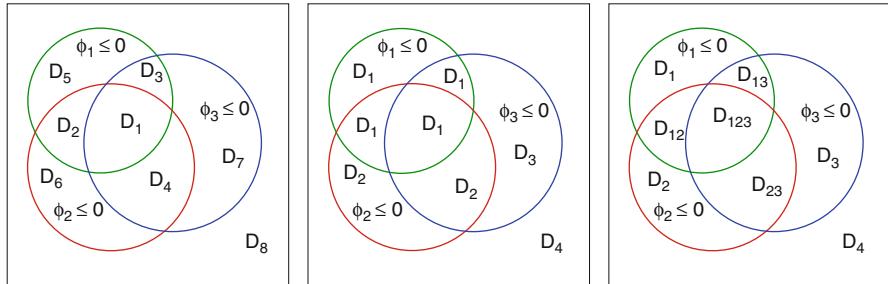

Fig. 6 Multiple level set representation for modeling multiphase inverse problems. *Left:* original color level set technique for describing eight different phases by the different sign combinations of three level set functions. *Center:* modified color level set technique used in the model for early detection of breast cancer from microwave data. The possible eight regions of the color level set presentation are filled with four different materials in a tailor-made fashion for this application. *Right:* modified color level set technique for modeling the history matching problem of a water-flooding process in a petroleum reservoir. Also here the eight different regions are filled by a specific combination of materials characteristic for the reconstruction scheme used in this application. Regions with more than one subindex correspond to “characteristic regions” with averaged parameter values

where b_1 , b_2 , b_3 , and b_4 denote the dielectric parameters of the skin, tumorous, fibroglandular, and fatty tissue, respectively. In (25), ϕ_1 , ϕ_2 , and ϕ_3 are the three different level set functions indicating the regions filled with the skin, tumorous, and fibroglandular tissue, respectively, and the contrast values b_v , $v = 1, \dots, 4$ are generally allowed to be smoothly varying functions inside each region. This combination of $m - 1$ level set functions for describing m different phases has certain advantages with respect to the standard color level set formulation during the reconstruction process, as it is pointed out in [52]. On the other hand, it is obvious that (26) can be considered a special case of the color level set technique (section “Color Level Set”) where the theoretically possible $2^3 = 8$ different values of the color level set description are enforced to fall into $m = 4$ different groups of characteristic values; see the central image of Fig. 6.

A Modification of Color Level Set for Reservoir Characterization

Another modification of the color level set technique has been used in [35] for the application of history matching in reservoir engineering; see section “Example 2: History Matching in Petroleum Engineering.” Given, as an example, $n = 4$ level set functions ϕ_1, \dots, ϕ_4 , we define the parameter (permeability) distribution inside the reservoir by

$$\begin{aligned} b = & b_1(1 - H(\phi_1))H(\phi_2)H(\phi_3) + b_2H(\phi_1)(1 - H(\phi_2))H(\phi_3) \\ & + b_3H(\phi_1)H(\phi_2)(1 - H(\phi_3)) + b_4H(\phi_1)H(\phi_2)H(\phi_3) \\ & + \frac{b_2 + b_3}{2} H(\phi_1)(1 - H(\phi_2))(1 - H(\phi_3)) \end{aligned}$$

$$\begin{aligned}
& + \frac{b_1 + b_3}{2} (1 - H(\phi_1))H(\phi_2)(1 - H(\phi_3)) \\
& + \frac{b_1 + b_2}{2} (1 - H(\phi_1))(1 - H(\phi_2))H(\phi_3) \\
& + \frac{b_1 + b_2 + b_3}{3} (1 - H(\phi_1))(1 - H(\phi_2))(1 - H(\phi_3)),
\end{aligned} \tag{27}$$

where the permeability values b_v , $v = 1, \dots, 4$ are assumed constant inside each region. The four lithofacies are represented as

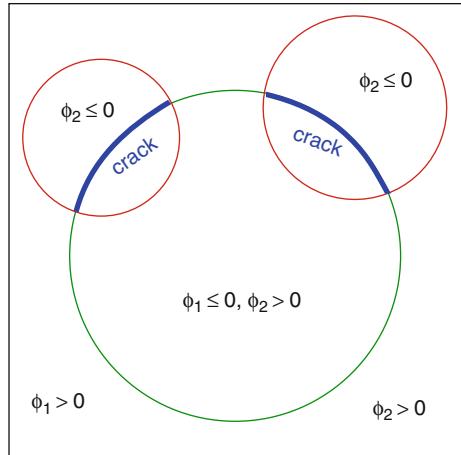

$$\begin{aligned}
D_1 &= \{\mathbf{x}, \quad \phi_1 \leq 0 \quad \text{and} \quad \phi_2 > 0 \quad \text{and} \quad \phi_3 > 0\} \\
D_2 &= \{\mathbf{x}, \quad \phi_2 \leq 0 \quad \text{and} \quad \phi_3 > 0 \quad \text{and} \quad \phi_1 > 0\} \\
D_3 &= \{\mathbf{x}, \quad \phi_3 \leq 0 \quad \text{and} \quad \phi_1 > 0 \quad \text{and} \quad \phi_2 > 0\} \\
D_4 &= \{\mathbf{x}, \quad \phi_1 > 0 \quad \text{and} \quad \phi_2 > 0 \quad \text{and} \quad \phi_3 > 0\}.
\end{aligned} \tag{28}$$

Let in the following $n = 4$ be the number of lithofacies. In this model, a point in the reservoir corresponds to the lithofacie D_l , ($l = 1, \dots, n - 1$) if ϕ_l has negative sign and all the other level set functions have positive sign. In addition, one lithofacie (which here is referred to as the “background” lithofacie with index $l = n$) corresponds to those points where none of the level set functions has a negative sign. Notice that typically this definition does not yield a complete covering of the whole domain Ω by the four (n) lithofacies; see the right image of Fig. 6. Those regions inside the domain where more than one level set function are negative are recognized as so-called critical regions and are introduced for providing a smooth evolution from the initial guess to the final reconstruction. Inside these critical regions, the permeability assumes values which are calculated as certain averages over values of the neighboring noncritical regions. They are indicated in the right image of Fig. 6 by using multiple subindices indicating which noncritical regions contribute to this averaging procedure. For more details regarding this model, and numerical experiments for the application of reservoir characterization, see [35].

A Modification of the Classical Level Set Technique for Describing Cracks or Thin Shapes

Cracks of finite thickness can be modeled by using two level set functions in a setup which amounts to a modification of the classical level set technique for binary media. For simplicity, assume that a crack or thin region of finite thickness is embedded in a homogeneous background. The classical level set technique described in section “The Basic Level Set Formulation for Binary Media” captures this situation in principle, since the crack can be interpreted as a simple shape (with possibly complicated topology) embedded in a homogeneous background. However, when it comes to shape evolution for such a crack-like structure, it is difficult to maintain a fixed thickness of the thin shape following the classical

Fig. 7 Multiple level set representation for modeling a disconnected crack. The zero level set of the first level set function defines the potential outline of the crack, of which the second level set function selects those parts that are actually occupied by the crack. The “ideal” crack has vanishing thickness, whereas the “real” crack modeled by the level set technique has a small finite thickness and is practically obtained by a narrow band technique

shape evolution scheme. This is so since the classical shape evolution applies an individually calculated velocity field value in the normal direction at each point of the entire shape boundary, such that the thickness of the thin region will not be maintained. For crack evolution, the deformations of adjacent boundary points need to be coordinated in order to maintain the thickness of the crack during the entire shape evolution; see Fig. 9.

A modified version of the classical level set technique has been proposed in [4, 77] which uses two level set functions for modeling crack propagation and crack reconstruction in this sense. Here, a small neighborhood (narrowband) of the zero level set of the first level set function defines the general outline of the crack, whereas the second level set function selects those parts of this band structure which in fact contribute to the possibly disconnected crack topology.

In more details, given a continuously differentiable level set function ϕ_1 and its zero level set

$$\Gamma_{\phi_1} = \{\mathbf{x} \in \Omega : \phi_1(\mathbf{x}) = 0\}. \quad (29)$$

The normal \mathbf{n} to Γ_{ϕ_1} is given by (61) and is pointing into the direction where $\phi(\mathbf{x}) \geq 0$. An (connected or disconnected) “ideal” (i.e., of thickness zero) crack with finite length completely contained inside Ω is constructed by introducing a second level set function ϕ_2 which selects one or more parts from the line Γ_{ϕ_1} ; see Fig. 7. This second level set function defines the region

$$B = \{\mathbf{x} \in \Omega : \phi_2(\mathbf{x}) \leq 0\}. \quad (30)$$

The “ideal” crack is then defined as a collection of finite subintervals of Γ_{ϕ_1}

$$S[\phi_1, \phi_2] = \Gamma_{\phi_1} \cap B. \quad (31)$$

An ideal “insulating” crack S (of thickness zero) is then supplemented with a vanishing electrical current condition across this set $S[\phi_1, \phi_2]$. However, in the simplified level set model, not the ideal crack is considered, but cracks of finite thickness $2\delta > 0$ with known conductivity b_i inside the crack and b_e outside it. Moreover, in the insulating case, it is assumed that $b_i \ll b_e$. In this model, a small neighborhood of Γ_{ϕ_1} is introduced as

$$\Gamma_{\phi_1}^\delta = \{\mathbf{y} \in \Omega : \mathbf{y} = \mathbf{x} - \tau \mathbf{n}(\mathbf{x}), |\tau| < \delta, \mathbf{x} \in \Gamma_{\phi_1}\}, \quad (32)$$

and the above-defined “ideal crack” S is associated now with a “real crack” counterpart

$$S_\delta = \Gamma_{\phi_1}^\delta \cap B. \quad (33)$$

The conductivity distribution is

$$b(\mathbf{x}) = \begin{cases} b_i & \text{for } \mathbf{x} \in S_\delta \\ b_e & \text{otherwise} \end{cases} \quad (34)$$

in the domain Ω . Certainly, the real crack can also alternatively be defined by

$$\tilde{S}_\delta = \{\mathbf{y} \in \Omega : \mathbf{y} = \mathbf{x} - \tau \mathbf{n}(\mathbf{x}), |\tau| < \delta, \mathbf{x} \in S\}, \quad (35)$$

which would slightly change the shape of the crack at the crack tips. Here, the form (33) is preferred. For the numerical treatment, see [4, 77].

4 Cost Functionals and Shape Evolution

One important technique for creating images with interfaces satisfying certain criteria is *shape evolution*, more specifically, *interface and profile evolution*. The general goal is to start with a set of shapes and profiles as initial guess, and then let both, shapes and profiles, evolve due to some appropriate evolution laws in order to improve the initial guess with increasing artificial evolution time. The focus in the following will be on shape evolution, since evolution laws for interior profiles fairly much follow classical and well-known concepts. Evolution of a shape or an interface can be achieved either by defining a velocity field on the domain Ω which deforms the boundaries of this shape or by defining evolution laws directly for the level set functions representing the shape. Some of these techniques will be presented next.

General Considerations

In many applications, images need to be evaluated for verifying their usefulness or *merit* for a given situation. This evaluation is usually based on a number of

criteria, among them being the ability of the image (in its correct interpretation) to reproduce the physically measured data (its *data fitness*). Other criteria include the consistence with any additionally available prior knowledge on the given situation or the closeness of the image to a set of reference images. In many cases, some form of *merit function* (often in terms of a properly defined *cost functional*) is defined whose value is intended to indicate the usefulness of the image in a given application. However, sometimes this decision is done based on visual inspection only.

In general, during this evaluation process, a family of images is created and the merit of each of these images is assessed. Then, one or more of these images are selected. Let $(b^{(1)}, \dots, b^{(\underline{i})}, \phi^{(1)}, \dots, \phi^{(\underline{j})})$ be a level set representation for the class of images to be considered. Then, creating this family of images can be described either in a continuous way by an artificial time evolution

$$\left(b^{(1)}(t), \dots, b^{(\underline{i})}(t), \phi^{(1)}(t), \dots, \phi^{(\underline{j})}(t) \right), \quad t \in [0, t_{\max}],$$

with an artificial evolution time t or in a discrete way

$$\left(b_k^{(1)}, \dots, b_k^{(\underline{i})}, \phi_k^{(1)}, \dots, \phi_k^{(\underline{j})} \right), \quad k = 1, \dots, \underline{k},$$

with a counting index k . Usually these images are created in a sequential manner, using evolution laws

$$\frac{d}{dt} \left(b^{(1)}(t), \dots, b^{(\underline{i})}(t), \phi^{(1)}(t), \dots, \phi^{(\underline{j})}(t) \right) = f(t),$$

with a multicomponent forcing term $f(t)$ or update formulas

$$\left(b_{k+1}^{(1)}, \dots, b_{k+1}^{(\underline{i})}, \phi_{k+1}^{(1)}, \dots, \phi_{k+1}^{(\underline{j})} \right) = F_k \left(b_k^{(1)}, \dots, b_k^{(\underline{i})}, \phi_k^{(1)}, \dots, \phi_k^{(\underline{j})} \right)$$

with update operators F_k . These evolution laws and update operators can also be defined on ensembles of images, which allows for statistical evaluation of each ensemble during the evaluation process. Any arbitrarily defined evolution law and set of update operators yield a family of images which can be evaluated, but typically those are preferred which point into a descent direction of some predefined *cost functional*. Some choices of such cost functionals will be discussed in the following.

Cost Functionals

In general, a cost functional can consist of various components, typically combined in an additive or multiplicative manner. Popular components for an image model $\underline{b} = (b^{(1)}, \dots, b^{(\underline{i})})$ and $\underline{\phi} = (\phi^{(1)}, \dots, \phi^{(\underline{j})})$ are:

1. Data misfit terms $\mathcal{J}_{\text{data}}(\underline{b}, \underline{\phi})$
2. Terms measuring closeness to a prior model inside each subdomain $\mathcal{J}_{\text{prior}}(\underline{b}, \underline{\phi})$
3. Terms enforcing geometric constraints on the interfaces $\mathcal{J}_{\text{geom}}(\underline{b}, \underline{\phi})$

In (1), the by far most popular data misfit term is the least squares misfit cost functional which, in general, is given as an expression of the form

$$\mathcal{J}_{\text{data}}(\underline{b}, \underline{\phi}) = \frac{1}{2} \left\| \mathcal{A}(\underline{b}, \underline{\phi}) - \tilde{g} \right\|^2 = \frac{1}{2} \left\| u_M[\underline{b}, \underline{\phi}] - \tilde{g} \right\|^2, \quad (36)$$

where $\mathcal{A}(\underline{b}, \underline{\phi})$ is the forward operator defined in (2) and $u_M[\underline{b}, \underline{\phi}]$ indicates the simulated data at the set of probing locations M for this guess. Other choices can be considered as well; see, for example, [37].

(2) corresponds to classical regularization techniques, applied to each subdomain, and is treated in many textbooks, such as [37, 71]. Therefore, it is not discussed in this chapter.

(3) has a long history in the shape optimization literature and in image processing applications. See, for example, [30, 87]. A few concepts are presented in Sect. 5.

Transformations and Velocity Flows

The first technique discussed here is *shape evolution by transformations and velocity flows*. This concept has been inspired by applications in continuum mechanics. Given a (possibly bounded) domain $\Omega \subset \mathbb{R}^n$ and a shape $D \subset \Omega$ with boundary ∂D which, as usual, is denoted as Γ . Let a smooth vector field $\mathbf{v} : \mathbb{R}^n \rightarrow \mathbb{R}^n$ be given with $\mathbf{v} \cdot \mathbf{n} = 0$ on $\partial\Omega$. A family of transformations S_t proceeds by

$$S_t(\mathbf{X}) = \mathbf{X} + t\mathbf{v}(\mathbf{X}) \quad (37)$$

for all $\mathbf{X} \in \Omega$. In short, $S_t = I + t\mathbf{v}$ where I stands for the identity map. This defines for each point (“particle”) \mathbf{X} in the domain, a propagation law prescribed by the ordinary differential equation

$$\dot{\mathbf{x}}(t, \mathbf{X}) = \mathbf{V}(t, \mathbf{x}(t, \mathbf{X})), \quad (38)$$

$$\mathbf{x}(0, \mathbf{X}) = \mathbf{X} \quad (39)$$

with the specific velocity choice

$$\mathbf{V}(t, \mathbf{x}(t, \mathbf{X})) = \mathbf{v}(\mathbf{X}). \quad (40)$$

Physically, it corresponds to the situation where each point \mathbf{X} of the domain travels with constant speed along a straight line which is defined by its initial velocity vector $\mathbf{v}(\mathbf{X})$. Notice that the definition (40) can with (37) also be written in a slightly more abstract fashion as

$$\mathbf{V}(t, \mathbf{x}) = \frac{\partial}{\partial t} S_t(\mathbf{X}) = \left(\frac{\partial}{\partial t} S_t \right) \circ S^{-1}(\mathbf{x}). \quad (41)$$

In fact, it turns out that the ideas in the above example can be considerably generalized from the specific case (40) to quite arbitrary smooth vector fields $\mathbf{V}(t, \mathbf{x})$ describing smooth families of transformations $T_t(\mathbf{X})$. The generating vector field $\mathbf{V}(t, \mathbf{x})$ is often called “velocity field.” It can be done as follows.

Let us given an arbitrary smooth family of transformations $T_t(\mathbf{X})$ which maps every point \mathbf{X} of the domain to the point $\mathbf{x}(t, \mathbf{X}) = T_t(\mathbf{X})$ at time t . The propagation of the point \mathbf{X} over time t is again described by the ordinary differential equations (38) and (39) where the velocity \mathbf{V} is defined by

$$\mathbf{V}(t, \mathbf{x}) = \left(\frac{\partial}{\partial t} T_t \right) \circ T^{-1}(\mathbf{x}). \quad (42)$$

Now the propagation of points is not restricted anymore to straight lines, but can be quite arbitrary. Vice versa, given a smooth vector field $\mathbf{V}(t, \mathbf{x})$, it gives rise to a family of transformations $T_t(\mathbf{X})$ via the differential equations (38) and (39) where every point $\mathbf{X} \in \Omega$ is mapped by $T_t(\mathbf{X})$ to the solution $\mathbf{x}(t, \mathbf{X})$ of (38), (39) at time t , i.e., $T_t(\mathbf{X})(\mathbf{x}) = \mathbf{x}(t, \mathbf{X})$. For more details on this duality of transformations and velocity flows, see the well-known monographs [30, 87].

Notice that the numerical treatment of such a velocity flow in the level set framework leads to a Hamilton–Jacobi-type equation. Some remarks regarding this link are given in section “The Level Set Framework for Shape Evolution.”

Eulerian Derivatives of Shape Functionals

Given the framework defined in section “Transformations and Velocity Flows,” the goal is now to define transformations and velocity flows which point into a descent direction for a given cost functional. Some useful concepts on how to obtain such descent directions are discussed here.

Let $D = D_0$ be a shape embedded in the domain at time $t = 0$. When the points in the said domain start moving under the propagation laws discussed above, the interior points of the shape, the boundary points, as well as the exterior points will move as well, and therefore the shape will deform. Denote the shape at time t by $D_t = T_t(D_0)$ where as before T_t is the family of transformations which correspond to a given velocity field $\mathbf{V}(t, \mathbf{x})$. Assume furthermore that a cost functional $\mathcal{J}(\mathbf{x}, t, D_t, \dots)$ is given which depends (among others) upon the current shape D_t . Deformation of shape will entail change of this cost. The so-called shape sensitivity analysis of structural optimization aims at quantifying these changes in the cost due to a given velocity flow (or family of transformations) in order to determine suitable descent flows.

Given a vector field $\mathbf{V}(t, \mathbf{x})$, the *Eulerian derivative* of the cost functional $\mathcal{J}(D_t)$ at time $t = 0$ in the direction \mathbf{V} is defined as the limit

$$d\mathcal{J}(D, \mathbf{V}) = \lim_{t \downarrow 0} \frac{\mathcal{J}(D_t) - \mathcal{J}(D)}{t}, \quad (43)$$

if this limit exists. The functional $\mathcal{J}(D_t)$ is *shape differentiable* (or simply *differentiable*) if the Eulerian derivative $d\mathcal{J}(D, \mathbf{V})$ exists for all directions \mathbf{V} and furthermore the mapping $\mathbf{V} \rightarrow d\mathcal{J}(D, \mathbf{V})$ is linear and continuous (in appropriate function spaces). It is shown in [30, 87] that if $\mathcal{J}(D)$ is shape differentiable, there exists a distribution $G(D)$ which is concentrated (supported) on $\Gamma = \partial D$ such that

$$d\mathcal{J}(D, \mathbf{V}) = \langle G(D), \mathbf{V}(0) \rangle. \quad (44)$$

This distribution G is the *shape gradient* of \mathcal{J} in D , which is a vector distribution. More specifically, let ϖ_Γ denote the trace (or restriction) operator on the boundary Γ . Then, the Hadamard-Zolésio structure theorem states that (under certain conditions) there exists a scalar distribution g such that the shape gradient G writes in the form $G = \varpi_\Gamma^*(g\mathbf{n})$, where ϖ^* is the transpose of the trace operator at Γ and where \mathbf{n} is the normal to Γ . For more details, see again [30, 87].

The Material Derivative Method

A useful concept for calculating Eulerian derivatives for cost functionals is the so-called material and shape derivative of states \mathbf{u} . In the application of inverse problems, these states \mathbf{u} typically are the solutions of the PDEs (IEs) which model the probing fields and which depend one way or another on the shape D .

Let as before \mathbf{V} be a smooth vector field with $\langle \mathbf{V}, \mathbf{n} \rangle = 0$ on $\partial\Omega$, and let $T_t(\mathbf{V})$ denote the corresponding family of transformations. Moreover, let $\mathbf{u} = \mathbf{u}[D_t]$ be a state function (of some Sobolev space) which depends on the shape $D_t \subset \Omega$ (denote as before $D_0 = D$). The *material derivative* $\dot{\mathbf{u}}[D, \mathbf{V}]$ of \mathbf{u} in the direction \mathbf{V} is defined as

$$\dot{\mathbf{u}}[D, \mathbf{V}] = \lim_{t \downarrow 0} \frac{\mathbf{u}[D_t] \circ T_t(\mathbf{V}) - \mathbf{u}[D]}{t}, \quad (45)$$

or

$$\dot{\mathbf{u}}[D, \mathbf{V}](\mathbf{X}) = \lim_{t \downarrow 0} \frac{\mathbf{u}[D_t](T_t(\mathbf{X})) - \mathbf{u}[D](\mathbf{X})}{t} \quad \text{for } \mathbf{X} \in \Omega, \quad (46)$$

where the square brackets in the notation indicate the dependence of the states and derivatives on the shape D_t and/or on the vector field \mathbf{V} . The material derivative corresponds to a Lagrangian point of view describing the evolution of the points in a moving coordinate system, e.g., located in the point $\mathbf{x}(t, \mathbf{X}) = T_t(\mathbf{X})$.

The *shape derivative* $\mathbf{u}'[D, \mathbf{V}]$ of \mathbf{u} in the direction \mathbf{V} in contrast corresponds to an Eulerian point of view observing the evolution from a fixed coordinate system, e.g., located in the point \mathbf{X} . It is defined as

$$\mathbf{u}'[D, \mathbf{V}] = \lim_{t \downarrow 0} \frac{\mathbf{u}[D_t] - \mathbf{u}[D]}{t}, \quad (47)$$

or

$$\mathbf{u}'[D, \mathbf{V}](\mathbf{X}) = \lim_{t \downarrow 0} \frac{\mathbf{u}[D_t](\mathbf{X}) - \mathbf{u}[D](\mathbf{X})}{t} \quad \text{for } \mathbf{X} \in \Omega. \quad (48)$$

The shape derivative and the material derivative are closely related to each other. It can be shown that

$$\mathbf{u}'[D, \mathbf{V}] = \dot{\mathbf{u}}[D, \mathbf{V}] - \nabla(\mathbf{u}[D]) \cdot \mathbf{V}(0) \quad (49)$$

provided that these quantities exist and are well defined. Subtracting $\nabla(\mathbf{u}[D]) \cdot \mathbf{V}(0)$ in (49) from the material derivative makes sure that the shape derivative actually becomes zero in the special case that the states \mathbf{u} do *not* depend on the shape D . The material derivative usually does not vanish in these situations.

Some Useful Shape Functionals

To become more specific, some useful examples for shape functionals which have been applied to shape inverse problems are provided herein.

1. Define for a given function ζ the shape integral

$$\mathcal{J}_1(D) = \int_{\Omega} \chi_D(\mathbf{x}) \zeta(\mathbf{x}) d\mathbf{x} = \int_D \zeta(\mathbf{x}) d\mathbf{x} \quad (50)$$

where χ_D is the characteristic function for the domain D . Then the Eulerian derivative is given by

$$d\mathcal{J}_1(D, \mathbf{V}) = \int_D \operatorname{div}(\zeta \mathbf{V}(0)) d\mathbf{x} = \int_{\Gamma} \zeta \langle \mathbf{V}(0), \mathbf{n} \rangle_{\mathbb{R}^n} d\Gamma. \quad (51)$$

2. Consider the shape functional

$$\mathcal{J}_2(D) = \int_{\Gamma} \zeta(\mathbf{x}) d\Gamma \quad (52)$$

for a sufficiently smooth function ζ defined on Ω such that the traces on Γ exist and are integrable. The *tangential divergence* $\operatorname{div}_{\Gamma} \mathbf{V}$ of the vector field \mathbf{V} at the boundary Γ is defined as

$$\operatorname{div}_{\Gamma} \mathbf{V} = (\operatorname{div} \mathbf{V} - \langle \mathbf{D}\mathbf{V} \cdot \mathbf{n}, \mathbf{n} \rangle)|_{\Gamma} \quad (53)$$

where $\mathbf{D}\mathbf{V}$ denotes the Jacobian of \mathbf{V} . Then,

$$d\mathcal{J}_2(D, \mathbf{V}) = \int_{\Gamma} (\langle \nabla \zeta, \mathbf{V}(0) \rangle + \zeta \operatorname{div}_{\Gamma} \mathbf{V}(0)) d\Gamma \quad (54)$$

Be \mathcal{N} an extension of the normal vector field \mathbf{n} on Γ to a local neighborhood of Γ . Then, the *mean curvature* κ of Γ is defined as $\kappa = \operatorname{div}_{\Gamma} \mathcal{N}|_{\Gamma}$. With that, $d\mathcal{J}_2(D, \mathbf{V})$ admits the alternative representation

$$d\mathcal{J}_2(D, \mathbf{V}) = \int_{\Gamma} \left(\frac{\partial \zeta}{\partial n} + \zeta \kappa \right) \langle \mathbf{V}(0), \mathbf{n} \rangle d\Gamma \quad (55)$$

3. A useful link between the shape derivative and the Eulerian derivative of the cost functional is

$$\mathcal{J}_3(D) = \int_D \mathbf{u}[D] d\mathbf{x} \quad (56)$$

which depends via the states $\mathbf{u}[D]$ on the shape D . Furthermore [30, 87]

$$d\mathcal{J}_3(D, \mathbf{V}) = \int_D \mathbf{u}'[D, \mathbf{V}] d\mathbf{x} + \int_{\Gamma} \mathbf{u}[D] \langle \mathbf{V}(0), \mathbf{n} \rangle_{\mathbb{R}^n} d\Gamma. \quad (57)$$

4. Consider a cost functional

$$\mathcal{J}_4(D) = \int_{\Gamma} \zeta(\Gamma) d\Gamma \quad (58)$$

where ζ is only defined at the shape boundary Γ . Then we cannot use the characterization (49) directly, since $\nabla(\zeta) \cdot \mathbf{V}(0)$ is not well defined. In that case, the shape derivative is defined as

$$\zeta'[\Gamma, \mathbf{V}] = \dot{\zeta}[\Gamma, \mathbf{V}] - \nabla_{\Gamma}(\zeta[\Gamma]) \cdot \mathbf{V}(0), \quad (59)$$

∇_{Γ} being the gradient along the boundary Γ of the shape (chosen such that $\nabla \zeta = \nabla_{\Gamma} \zeta + \frac{\partial \zeta}{\partial n} \mathbf{n}$ whenever all these quantities are well defined). Then, the Eulerian derivative of the cost functional $\mathcal{J}_4(D)$ can be characterized as

$$d\mathcal{J}_4(D, \mathbf{V}) = \int_{\Gamma} \zeta'[\Gamma, \mathbf{V}] d\Gamma + \int_{\Gamma} \kappa \zeta \langle \mathbf{V}(0), \mathbf{n} \rangle_{\mathbb{R}^n} d\Gamma \quad (60)$$

where again κ denotes the mean curvature on Γ .

The Level Set Framework for Shape Evolution

So far, shape evolution has been discussed independently of its representation by a level set technique. Any of the abovementioned shape evolutions can practically be described by employing a level set representation of the shapes.

First, some convenient representations of geometric quantities in the level set framework are listed:

1. The outward normal direction [74, 85] is given by

$$\mathbf{n}(\mathbf{x}) = \frac{\nabla\phi}{|\nabla\phi|}. \quad (61)$$

2. The local curvature $\kappa(\mathbf{x})$ of ∂D , being the divergence of the normal field $\mathbf{n}(\mathbf{x})$, is

$$\kappa(\mathbf{x}) = \nabla \cdot \mathbf{n}(\mathbf{x}) = \nabla \cdot \left(\frac{\nabla\phi}{|\nabla\phi|} \right). \quad (62)$$

3. The following relation is often useful

$$\delta(\phi) = \frac{\delta_{\partial D}(\mathbf{x})}{|\nabla\phi(\mathbf{x})|} \quad (63)$$

where $\delta_{\partial D}$ is the n -dimensional Dirac delta distribution concentrated on ∂D .

Notice that the right-hand sides of (61) and (62) make sense at every point of the domain Ω where the level set function ϕ is sufficiently smooth, giving rise to a natural extension of these quantities from the boundary ∂D to a local neighborhood.

Assume now that a sufficiently smooth flow field $\mathbf{V}(\mathbf{x}, t)$ is given and that a shape D is represented by the *continuously differentiable level set function* ϕ with $|\nabla\phi| \neq 0$ at the boundary of the shape. Then, the deformation of the shape due to the flow field $\mathbf{V}(\mathbf{x}, t)$ in the level set framework can be obtained as follows.

Since the velocity fields are assumed to be sufficiently smooth, a boundary point \mathbf{x} remains at the boundary of $\partial D(t)$ during the evolution of the shape. Let $\phi(\mathbf{x}, t)$ be the set of level set functions describing the shape at every time of the evolution. Differentiating $\phi(\mathbf{x}, t) = 0$ with respect to t yields

$$\frac{\partial\phi}{\partial t} + \nabla\phi \cdot \frac{d\mathbf{x}}{dt} = 0. \quad (64)$$

Identifying $\mathbf{V}(\mathbf{x}, t)$ to $\frac{d\mathbf{x}}{dt}$ and using (61), one arrives at

$$\frac{\partial\phi}{\partial t} + |\nabla\phi| \mathbf{V}(\mathbf{x}, t) \cdot \mathbf{n}(\mathbf{x}, t) = 0. \quad (65)$$

Defining the normal velocity as

$$F(\mathbf{x}, t) = \mathbf{V}(\mathbf{x}, t) \cdot \mathbf{n}(\mathbf{x}, t) \quad (66)$$

the *Hamilton–Jacobi-type equation* for describing the evolution of the level set function follows as

$$\frac{\partial \phi}{\partial t} + F(\mathbf{x}, t) \cdot |\nabla \phi| = 0. \quad (67)$$

5 Shape Evolution Driven by Geometric Constraints

It is possible to define a shape evolution without any data misfit functional being involved. This type of shape evolution often occurs in applications of image processing or computational physics. For example, starting from an initial shape, the goal might be to define a shape evolution which aims at reducing the cost of the image with respect to one or more geometric quantities, typically encoded in some geometric cost functional. Based on the theory developed in Sect. 4, some useful expressions will be derived here for calculating such descent directions. The then obtained geometrically driven shape evolutions can also be used for adding additional constraints or regularization during the shape evolution driven by data misfit, if desired. This is achieved practically by adding appropriate geometrical cost terms to the data misfit term and calculating descent directions for this combined cost.

Penalizing Total Length of Boundaries

Assume that $\Gamma = \partial D$ is a smooth submanifold in Ω . The total length (or surface) of Γ is defined as

$$\mathcal{J}_{\text{len}\Gamma}(D) = \int_{\Gamma} d\Gamma = \int_{\Omega} \delta_{\partial D}(\mathbf{x}) d\mathbf{x}. \quad (68)$$

Applying a flow by a smooth vector field $\mathbf{V}(\mathbf{x}, t)$, Eq. (55) yields with $\zeta = 1$ an expression for the corresponding change in the cost (68) which is

$$d\mathcal{J}_{\text{len}\Gamma}(D, \mathbf{V}) = \int_{\Gamma} \kappa \langle \mathbf{V}(0), \mathbf{n} \rangle d\Gamma. \quad (69)$$

If the shape D is represented by a continuously differentiable level set function ϕ , an alternative derivation can be given. First, using (63), write (68) in the form

$$\mathcal{J}_{\text{len}\Gamma}(D(\phi)) = \int_{\Omega} \delta(\phi) |\nabla \phi(\mathbf{x})| d\mathbf{x}. \quad (70)$$

Perturbing now $\phi \rightarrow \phi + \psi$, formal calculation (see, e.g., [92]) yields that the cost functional is perturbed by

$$\left\langle \frac{\partial \mathcal{J}_{\text{len}\Gamma}}{\partial \phi}, \psi \right\rangle = \int_{\Omega} \delta(\phi) \psi(\mathbf{x}) \nabla \cdot \frac{\nabla \phi}{|\nabla \phi|} d\mathbf{x}. \quad (71)$$

Therefore, using (62), it can be identified

$$\frac{\partial \mathcal{J}_{\text{len}\Gamma}}{\partial \phi} = \delta(\phi) \nabla \cdot \frac{\nabla \phi}{|\nabla \phi|} = \delta(\phi) \kappa \quad (72)$$

where κ is now an extension (defined, e.g., by (62)) of the local curvature to a small neighborhood of Γ . For both representations (69) and (72), minimizing the cost by a gradient method leads to curvature-driven flow equations, which is $\mathbf{V}(0) = -\kappa \mathbf{n}$. This curvature-dependent velocity has been widely used to regularize the computation of motion of fronts via the level set method [48], as well in the field of image processing [70], and has been introduced also recently for regularizing inverse problems; see, e.g., [41, 79, 82].

Two popular concepts related to the above shape evolution are the Mumford–Shah and the total variation functionals, which are frequently employed in image segmentation applications. This relationship is briefly described in the following.

The popular *Mumford–Shah functional for image segmentation* [70] contains, in addition to a fidelity term inside each region of the segmented image, a term which encourages to shorten total curve length of the interfaces. This latter term can be written for piecewise constant binary media (see section “The Basic Level Set Formulation for Binary Media” with constant profiles in each region) as

$$\mathcal{J}_{\text{MS}} = \int_{\Omega} |\nabla H(\phi)| d\mathbf{x}. \quad (73)$$

Taking into account that $\nabla H(\phi) = H'(\phi) \nabla \phi = \delta(\phi) |\nabla \phi| \mathbf{n}$, it is seen that $\mathcal{J}_{\text{MS}} = \mathcal{J}_{\text{len}\Gamma}(D(\phi))$ as given in (70), which again yields the curvature-driven flow Eq. (72). For more details, see [26, 38, 95].

The *total variation (TV) functional*, on the other hand, can be written, again for the situation of piecewise constant binary media, as

$$\mathcal{J}_{\text{TV}} = \int_{\Omega} |\nabla b(\phi)| d\mathbf{x} = |b_e - b_i| \int_{\Omega} |\nabla H(\phi)| d\mathbf{x}. \quad (74)$$

Therefore, it coincides with the Mumford–Shah functional \mathcal{J}_{MS} up to the factor $|b_e - b_i|$. Roughly it can be said that the TV functional (74) penalizes the product of the jump between different regions and the arc length of their interfaces, whereas the Mumford–Shah functional (73) penalizes only this arc length. Refer for more information to [25, 38].

Penalizing Volume or Area of Shape

It is again assumed that $\Gamma = \partial D$ is a smooth submanifold in Ω . Define the total area (volume) of D as

$$\mathcal{J}_{\text{vol}D}(D) = \int_D d\mathbf{x} = \int_{\Omega} \chi_D(\mathbf{x}) d\mathbf{x}, \quad (75)$$

where the *characteristic function* $\chi_D : \Omega \rightarrow \{0, 1\}$ for a given shape D is defined as

$$\chi_D(\mathbf{x}) = \begin{cases} 1, & \mathbf{x} \in D \\ 0, & \mathbf{x} \in \Omega \setminus D. \end{cases} \quad (76)$$

Applying a flow by a smooth vector field $\mathbf{V}(\mathbf{x}, t)$, Eqs. (50) and (51) yield with $\zeta = 1$

$$d\mathcal{J}_{\text{vol}D}(D, \mathbf{V}) = \int_D \text{div} \mathbf{V}(0) d\mathbf{x} = \int_{\Gamma} \langle \mathbf{V}(0), \mathbf{n} \rangle d\Gamma. \quad (77)$$

Again, if the shape D is represented by a continuously differentiable level set function ϕ , an alternative derivation can be given. First, using the Heaviside function H , let us write (75) in the form

$$\mathcal{J}_{\text{vol}D}(D) = \int_{\Omega} H(\phi) d\mathbf{x}. \quad (78)$$

Perturbing as before $\phi \rightarrow \phi + \psi$, it follows

$$\left\langle \frac{\partial \mathcal{J}_{\text{vol}D}}{\partial \phi}, \psi \right\rangle = \int_{\Omega} \delta(\phi) \psi(\mathbf{x}) d\mathbf{x} \quad (79)$$

such that

$$\frac{\partial \mathcal{J}_{\text{vol}D}}{\partial \phi} = \delta(\phi). \quad (80)$$

In both formulations, a descent flow is given by a motion with constant speed in the negative direction of the normal \mathbf{n} to the boundary Γ , which is $\mathbf{V}(0) = -\mathbf{n}$.

6 Shape Evolution Driven by Data Misfit

An essential goal in the solution of inverse problems is to find an image which is able to reproduce the measured data in a certain sense. As far as interfaces are concerned, this gives rise to the need of finding descent directions for shape evolution with

respect to the data misfit functional. In the following, some concepts are presented which aim at providing these descent directions during the shape evolution. These concepts can be combined arbitrarily with the above-discussed concepts for shape evolution driven by geometric terms.

Shape Deformation by Calculus of Variations

Historically, the first approach for applying a level set technique for solving an inverse problem in [82] has used concepts from the calculus of variations for calculating descent directions for the data misfit functional. In many applications, this approach is still a very convenient way of deriving evolution laws for shapes. In the following, the main ideas of this approach are briefly reviewed, following [82]. The goal is to obtain expressions for the deformation of already existing shapes according to a normal velocity field defined at the boundary of these shapes. Topological changes are not formally included in the consideration at this stage (even though they occur automatically when implementing the discussed schemes in a level set-based numerical framework). The formal treatment of topological changes is a topic of active current research and will be discussed briefly in section “Topological Derivatives.”

Least Squares Cost Functionals and Gradient Directions

Typically, appropriate function spaces are needed for defining and calculating appropriate descent directions with respect to the data misfit cost functional. Without being very specific, in the following, the general notation P is used for denoting the space of parameters b and, if not otherwise specified, Z for denoting the space of measurements \tilde{g} . For simplicity, these function spaces are considered being appropriately chosen Hilbert or vector spaces. Certainly, other types of spaces can be used as well, which might lead to interesting variants of the described concepts.

Consider now the least squares cost functional

$$\mathcal{J}(b) = \frac{1}{2} \|\mathcal{R}(b)\|_Z^2 = \frac{1}{2} \langle \mathcal{R}(b), \mathcal{R}(b) \rangle_Z, \quad (81)$$

where \langle , \rangle_Z denotes the canonical inner product in data space Z . Assume that $\mathcal{R}(b)$ admits the expansion

$$\mathcal{R}(b + \delta b) = \mathcal{R}(b) + \mathcal{R}'(b)\delta b + O(\|\delta b\|_P^2), \quad (82)$$

letting $\|\cdot\|_P$ be the canonical norm in parameter space P , for a sufficiently small perturbation (variation) $\delta b \in P$. The linear operator $\mathcal{R}'(b)$ (if it exists) is often called the *Fréchet derivative* of \mathcal{R} . Plugging (82) into (81) yields the relationship

$$\mathcal{J}(b + \delta b) = \mathcal{J}(b) + \operatorname{Re}\{\mathcal{R}'(b)^*\mathcal{R}(b), \delta b\}_P + O(\|\delta b\|_P^2) \quad (83)$$

where the symbol Re indicates the real part of the corresponding quantity. The operator $\mathcal{R}'(b)^*$ is the formal adjoint operator of $\mathcal{R}'(b)$ with respect to spaces Z and P :

$$\langle \mathcal{R}'(b)^* g, \hat{b} \rangle_P = \langle g, \mathcal{R}'(b) \hat{b} \rangle_Z \quad \text{for all } \hat{b} \in P, g \in Z. \quad (84)$$

The quantity

$$\mathbf{grad}_b \mathcal{J} = \mathcal{R}'(b)^* \mathcal{R}(b) \quad (85)$$

is called the *gradient direction* of \mathcal{J} in b .

It is assumed that the operators $\mathcal{R}'(b)$ and $\mathcal{R}'(b)^*$ take into account the correct interface conditions at ∂D , which is important when actually evaluating these derivatives in a “direct” or in an “adjoint” fashion. In many practical applications, the situation can occur that (formally) the fields need to be evaluated at interfaces where jumps occur. In these situations, appropriate limits can be considered. Alternatively, the tools developed in section “Shape Sensitivity Analysis and the Speed Method” can be applied there. The existence and special form of Fréchet derivatives $\mathcal{R}'(b)$ (and the corresponding shape derivatives) for parameter distributions b with discontinuities along interfaces are problem specific and beyond the scope of this chapter. Refer to the cited literature, for example, [9, 15, 49, 53, 54, 58, 78]. In many practical implementations, the interface ∂D is de facto replaced by a narrow transition zone with smoothly varying parameters, in which case the interface conditions disappear.

Change of b Due to Shape Deformations

Assume that every point \mathbf{x} moves in the domain Ω a small distance $\mathbf{y}(\mathbf{x})$ and that the mapping $\mathbf{x} \rightarrow \mathbf{y}(\mathbf{x})$ is sufficiently smooth, such that the basic structure of the shape D remains preserved. Then, the points located on the boundary $\Gamma = \partial D$ will move to the new locations $\mathbf{x}' = \mathbf{x} + \mathbf{y}(\mathbf{x})$, and the boundary Γ will be deformed into the new boundary $\Gamma' = \partial D'$. Assume furthermore that the parameter distribution in Ω has the special form (4), such that it will change as well. In the following, the first goal is to quantify this change in the parameter distribution $b(\mathbf{x})$ due to an infinitesimal deformation as described above.

Consider the inner product of δb with a test function f

$$\langle \delta b, f \rangle_\Omega = \int_{\Omega} \delta b(\mathbf{x}) \overline{f(\mathbf{x})} d\mathbf{x} = \int_{\operatorname{syndiff}(D, D')} \delta b(\mathbf{x}) \overline{f(\mathbf{x})} d\mathbf{x}, \quad (86)$$

where the overline means “complex conjugate” and $\operatorname{syndiff}(D, D') = (D \cup D') \setminus (D \cap D')$ is the symmetric difference of the sets D and D' (see Fig. 8). Since the difference in D and D' is infinitesimal, the area integral reduces to a line integral. Let $\mathbf{n}(\mathbf{x})$ denote the outward normal to \mathbf{x} . Then, the integral in (86) becomes

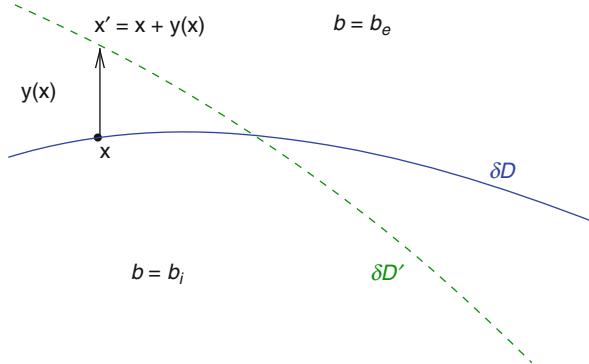

Fig. 8 Deformation of shapes using calculation of small variations

$$\langle \delta b, f \rangle_{\partial D} = \int_{\partial D} (b_i(\mathbf{x}) - b_e(\mathbf{x})) \mathbf{y}(\mathbf{x}) \cdot \mathbf{n}(\mathbf{x}) \overline{f(\mathbf{x})} ds(\mathbf{x}), \quad (87)$$

where $ds(\mathbf{x})$ is the incremental arclength. Here it has been used that in the limit $\delta b(\mathbf{x}) = b_i(\mathbf{x}) - b_e(\mathbf{x})$ at the boundary point $\mathbf{x} \in \partial D$ due to (4). It follows the result

$$\delta b(\mathbf{x}) = \varpi_{\partial D} \left((b_i(\mathbf{x}) - b_e(\mathbf{x})) \mathbf{y}(\mathbf{x}) \cdot \mathbf{n}(\mathbf{x}) \right) \quad (88)$$

where $\varpi_{\partial D}$ is the n -dimensional restriction operator which restricts functions defined in Ω to the boundary ∂D of the shape D ($n = 2$ or 3 , usually). Therefore, $\delta b(\mathbf{x})$ is interpreted now as a surface measure on ∂D . Using the n -dimensional Dirac delta distribution $\delta_{\partial D}$ concentrated on the boundary ∂D of the shape D , (88) can be written in the form

$$\delta b(\mathbf{x}) = (b_i - b_e) \mathbf{y}(\mathbf{x}) \cdot \mathbf{n}(\mathbf{x}) \delta_{\partial D}(\mathbf{x}) \quad (89)$$

which is a distribution defined on the entire domain Ω but concentrated on ∂D where it has the same strength as the corresponding surface measure. Although, strictly speaking, they are different mathematical objects, they are identified in the following for simplicity. Compare (87) also to the classical shape or domain derivative as, for example, calculated in [49], focusing there on the effect of the infinitesimal change in the boundary of a scatterer on the far-field pattern of a scattering experiment.

Variation of Cost Due to Velocity Field $\mathbf{v}(\mathbf{x})$

A popular approach for generating small displacements $\mathbf{y}(\mathbf{x})$ (as discussed in section “Change of b Due to Shape Deformations”) for moving the boundary ∂D is to assign to each point in the domain a *velocity field* $\mathbf{v}(\mathbf{x})$ and to let the points $\mathbf{x} \in \Omega$ move a small artificial evolution time $[0, \tau]$ with constant velocity $\mathbf{v}(\mathbf{x})$. Then

$$\mathbf{y}(\mathbf{x}) = \mathbf{v}(\mathbf{x})\tau. \quad (90)$$

Plugging this into (89) for $t \in [0, \tau]$, the corresponding change in the parameters follows as

$$\delta b(\mathbf{x}; t) = (b_i - b_e) \mathbf{v}(\mathbf{x}) \cdot \mathbf{n}(\mathbf{x}) t \delta_{\partial D}(\mathbf{x}). \quad (91)$$

Plugging expression (91) into (83) and neglecting terms of higher than linear order yields

$$\begin{aligned} \mathcal{J}(b(t)) - \mathcal{J}(b(0)) &= \operatorname{Re} \langle \mathbf{grad}_b \mathcal{J}, \delta b(\mathbf{x}; t) \rangle_P \\ &= \operatorname{Re} \langle \mathbf{grad}_b \mathcal{J}, (b_i - b_e) \mathbf{v}(\mathbf{x}) \cdot \mathbf{n}(\mathbf{x}) t \delta_{\partial D}(\mathbf{x}) \rangle_P \end{aligned} \quad (92)$$

or, in the limit $t \rightarrow 0$, evaluating the Dirac delta distribution,

$$\left. \frac{\partial \mathcal{J}(b)}{\partial t} \right|_{t=0} = \operatorname{Re} \int_{\partial D} \mathbf{grad}_b \mathcal{J} \overline{(b_i - b_e)} \mathbf{v}(\mathbf{x}) \cdot \mathbf{n}(\mathbf{x}) ds(\mathbf{x}), \quad (93)$$

where the overline means “complex conjugate” and $\mathbf{grad}_b \mathcal{J}$ is defined in (85). Similar expressions will be derived further below using formal shape sensitivity analysis. (Compare, e.g., for the situation of TM-waves, the expression (97) calculated by using (93) with the analogous expressions (100) and (105) calculated by using formal shape sensitivity analysis.)

If a velocity field $\mathbf{v}(\mathbf{x})$ can be found such that $\left. \frac{\partial \mathcal{J}(b)}{\partial t} \right|_{t=0} < 0$, then it is expected (for continuity reasons) that this inequality holds in a sufficiently small time interval $[0, \tau]$ and that therefore the total cost during the artificial flow will be reduced. This will be the general strategy in most optimization type approaches for solving the underlying inverse problem. See the brief discussion in section “Shape Evolution and Shape Optimization.”

Notice that only the normal component of the velocity field

$$F(\mathbf{x}) = \mathbf{v}(\mathbf{x}) \cdot \mathbf{n}(\mathbf{x}) \quad (94)$$

at the boundary ∂D of the shape D is of relevance for the change in the cost (compare the remarks made already in section “The Level Set Framework for Shape Evolution”). This is because tangential components of \mathbf{v} do not contribute to shape deformations. In a parameterized way of thinking, they only “re-parameterize” the existing boundary.

Example: Shape Variation for TM-Waves

An instructive example is given here in order to demonstrate the above concepts for a practical application. Consider TM-waves in a typical imaging situation of subsurface imaging or of microwave breast screening as in the case study of section “Example 1: Microwave Breast Screening.” Assume for simplicity that the basic level set model of section “The Basic Level Set Formulation for Binary Media”

is applied here. The cost functional measuring the mismatch between calculated data $u_M[D]$ corresponding to the shape D and physically measured data \tilde{g} is defined as

$$\mathcal{J}(D) = \frac{1}{2} \|u_M[D] - \tilde{g}\|_{L^2(M)}^2, \quad (95)$$

where the calculated measurements u_M are given as the electric field values $u(\mathbf{x})$ at the set of receiver locations M . Using a properly defined adjoint state $z(\mathbf{x})$ (see, e.g., [30, 34, 71] for details on adjoint states), it can be shown by straightforward calculation that $\mathcal{R}'(b)^*\mathcal{R}(b)$ takes the form

$$(\mathbf{grad}_b \mathcal{J})(\mathbf{x}) = \overline{u(\mathbf{x})z(\mathbf{x})}, \quad (96)$$

where $u(\mathbf{x})$ denotes the solution of the forward problem and $\mathbf{grad}_b \mathcal{J}$ is defined as in (85). Therefore, it follows that

$$\left. \frac{\partial \mathcal{J}(b)}{\partial t} \right|_{t=0} = \operatorname{Re} \int_{\partial D} u(\mathbf{x})z(\mathbf{x})(b_i - b_e)\mathbf{v}(\mathbf{x}) \cdot \mathbf{n}(\mathbf{x}) ds(\mathbf{x}), \quad (97)$$

where it is used that the real part of a complex number and its complex conjugate are identical. Similar expressions based on adjoint field calculations can be derived for a large variety of applications; see, for example, [34, 39, 45, 71, 84, 89, 90].

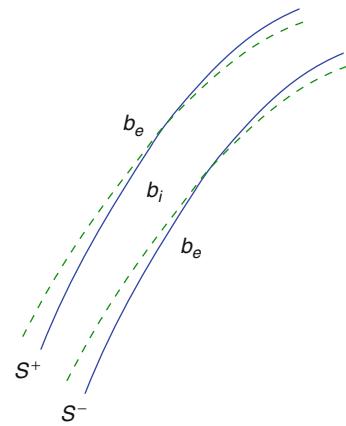

Example: Evolution of Thin Shapes (Cracks)

Another application of this technique has been presented in [4, 77] for finding cracks in a homogeneous material from boundary data; see section ‘‘Example 3: Crack Detection.’’ The evolution of cracks as defined in section ‘‘A Modification of the Classical Level Set Technique for Describing Cracks or Thin Shapes’’ requires the simultaneous consideration of two level set functions. Evolution of the first level set function amounts to displacement of the thin region (crack) in the transversal direction, whereas evolution of the second level set function describes the process of crack growth or shrinkage in the longitudinal direction, which comes with the option of crack splitting and merging. Descent directions for both level set functions can be calculated by the following arguments presented above. It needs to be taken into account, however, that, due to the specific construction of a crack with finite thickness, deformation of the zero level set of the first level set function is associated with a displacement of the crack boundary at two adjacent locations, which both contribute to a small variation in the cost. See Fig. 9.

Assume that a small displacement is applied to the zero level set of the first level set function defining S in the notation of section ‘‘A Modification of the Classical Level Set Technique for Describing Cracks or Thin Shapes.’’ This is reflected by two contributions to the least squares data misfit cost, one from the deformation of S^- in Fig. 9 and the other one from the deformation of S^+ in Fig. 9. It follows that a descent velocity is now given as $\mathbf{v}(\mathbf{x}) = F_{\varphi_1}(\mathbf{x})\mathbf{n}(\mathbf{x})$ with

$$F_{\varphi_1}(\mathbf{x}) = -(b_i - b_e) [\mathbf{grad}_b \mathcal{J}|_{S^+} - \mathbf{grad}_b \mathcal{J}|_{S^-}] \quad \text{on } S, \quad (98)$$

Fig. 9 Deformation of a thin shape (crack) using calculus of small variations

with $\mathbf{grad}_b \mathcal{J}$ being defined in (85). In (98), for each $\mathbf{x} \in \Gamma_{\phi_1}$, two adjacent points of $\mathbf{grad}_b \mathcal{J}|_{S^+}$ and $\mathbf{grad}_b \mathcal{J}|_{S^-}$ contribute to the value of $F_{\phi_1}(\mathbf{x})$ which can be found in the normal direction to Γ_{ϕ_1} in \mathbf{x} .

In a similar way, a descent direction with respect to the second level set function ϕ_2 can be obtained. Its detailed derivation depends slightly on the way how the crack tips are constructed in section “A Modification of the Classical Level Set Technique for Describing Cracks or Thin Shapes,” where two alternative choices are given. Overall, a descent velocity can be calculated following classical rules for those points \mathbf{x} of ∂B (i.e., for those points of the zero level set of ϕ_2) which satisfy $\mathbf{x} \in \partial B \cap \Gamma_{\phi_1}^\delta$ or, alternatively, $\mathbf{x} \in \partial B \cap \Gamma_{\phi_1}$. Then, the obtained velocity field needs to be extended first to the remaining parts of ∂B and then to the rest of Ω . Notice that the specific form of $\mathbf{grad}_b \mathcal{J}$ might be slightly different here from the one given in (96) due to the slightly different PDE which might be involved here (depending on the application). For more details, refer to [4, 77].

Shape Sensitivity Analysis and the Speed Method

In this section, an alternative technique is presented for formally defining shape derivatives and modeling shape deformations driven by cost functionals. This theory, called *shape sensitivity analysis*, is quite general and powerful, such that it is used heavily in various applications. Only very few concepts of it can be mentioned here which are employed when calculating descent directions with respect to data misfit cost functionals.

The tools, as presented here, have been used and advanced significantly during the last twenty years in the framework of optimal shape design [30, 87]. Having this powerful theory readily available, it is therefore quite natural that these methods have been applied very early already to the applications of shape-based inverse problems with level sets. The theory of this section is again mainly concentrated

upon modeling in a formally accurate way the deformation of already existing shapes. It does not incorporate topological changes. These will be discussed briefly in section “Topological Derivatives.”

Example: Shape Sensitivity Analysis for TM-Waves

Again the situation of inverse scattering by TM-waves is considered here. The below discussion closely follows the results presented in [64]. The main tools used here are the material and shape derivative defined in section “The Material Derivative Method.”

The cost functional measuring the mismatch between calculated data $u_M[D]$ corresponding to the shape D and physically measured data \tilde{g} is defined by (95). When perturbing the shape by a velocity field $\mathbf{V}(t, \mathbf{x})$, the electric field at the (fixed) probing line changes according to $u \rightarrow u + u'$, where u' is the shape derivative defined in section “The Material Derivative Method.” Plugging this into (95) and neglecting terms of higher than linear order, it is verified that

$$d\mathcal{J}(D, \mathbf{V}) = \operatorname{Re} \int_M u'(\mathbf{x}) \overline{(u_M - \tilde{g})(\mathbf{x})} d\mathbf{x}. \quad (99)$$

Now, the shape derivative u' can be calculated by first computing the material derivative (also defined in section “The Material Derivative Method”) and then using one of the relationships between the material derivative and the shape derivative (see sections “The Material Derivative Method” and “Some Useful Shape Functionals”). Using also here an adjoint state z , the Eulerian derivative can be characterized and calculated as

$$d\mathcal{J}(D, \mathbf{V}) = \operatorname{Re} \int_{\Gamma} (b_{\text{int}} - b_{\text{ext}}) u(\mathbf{x}) z(\mathbf{x}) \mathbf{V}(0, \mathbf{x}) \cdot \mathbf{n} d\Gamma. \quad (100)$$

Notice that this is exactly the same result as we arrived at in (97). For more details, refer to [64].

Shape Derivatives by a Min–Max Principle

In order to avoid the explicit calculation of material and shape derivatives of the states with respect to the flow fields, an alternative technique can be used as reported in [29, 30, 78]. It is based on a reformulation of the derivative of a shape functional $\mathcal{J}(D)$ with respect to time as the partial derivative of a saddle point (or a “min–max”) of a suitably defined Lagrangian. In the following, the basic features of this approach will be outlined, focusing in particular on the shape derivative for TM-waves.

Let again the cost functional $\mathcal{J}(D(t))$ be defined as in (95) by

$$\mathcal{J}(D(t)) = \frac{1}{2} \|u_M[D(t)] - \tilde{g}\|_{L^2(M)}. \quad (101)$$

The goal is to write $\mathcal{J}(D(t))$ in the form

$$\mathcal{J}(D(t)) = \min_u \max_z \mathcal{L}(t, u, z) \quad (102)$$

for some suitably defined Lagrangian $\mathcal{L}(t, u, z)$. Here and in the following, the complex nature of the forward fields u and the adjoint fields z is (partly) neglected in order to simplify notation (more rigorous expressions can be found in [78]). The Lagrangian $\mathcal{L}(t, u, z)$ takes the form

$$\begin{aligned} \mathcal{L}(t, u, z) = & \frac{1}{2} \int_M \left| \int_{\Omega} \eta(\mathbf{x}') G_{12}(\mathbf{x}, \mathbf{x}') u(\mathbf{x}') d\mathbf{x}' - \tilde{g}(x) \right|^2 dx \\ & + \operatorname{Re} \int_{\Omega} \left(u(\mathbf{x}) - u^{\text{inc}}(\mathbf{x}) - \int_{\Omega} \eta(\mathbf{x}') G_{22}(\mathbf{x}, \mathbf{x}') u(\mathbf{x}') d\mathbf{x}' \right) z(\mathbf{x}) dx. \end{aligned} \quad (103)$$

Next, it can be shown that this Lagrangian has a unique saddle point denoted by (u^*, z^*) , which is characterized by an optimality condition with respect to u and z . In fact, the uniqueness follows from the well-posedness and uniqueness of the solutions of the direct and adjoint state equations; see [31, 78]. The key observation is now that

$$\frac{d\mathcal{J}}{dt} = \frac{\partial}{\partial t} \left(\min_u \max_z \mathcal{L}(t, u, z) \right) = \frac{\partial}{\partial t} \mathcal{L}(t, u^*, z^*) \quad (104)$$

which says that the time derivative of the original cost functional can be replaced by the partial time derivative of a saddle point. Following these ideas, the result is derived

$$\frac{d\mathcal{J}}{dt} = \operatorname{Re} \int_{\Gamma} (b_{\text{int}} - b_{\text{ext}}) u(\mathbf{x}) z(\mathbf{x}) \mathbf{V}(0) \cdot \mathbf{n} d\Gamma \quad (105)$$

which holds for *TM-waves* and which is identical to the previously derived expressions (97) and (100).

Similar expressions (now involving expressions of the form $\nabla u(\mathbf{x}) \nabla z(\mathbf{x})$ rather than $u(\mathbf{x})z(\mathbf{x})$ at the interfaces) can be derived also for so-called TE-waves; see [78]. The above outlined min–max approach is in fact wide ranging and can be extended to 3D vector scattering, geometrical regularizations, simultaneous searches of shape and contrast, etc. It de facto applies as soon as one has well-posedness of the direct and adjoint problems. For more details, refer to [29, 30, 78, 79].

Formal Shape Evolution Using the Heaviside Function

A third possibility for describing and modeling shape deformations driven by data misfit (in addition to using calculus of variation as in section “Shape Deformation by

Calculus of Variations” or shape sensitivity analysis as in section “Shape Sensitivity Analysis and the Speed Method”) is the use of the characteristic function and formal (basic) distribution theory. In contrast to the previous two techniques which first calculate velocity fields in the normal direction to the interfaces and then move the interfaces accordingly using a level set technique (or any other computational front propagation technique), typically leading to a Hamilton–Jacobi-type formalism (compare the remarks in section “The Level Set Framework for Shape Evolution”), the method presented in the following does not explicitly use the concept of velocity vector fields, but instead tries to design evolution laws directly for the describing level set functions (thereby not necessarily leading to Hamilton–Jacobi-type evolution laws).

Notice that many of the level set formulations presented in Sect. 3 give rise to similar concepts as discussed in the following. On the other hand, typically also the concepts discussed in sections “Shape Deformation by Calculus of Variations” and “Shape Sensitivity Analysis and the Speed Method” can be translated, once suitable velocity fields have been determined, into level set evolutions using the various representations of Sect. 3. Details on how these evolution laws can be established can be found in the literature cited in Sect. 3.

The formalism discussed in the following is in fact very flexible and quite easy to handle if standard rules for calculations with distributions are taken into account. Moreover, it often leads to very robust and powerful reconstruction algorithms. Certainly, it also has some limitations: in the form presented here, it is mainly applicable for “penetrable objects” with finite jumps in the coefficients between different regions. This means that it does not generally handle inverse scattering from impenetrable obstacles if very specific and maybe quite complicated boundary conditions need to be taken into account at the scatterer surfaces. For those applications, the theory based on shape sensitivity analysis is more appropriate. Nevertheless, since many inverse scattering problems can be described in the form presented in the following, possibly incorporating some finite jump conditions of the forward and adjoint fields or their normal components across the interfaces (which can be handled by slightly “smearing out” these interfaces over a small transition zone), this theory based on formal distribution theory provides an interesting alternative when deriving level set-based shape evolution equations for solving inverse scattering problems.

The main idea of this technique is demonstrated by giving two examples related to the test cases from sections “Example 1: Microwave Breast Screening” and “Example 2: History Matching in Petroleum Engineering.”

Example: Breast Screening–Smoothly Varying Internal Profiles

In the example of breast screening as discussed in section “Example 1: Microwave Breast Screening,” three level set functions and four different interior parameter profiles need to be reconstructed from the given data simultaneously. Some of the interior profiles are assumed to be constant, whereas others are smoothly varying. In the following, the theory is developed under the assumption that all interior parameter profiles are smoothly varying. The case of constant parameter profiles

in some region is captured in the next section where a similar case is discussed for the application of reservoir engineering.

Let $\mathcal{R}(b(\phi_1, \phi_2, \phi_3, b_1, b_2, b_3, b_4))$ denote the difference between measured data and data corresponding to the latest best guess $(\phi_1, \phi_2, \phi_3, b_1, b_2, b_3, b_4)$ of level set functions and interior profiles in the image model discussed in section “A Modification of Color Level Set for Tumor Detection.” Then, the least squares data misfit for tumor detection is given by

$$\mathcal{J}(b(\phi_1, \phi_2, \phi_3, b_1, b_2, b_3, b_4)) = \frac{1}{2} \|\mathcal{R}(b(\phi_1, \phi_2, \phi_3, b_1, b_2, b_3, b_4))\|^2. \quad (106)$$

Introducing an artificial evolution time t for the above specified unknowns of the inverse problem, the goal is to find evolution laws

$$\frac{d\phi_v}{dt} = f_v(\mathbf{x}, t), \quad v = 1, \dots, 3, \quad (107)$$

$$\frac{db_v}{dt} = g_v(\mathbf{x}, t), \quad v = 1, \dots, 4, \quad (108)$$

such that the cost \mathcal{J} decreases with increasing evolution time. With level set functions and interior profiles evolving, also the cost will change, $\mathcal{J} = \mathcal{J}(t)$, such that formally its time derivative can be calculated by using the chain rule

$$\begin{aligned} \frac{d\mathcal{J}}{dt} &= \frac{d\mathcal{J}}{db} \left[\sum_{v=1}^3 \frac{\partial b}{\partial \phi_v} \frac{d\phi_v}{dt} + \sum_{v=1}^4 \frac{\partial b}{\partial b_v} \frac{db_v}{dt} \right] \\ &= \text{Re} \left\langle \mathbf{grad}_b \mathcal{J}, \sum_{v=1}^3 \frac{\partial b}{\partial \phi_v} f_v + \sum_{v=1}^4 \frac{\partial b}{\partial b_v} g_v \right\rangle_P. \end{aligned} \quad (109)$$

Here, Re indicates to take the real part of the following complex quantity and $\langle \cdot, \cdot \rangle_P$ denotes a suitable inner product in parameter space P , and $\mathbf{grad}_b \mathcal{J}$ is defined in (85). It is verified easily that in the situation of section “A Modification of Color Level Set for Tumor Detection”

$$\frac{\partial b}{\partial \phi_1} = \delta(\phi_1) \left(-b_1 + b_2(1 - H(\phi_2)) \right. \quad (110)$$

$$\left. + H(\phi_2) \left\{ b_3(1 - H(\phi_3)) + b_4 H(\phi_3) \right\} \right),$$

$$\frac{\partial b}{\partial \phi_2} = H(\phi_1) \delta(\phi_2) [-b_2 + b_3, (1 - H(\phi_3)) + b_4 H(\phi_3)], \quad (111)$$

$$\frac{\partial b}{\partial \phi_3} = H(\phi_1) H(\phi_2) \delta(\phi_3) \{-b_3 + b_4\}, \quad (112)$$

and

$$\frac{\partial b}{\partial b_1} = 1 - H(\phi_1), \quad (113)$$

$$\frac{\partial b}{\partial b_2} = H(\phi_1)(1 - H(\phi_2)), \quad (114)$$

$$\frac{\partial b}{\partial b_3} = H(\phi_1)H(\phi_2)(1 - H(\phi_3)), \quad (115)$$

$$\frac{\partial b}{\partial b_4} = H(\phi_1)H(\phi_2)H(\phi_3). \quad (116)$$

Descent directions are therefore given by

$$f_v(t) = -C_v(t) \operatorname{Re} \left[\mathbf{grad}_b \mathcal{J} \frac{\partial b}{\partial \phi_v} \right], \quad v = 1, \dots, 3, \quad (117)$$

$$g_v(t) = -\hat{C}_v(t) \operatorname{Re} \left[\mathbf{grad}_b \mathcal{J} \frac{\partial b}{\partial b_v} \right], \quad v = 1, \dots, 4, \quad (118)$$

with some appropriately chosen positive-valued speed factors $C_v(t)$ and $\hat{C}_v(t)$. An efficient way to compute $\mathbf{grad}_b \mathcal{J}$ is again to use the *adjoint formulation*; see (96) and for more details [34, 52, 71].

Notice that it might be convenient to approximate the Dirac delta on the right-hand side of (110)–(112) in the formulation of the level set evolution by either a narrowband scheme or by a positive constant which allows for topological changes in the entire computational domain driven by the least squares data misfit. For more details, see the brief discussion in section “Shape Evolution and Shape Optimization” and the slightly more detailed discussions held in [31, 52]. Following the latter scheme, one possible numerical discretization of the expressions (107) and (108) in time $t = t^{(n)}$, $n = 0, 1, 2, \dots$, then yields the update rules

$$\phi_v^{(n+1)} = \phi_v^{(n)} - \delta t^{(n)} C_v(t^{(n)}) \operatorname{Re} \left[\mathbf{grad}_b \mathcal{J} \frac{\partial b}{\partial \phi_v} \right]^{(n)}, \quad v = 1, \dots, 3, \quad (119)$$

$$b_v^{(n+1)} = b_v^{(n)} - \delta t^{(n)} \hat{C}_v(t^{(n)}) \operatorname{Re} \left[\mathbf{grad}_b \mathcal{J} \frac{\partial b}{\partial b_v} \right]^{(n)}, \quad v = 1, \dots, 4. \quad (120)$$

Example: Reservoir Characterization–Parameterized Internal Profiles

In the example of history matching in reservoir engineering as discussed in section “Example 2: History Matching in Petroleum Engineering,” one level set function and two interior parameter profiles need to be reconstructed from the given data, where one interior parameter profile is assumed to be smoothly varying, and the other one is assumed to overall follow a bilinear pattern. The case of smoothly varying interior parameter profiles is completely analogous to the situation

discussed in the previous section for microwave breast screening, such that it is not considered here. In the following, the situation is treated where both interior profiles follow a parameterized model with a certain set of given basis functions. In the history matching application as well as in the microwave breast screening application, the mixed cases of partly parameterized (e.g., with a constant or a bilinear profile) and partly smooth profiles are straightforward to implement as combinations of these two general approaches.

In this approach, it is assumed that the two internal profiles can be written in the parameterized form

$$b_i(\mathbf{x}) = \sum_{j=1}^{N_i} \alpha_j a_j(\mathbf{x}), \quad b_e(\mathbf{x}) = \sum_{k=1}^{N_e} \beta_k b_k(\mathbf{x}), \quad (121)$$

where a_j and b_k are the selected basis functions for each of the two domains D and $\Omega - D$, respectively. See the model discussed in section “A Modification of Color Level Set for Reservoir Characterization.” In the inverse problem, the level set function ϕ and the weights α_j and β_k need to be estimated with the goal to reproduce the measured data in some sense. In order to obtain an (artificial) evolution of the unknown quantities ϕ , α_j , and β_k , the following three general evolution equations for the level set function and for the weight parameters are formulated

$$\frac{d\phi}{dt} = f(\mathbf{x}, t, \phi, \mathcal{R}), \quad (122)$$

$$\frac{d\alpha_j}{dt} = g_j(t, \phi, \mathcal{R}), \quad \frac{d\beta_k}{dt} = h_k(t, \phi, \mathcal{R}). \quad (123)$$

In the same way as before, the goal is to define the unknown terms f , g_j , and h_k such that the mismatch in the production data decreases during the evolution. For this purpose, we reformulate the cost functional now as

$$\mathcal{J}(b(\phi, \alpha_j, \beta_k)) = \frac{1}{2} \|\mathcal{R}(b(\phi, \alpha_j, \beta_k))\|^2, \quad (124)$$

where α_j denotes the weight parameters for region D and β_k denotes the weight parameters for region $\Omega - D$. Formal differentiation of this cost functional with respect to the artificial time variable t yields, in a similar way as before, the descent directions [35]

$$f_{SD}(\mathbf{x}) = -C_1 \chi_{NB}(\phi) (b_e - b_i) \mathbf{grad}_b \mathcal{J}, \quad (125)$$

$$g_{jSD}(t) = -C(\alpha_j) \int_{\Omega} a_j(1 - H(\phi)) \mathbf{grad}_b \mathcal{J} d\mathbf{x}, \quad (126)$$

$$h_{kSD}(t) = -C(\beta_k) \int_{\Omega} b_k H(\phi) \mathbf{grad}_b \mathcal{J} d\mathbf{x}, \quad (127)$$

where C_1 , $C(\alpha_j)$, and $C(\beta_k)$ are again positive-valued speed factors which are used for steering the speed of evolution for each of the unknowns ϕ , α_j , and β_k individually. The narrowband function $\chi_{NB}(\phi)$ is introduced for computational convenience and can be omitted if desired. For details on this narrowband formulation, see the brief discussion held in section “Shape Evolution and Shape Optimization.”

7 Regularization Techniques for Shape Evolution Driven by Data Misfit

Regularization of shape evolution can be achieved by additional additive or multiplicative terms in the cost functional which control geometric terms, as discussed in Sect. 5. Alternatively, some form of regularization can be obtained by restricting the velocity fields, level set updates, or level set functions to certain classes, often without the need to introduce additional terms into the cost functional. Some of these techniques are presented in the following.

Regularization by Smoothed Level Set Updates

In the binary case (see section “The Basic Level Set Formulation for Binary Media”), a properly chosen level set function ϕ uniquely specifies a shape $D[\phi]$. This can be described by a nonlinear operator Π mapping level set functions to parameter distributions

$$\Pi(\phi)(\mathbf{x}) = \begin{cases} b_i(\mathbf{x}), & \phi(\mathbf{x}) \leq 0, \\ b_e(\mathbf{x}), & \phi(\mathbf{x}) > 0. \end{cases} \quad (128)$$

We obviously have the equivalent characterization

$$\Pi(\phi)(\mathbf{x}) = b_i(\mathbf{x})\chi_D(\mathbf{x}) + b_e(\mathbf{x})(1 - \chi_D(\mathbf{x})) \quad (129)$$

where χ_D is the characteristic function of the shape D . The “level set-based residual operator” $\mathcal{T}(\phi)$ follows as

$$\mathcal{T}(\phi) = \mathcal{R}(\Pi(\phi)). \quad (130)$$

Formal differentiation by the chain rule yields

$$\mathcal{T}'(\phi) = \mathcal{R}'(\Pi(\phi))\Pi'(\phi). \quad (131)$$

The (formal) gradient direction of the least square cost functional

$$\hat{\mathcal{J}}(\phi) = \frac{1}{2} \|\mathcal{R}(b(\phi))\|_Z^2 \quad (132)$$

is then given by

$$\mathbf{grad}_{\mathcal{J}}(\phi) = \mathcal{T}'(\phi)^* \mathcal{T}(\phi), \quad (133)$$

where $\mathcal{T}'(\phi)^*$ is the L_2 -adjoint of $\mathcal{T}'(\phi)$. Moreover, formally it is calculated by standard differentiation rules that

$$\Pi'(\phi) = (b_i - b_e)\delta(\phi). \quad (134)$$

Notice that, strictly speaking, the right-hand side of (131) is not an L_2 -function due to the Delta distribution which is seen in (134). Nevertheless, in order to obtain practically useful expressions in a straightforward way, it is convenient to proceed with the formal considerations and, whenever necessary, to approximate the Dirac delta distribution $\delta(\phi)$ by a suitable L_2 -function; see the brief discussion on this topic held in section ‘‘Shape Evolution and Shape Optimization.’’ For example, the narrowband function $\chi_{\phi,d}(\mathbf{x})$ as defined in (151) can be used for that purpose. Then,

$$\mathcal{T}'(\phi)^* = \Pi'(\phi)^* \mathcal{R}'(\Pi(\phi))^*. \quad (135)$$

Assuming now that $\phi \in W_1(\Omega)$ with

$$W_1(\Omega) = \left\{ \phi : \phi \in L_2(\Omega), \nabla \phi \in L_2(\Omega), \frac{\partial \phi}{\partial \nu} = 0 \text{ at } \partial \Omega \right\}, \quad (136)$$

the adjoint operator $\mathcal{T}'(\phi)^*$ needs to be replaced by a new adjoint operator $\mathcal{T}'(\phi)^\circ$ which maps back from the data space into this Sobolev space $W_1(\Omega)$. Using the weighted inner product

$$\langle v, w \rangle_{W_1(\Omega)} = \alpha \langle v, w \rangle_{L_2(\Omega)} + \beta \langle \nabla v, \nabla w \rangle_{L_2(\Omega)} \quad (137)$$

with $\alpha \geq 1$ and $\beta > 0$ being carefully chosen regularization parameters, it follows

$$\mathcal{T}'(\phi)^\circ = (\alpha I - \beta \Delta)^{-1} \mathcal{T}'(\phi)^*. \quad (138)$$

The positive definite operator $(\alpha I - \beta \Delta)^{-1}$ has the effect of mapping the L_2 gradient $\mathcal{T}'(\phi)^* \mathcal{T}(\phi)$ from $L_2(\Omega)$ towards the smoother Sobolev space $W_1(\Omega)$. In fact, different choices of the weighting parameters α and β visually have the effect of ‘‘smearing out’’ the unregularized updates to a different degree. In particular, high-frequency oscillations or discontinuities of the updates for the level set function are removed, which yields shapes with more regular boundaries. Notice that for $\phi \in W_1(\Omega)$, the trace $\phi|_\Gamma$ (which is the zero level set) is only within the intermediate Sobolev space $W_{1/2}(\Gamma)$ due to the trace theorem. Therefore, the ‘‘degree of smoothness’’ of the reconstructed shape boundaries Γ lies somewhere in between $L_2(\Gamma)$ and $W_1(\Gamma)$.

Sometimes it is difficult or inconvenient to apply the mapping (138) to the calculated updates $\mathcal{T}'(\phi)^*\mathcal{T}(\phi)$. Then, an approximate version can be applied instead which is derived next. Denote $f_r = \mathcal{T}'(\phi)^\circ\mathcal{T}(\phi)$ and $f_d = \mathcal{T}'(\phi)^*\mathcal{T}(\phi)$. f_r can formally be interpreted as the minimizer of the cost functional

$$\hat{\mathcal{J}}(f) = \frac{\alpha - 1}{2}\|f\|_{L_2}^2 + \frac{\beta}{2}\|\nabla f\|_{L_2}^2 + \frac{1}{2}\|f - f_d\|_{L_2}^2. \quad (139)$$

In particular, the minimization process of (139) can be attempted by applying a gradient method instead of explicitly applying $(\alpha I - \beta\Delta)^{-1}$ to f_d . The gradient flow of (139) yields a modified heat (or diffusion) equation of the form

$$\begin{aligned} v_t - \beta\Delta v &= f_d - \alpha v \quad \text{for } t \in [0, \tau] \\ v(0) &= f_d, \end{aligned} \quad (140)$$

with time-dependent heating term $f_d - \alpha v$, where $\hat{v} = v(\tau)$ evolves towards the minimizer f_r of (139) for $\tau \rightarrow \infty$. Practically, it turns out that a satisfactory regularization effect is achieved if instead of (140) the simplified heat equation is solved for a few time steps only:

$$\begin{aligned} v_t - \beta\Delta v &= 0 \quad \text{for } t \in [0, \tau] \\ v(0) &= f_d, \end{aligned} \quad (141)$$

for τ small, using $\hat{v} = v(\tau)$ instead of f_r as update. For more details, see [44].

The above-described regularization schemes only operate on the updates (or forcing terms f in a time-dependent setting) but *not* on the level set function itself. In particular, in the case that a satisfactory solution of the shape reconstruction problem has already been achieved such that the data residuals become zero, the evolution will stop (which sometimes is desirable). In the following subsection, we will mention some alternative regularization methods where the evolution in the above-described situation would continue until an extended cost functional combining data misfit with additional geometric terms or with additional constraints on the final level set functions is minimized.

Regularization by Explicitly Penalizing Rough Level Set Functions

Instead of smoothing the updates to the level set functions, additional terms can be added to the data misfit cost functional which have the effect of penalizing certain characteristics of the level set function. For example, a Tikhonov–Philips term for the level set function can be added to (81), which will yield the minimization problem

$$\min_{\phi} \mathcal{J}(\phi) = \frac{1}{2}\|\mathcal{R}(b(\phi))\|_Z^2 + \rho(\phi), \quad (142)$$

where $\|\cdot\|_Z$ denotes the canonical norm in the data space Z and where ρ denotes some additional regularization term, typically involving the norm or semi-norm in the space of level set functions, for example, $\rho(\phi) = \|\nabla\phi\|_{L_2}^2$. A discussion of different choices for $\rho(\phi)$ is provided in [93]. Alternative functionals could be applied to the level set function ϕ , as, for example, Mumford–Shah, total variation, etc., which would allow for jumps in the representing level set functions.

Regularization by Smooth Velocity Fields

In the previous two subsections, regularization tools have been discussed, which are directly linked to the level set formulation of shape evolution. In section “Regularization by Smoothed Level Set Updates,” smoothing operators have been applied to the updates of the level set functions (or forcing terms) which are considered as being defined on the whole domain Ω . The additional terms discussed in section “Regularization by Explicitly Penalizing Rough Level Set Functions,” on the other hand, will yield additional evolutions terms which typically have to be applied directly to the describing level set functions during the shape evolution.

An alternative concept of regularizing shape evolution, which does not directly refer to an underlying level set representation of the shapes, consists in choosing function spaces for the normal velocity fields which drive the shape evolution. These velocity fields are, as such, only defined on the zero level set, i.e., on the boundaries of the given shapes (unless extension velocities are defined for a certain reason). For example, the velocity field could be taken as an element of a Sobolev space $W_1(\Gamma)$ equipped with the inner product

$$\langle v, w \rangle_{W_1(\Gamma)} = \int_{\Gamma} \left(\frac{\partial v}{\partial s} \frac{\partial w}{\partial s} + vw \right) ds, \quad (143)$$

where ds is the surface increment at the boundary. This leads to a postprocessing operator applied to the gradient directions which are restricted to the boundary Γ . The action of this postprocessing operator can be interpreted as mapping the given velocity field from $L_2(\Gamma)$ towards the smoother subspace $W_1(\Gamma)$, much as it was described in section “Regularization by Smoothed Level Set Updates” for the spaces $L_2(\Omega)$ and $W_1(\Omega)$. For the above given norm (143), this is modeled by a Laplace–Beltrami operator

$$-\frac{\partial^2 v}{\partial s^2} + v = f_d|_{\Gamma}. \quad (144)$$

Weighted versions of (143) and (144), with parameters α and β as in (137), can be defined as well. These operators have the effect of smoothing the velocity fields along the boundary Γ and therefore lead to regularized level set evolutions if suitable extension velocities are chosen. Alternatively, diffusion processes along the boundary can be employed for achieving a similar effect of smoothing velocity fields. For a more detailed description of various norms and the corresponding surface flows, see [17, 50, 87].

Simple Shapes and Parameterized Velocities

An even stronger way of regularizing shape evolution is to restrict the describing level set functions or the driving velocities to be members of finite-dimensional function spaces spanned by certain sets of basis functions. As basis functions, for example, polynomials, sinusoidal or exponential functions, or any other set of linearly independent functions tailored to the specific inverse problem, can be used. Closely related to this approach is also the strategy of restricting the shapes (and thereby the shape evolution) to a small set of geometric objects, as, for example, ellipsoids. See the discussion in [31] where evolution laws for a small sample of basic shapes are derived. In a related manner, [11] considers a multiscale multiregion level set technique which adaptively adjusts the support and number of basis functions for the level set representation during the shape evolution. Also related to this approach is the projection mapping strategy for shape velocities as proposed in [12].

8 Miscellaneous On-Shape Evolution

Shape Evolution and Shape Optimization

Shape evolution and shape optimization are closely related. Assume given any velocity function $F(\mathbf{x}) = \mathbf{v}(\mathbf{x}) \cdot \mathbf{n}(\mathbf{x})$ pointing into a descent direction of the cost \mathcal{J} , such that $\frac{\partial \mathcal{J}(b)}{\partial t} \Big|_{t=0} < 0$. Then, the cost will decrease in the artificial time evolution during a sufficiently small time interval $[0, \tau]$. On the practical level, the corresponding Hamilton–Jacobi-type evolution equation for the representing level set function to be solved during the time interval $[0, \tau]$ reads

$$\frac{\partial \phi}{\partial t} + F |\nabla \phi| = 0, \quad (145)$$

where the variables (\mathbf{x}, t) have been dropped in the notation. Using, for example, a straightforward time-discretization scheme with finite differences yields

$$\frac{\phi(\tau) - \phi(0)}{\tau} + F |\nabla \phi| = 0. \quad (146)$$

Interpreting $\phi^{(n+1)} = \phi(\tau)$ and $\phi^{(n)} = \phi(0)$ yields the iteration

$$\phi^{(n+1)} = \phi^{(n)} + \tau \delta \phi^{(n)}, \quad \phi^{(0)} = \phi_0, \quad (147)$$

where τ plays the role of the step size (which might be determined by a line-search strategy) and where

$$\delta \phi^{(n)} = F |\nabla \phi^{(n)}| \quad (148)$$

for $\mathbf{x} \in \partial D$.

In the level set optimization approach, on the other hand, updates v for a level set function $\phi \rightarrow \phi + v$ are sought which reduce a given cost. Take, for example, the situation of the basic level set formulation described in section “The Basic Level Set Formulation for Binary Media.” Analogously to section “Least Squares Cost Functionals and Gradient Directions,” a small perturbation v then has the effect on the cost

$$\begin{aligned} \frac{d \mathcal{J}}{d\phi} v &= \frac{d \mathcal{J}}{db} \frac{db}{d\phi} v = \text{Re} \left\langle \mathbf{grad}_b \mathcal{J}, \frac{db}{d\phi} v \right\rangle_P \\ &= \text{Re} \left\langle \mathbf{grad}_b \mathcal{J}, (b_e(\mathbf{x}) - b_i(\mathbf{x})) \delta(\phi) v \right\rangle_P, \end{aligned} \quad (149)$$

with $\mathbf{grad}_b \mathcal{J}$ defined in (85). Apart from the term $\delta(\phi)$, this yields similar expressions for the discrete updates as (147) if choosing $F|\nabla\phi^{(n)}| = -\text{Re}(b_e(\mathbf{x}) - b_i(\mathbf{x}))\mathbf{grad}_b \mathcal{J}$.

In fact, the term $\delta(\phi)$ is the one which causes the biggest conceptual problem when interpreting the above scheme in an optimization framework. Notice that, strictly speaking, the mapping from the level set function to the data (or to the corresponding least square cost) is not differentiable in standard (e.g., L_2) function spaces. This is indicated by the appearance of this Dirac delta distribution $\delta(\phi)$ in (149), which is not an L_2 function.

There are several ways to circumvent these difficulties, mainly aiming at replacing this troublesome Delta distribution by a better behaved approximation of it. First, in the narrowband approach, the Dirac delta is replaced by a narrow band function $\chi_{\phi,d}(\mathbf{x})$ which yields

$$F_d |\nabla\phi^{(n)}|(\mathbf{x}) = -\text{Re} ((b_e - b_i) \chi_{\phi,d}(\mathbf{x}) \mathbf{grad}_b \mathcal{J}) \quad \text{for all } \mathbf{x} \in \Omega. \quad (150)$$

Here, $\chi_{\phi,d}(\mathbf{x})$ is an arbitrary positive-valued approximation to $\delta(\phi)$ where the subscript d indicates the degree of approximation. For example, it can be chosen as

$$\chi_{\phi,d}(\mathbf{x}) = \begin{cases} 1, & \text{there exists } \mathbf{x}_0 \in \Omega \text{ with } |\mathbf{x} - \mathbf{x}_0| < d \text{ and } \phi(\mathbf{x}_0) = 0 \\ 0, & \text{otherwise} \end{cases} \quad (151)$$

which has the form of a “narrowband” function. Other approximations with certain additional properties (e.g., on smoothness) are possible as well. This search direction obviously also provides a descent flow for \mathcal{J} . In fact, the term $|\nabla\phi^{(n)}|$ can also be neglected in (150), without losing the descent property of the resulting flow, since formally it can be assumed that $|\nabla\phi^{(n)}| > 0$ (repeated recalculation of a signed distance function would even enforce $|\nabla\phi^{(n)}| = 1$).

The Dirac delta could as well be replaced by a positive constant, say 1, which yields another choice for a descent direction

$$F_{\text{top}}(\mathbf{x}) = -\text{Re} (b_e - b_i) \mathbf{grad}_b \mathcal{J} \quad \text{for all } \mathbf{x} \in \Omega. \quad (152)$$

This new direction $F_{\text{top}}(\mathbf{x})$ has the property that it applies updates driven by data sensitivities on the entire domain and thereby enables the creation of objects far away from the actual zero level set by lowering a positive level set function until its values arrive at zero. Certainly, at this moment when the level set function changes at some points far away from the zero level set from positive to negative values, a new object is created, and the descent property with respect to the cost needs to be evaluated by introducing some concept evaluating the effect of object creation on the data misfit. A formal way of doing so is briefly discussed in section “Topological Derivatives” further below. The opposite effect that inside a given shape, with some distance from the zero level set, the values of the level set function switch from negative to positive values can also occur, in which case a hole is created inside the shape. Also here, justification of this hole creation with respect to its effect on the data misfit cost is needed and can be treated as well by the tools discussed in section “Topological Derivatives.”

Notice that, in the more classical level set framework, these replacements of the Dirac delta by functions with extended support can be interpreted as different ways of defining extension velocities for the numerical level set evolution scheme. Refer to [7, 19, 45, 47, 84] and the further references given there for numerical approaches which are focusing on incorporating topology changes during the shape reconstruction.

Once optimization schemes are considered for level set-based shape reconstruction, a rich set of classical optimization schemes can be adapted and applied to this novel application. For example, Newton-type optimization techniques and second-order shape derivatives can be defined and calculated. Strategies for doing so are available in the literature; see, for example, [30]. Also quasi-Newton-, Gauss–Newton-, or Levenberg–Marquardt-type schemes look promising in this framework. Some related approaches can be found, for example, in [18, 50, 82, 90, 93]. There exists a large amount of literature concerned with shape optimization problems in various applications. One important application is, for example, the structural optimal shape design problem, where the shape of a given object (a tool, bridge, telegraph pole, airplane wing, etc.) needs to be optimized subject to certain application-specific constraints [3, 87, 96]. Another example is the optimization of a bandgap structure or of maximal eigenvalues [46, 56, 75]. Some techniques from nonlinear optimization which have been successful in those applications consequently have also found their way into the treatment of shape inverse problems. For brevity, we simply refer here to the discussions presented in [2, 18, 20, 43, 50, 82, 90, 93] and the many further references therein. Alternative nonlinear algebraic reconstruction techniques are employed in [34] and fixed point techniques in [22, 23].

Some Remarks on Numerical Shape Evolution with Level Sets

Not much is said here regarding numerical schemes for solving Hamilton–Jacobi equations numerically or for solving the related optimality systems for shape inverse problems numerically. In the framework of imaging science, various schemes have

been developed and discussed extensively in the vast literature on numerical level set evolution; see, for example, the books and reviews [74, 85, 91], to mention just a few examples. These schemes include CFL conditions, re-initialization of level set functions, signed distance functions, the fast marching method, higher-order upwind schemes like ENO (essentially non-oscillating) and WENO (weighted essentially non-oscillating), artificial viscosity solutions, numerical discretizations of mean curvature terms in the level set framework, etc. All these techniques can be applied when working on the treatment of inverse problems by a level set formulation.

It is emphasized here, however, that the application of image reconstruction from indirect data comes with a number of additional problems and complications which are due to the ill-posedness of the inverse problem and to the often high complexity of the PDE (or IE) involved in the simulation of the data. Therefore, each particular image reconstruction problem from indirect data requires a careful study of numerical schemes which typically are tailor-made for the specific application. Overall, a careful choice of numerical discretization schemes and regularization parameters is indeed essential for a stable and efficient solution of the shape reconstruction problem. Moreover, also design parameters of the experimental setup (as, e.g., source and receiver locations) during the data collection have a significant impact on the shape evolution later on in the reconstruction process. Judicious choices here pay off in form of faster and more reliable reconstructions.

Speed of Convergence and Local Minima

Level set methods for shape reconstruction in inverse problems have initially been claimed to suffer from slow convergence due to inherent time-discretization constraints (the CFL condition) for the Hamilton–Jacobi equation and due to the (so far) exclusive use of first-order shape derivatives. Also, it had been observed that the shape evolution sometimes gets trapped in local minima, such that, for example, some topological components are missed by the shape evolution when starting with an inappropriate initial guess.

However, these initial problems seem to have been resolved by now, and it appears that level set methods have in fact become quite efficient and stable when following certain straightforward guidelines and often even clearly outperform many classical pixel-based reconstruction schemes when additional prior information is available.

Firstly, the search for a good starting guess for the shape evolution can usually be done by either specific preprocessing steps (as, e.g., in [98]) or by employing more traditional search routines for only a few iteration steps. This helps avoiding “long-distance evolutions” during the succeeding shape reconstruction process.

A similar effect is achieved by the incorporation of some form of “topological derivative” in the shape evolution algorithm; see the brief discussion of this topic in the following section “Topological Derivatives.” With this topological derivative technique, “seed” objects occur during the evolution just at the correct locations to be deformed in only few more iterations to their final shapes.

The topological derivative (or an appropriately designed extension velocity which has a similar effect) can also help in avoiding the shape evolution to become trapped in local minima due to barriers of low sensitivity where velocity fields become very small. Again by the effect of the creation of “seed” objects in areas of higher sensitivity, the shape evolution can jump over these barriers and quickly arrive at the final reconstruction. When an object is extended over an area of low sensitivity, then, certainly, any reconstruction scheme has difficulties with its reconstruction inside this zone, such that additional prior information might be needed for arriving at a satisfactory result inside this zone of low sensitivity (regardless which reconstruction technique is used).

In addition, also higher-order shape derivatives have been developed in the literature (see, e.g., [30]) which can be used for deriving higher-order shape-based reconstruction schemes. So far, however, their usefulness as part of a level set-based shape inversion technique has been investigated only to a very limited extent.

Finally, in an optimization framework, line-search techniques can replace the CFL condition for marching toward the sought minimum of a cost functional. This can speed up convergence significantly.

Keeping these simple strategies in mind, level set-based reconstruction techniques can in fact be much faster than more traditional schemes, in particular when the contrast value of the parameters is assumed to be known and does not need to be recovered simultaneously with the shape. For very ill-posed inverse problems, traditional techniques need a large number of iterations to converge to the right balance between correct volume and contrast value of the sought objects.

Topological Derivatives

Even though the level set formulation allows for automatic topology changes during the shape evolution, the concepts on calculating descent directions derived so far do not really apply at the moment when a topological change occurs. This is typically no problem for the case of splitting and merging of shapes, since descent directions are only calculated for discrete time steps, such that practically always never the need arises to calculate a descent direction just when such a topological change occurs. Still, from a theoretical perspective, it would be interesting to calculate expressions also for topological derivatives which capture the splitting and merging of shapes.

Another situation where topological changes occur in shape evolution is the creation and annihilation of shape components. These situations also occur automatically in the level set framework when a suitable extension velocity is chosen. However, for these two situations, explicit expressions have been derived in the literature which describe the impact of an infinitesimal topological change on the least squares data misfit cost. These are generally known as *topological derivatives*.

The technique of topological derivatives has received much attention lately as a direct way of image reconstruction. The idea in these approaches is usually to calculate a value of the topological derivative (or topological sensitivity) at each

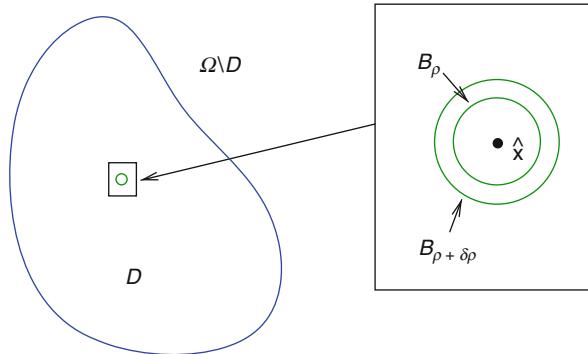

Fig. 10 Creating a hole B_ρ inside the shape D

location of the imaging domain and then adding small geometric objects at those places where this topological sensitivity is the most negative.

Certain issues arise here, as, for example, the question on how large these new objects should be, how close to each other or to the domain boundary they can be, and which contrast value should be applied for the so created small object. So far, in most cases, just one update in line with the above said is done, and thereafter the image reconstruction is either stopped or continued by a shape evolution of the so constructed set of objects. Nevertheless, the possibility of iterative topological reconstruction techniques remains an interesting challenge. Furthermore, the combination of simultaneous topological and shape evolution seems to be a very promising approach which combines the flexibility of level set evolution with the sensitivity driven creation and annihilation of shapes. This effect occurs in practice automatically if appropriate extension velocities are chosen in the regular level set shape evolution technique.

In the following, a more formal approach to topological changes is presented which has the advantage of providing a stronger mathematical justification of topological changes in the goal of data misfit reduction. The discussion will be based on the general ideas described in the references [15, 22, 23, 39, 40, 69, 73, 83, 86]. The *topological derivative* as described here aims at introducing either a small hole (let us call it B_ρ) into an existing shape D or at adding a new object (let us call it D_ρ) into the background material at some distance away from an already existing shape D (see Fig. 10). We will concentrate in the following on the first process, namely, adding a small hole into an existing shape. The complementary situation of creating a new shape component follows the same guidelines.

Denote $\tilde{D}_\rho = D \setminus B_\rho$, where the index ρ indicates the “size” of the hole B_ρ and where it is assumed that the family of new holes defined by this index is “centered” at a given point \hat{x} . (In other words, one has $\hat{x} \in B_\rho \subset B_{\rho'}$ for any $0 < \rho < \rho' < 1$.) It is assumed that all boundaries are sufficiently smooth. Consider then a cost functional $\mathcal{J}(D)$ which depends on the shape D . The topological derivative \mathcal{D}_T is defined as

$$\mathcal{D}_T(\hat{\mathbf{x}}) = \lim_{\rho \downarrow 0} \frac{\mathcal{J}(\tilde{D}_\rho) - \mathcal{J}(D)}{f(\rho)}, \quad (153)$$

where $f(\rho)$ is a function which approaches zero monotonically, i.e., $f(\rho) \rightarrow 0$ for $\rho \rightarrow 0$. With this definition, the asymptotic expansion follows

$$\mathcal{J}(\tilde{D}_\rho) = \mathcal{J}(D) + f(\rho)\mathcal{D}_T(\hat{\mathbf{x}}) + o(f(\rho)). \quad (154)$$

Early applications of this technique (going back to [22, 23, 83]) were focusing on introducing ball-shaped holes into a given domain in connection to Dirichlet or Neumann problems for a Laplace equation. Here, the function $f(\rho)$ is mainly determined by geometrical factors of the created shape, and the topological derivative $\mathcal{J}(\tilde{D}_\rho)$ can be determined by solving one forward and one adjoint problem for the underlying Laplace equation. In fact, for the *Neumann problem for the Laplace equation* using ball-shaped holes, the relationship (153) takes the original form introduced in [22, 23, 83] where $f(\rho)$ is just the negative of the volume measure of the ball, i.e., $f(\rho) = -\pi\rho^2$ in 2D and $f(\rho) = -4\pi\rho^3/3$ in 3D. For more details and examples, see [22]. In general, the details of the behavior of the limit in (153), as well as of the function $f(\rho)$ if the limit exists, depend strongly on the shape of the hole, on the boundary condition at the hole interface, and on the underlying PDE.

An attempt has been made recently to find alternative definitions for the topological derivative. One such approach has been presented in [39, 40, 73]. Instead of taking the point of view that a hole is “created,” the topological derivative is modeled via a limiting process where an already existing hole gradually shrinks until it disappears. For example, perturb the parameter ρ of an existing hole by a small amount $\delta\rho$. Then, the cost $\mathcal{J}(\tilde{D}_\rho)$ is perturbed to $\mathcal{J}(\tilde{D}_{\rho+\delta\rho})$, and the following limit appears:

$$\mathcal{D}_T^*(\hat{\mathbf{x}}) = \lim_{\rho \rightarrow 0} \left\{ \lim_{\delta\rho \rightarrow 0} \frac{\mathcal{J}(\tilde{D}_{\rho+\delta\rho}) - \mathcal{J}(\tilde{D}_\rho)}{f(\rho + \delta\rho) - f(\rho)} \right\}. \quad (155)$$

In [40, 73] the authors show a relationship between (153) and (155), which reads as

$$\mathcal{D}_T(\hat{\mathbf{x}}) = \mathcal{D}_T^*(\hat{\mathbf{x}}) = \lim_{\rho \rightarrow 0} \frac{1}{f'(\rho)|\mathbf{V}_n|} \mathcal{D}_{\mathbf{V}_n}(\rho), \quad (156)$$

where $\mathcal{D}_{\mathbf{V}_n}(\rho)$ is a specific form of a shape derivative related to a velocity flow \mathbf{V}_n in the inward normal direction of the boundary ∂B_ρ with speed $|\mathbf{V}_n|$. For more details, refer to [40, 73]. A related link between shape derivative and topological derivative has been demonstrated also in [22]. Recently published-related work on this topic is briefly reviewed in [33].

9 Case Studies

Case Study: Microwave Breast Screening

In section ‘‘Example 1: Microwave Breast Screening,’’ a complex breast model is presented for tackling the problem of early breast cancer detection from microwave data. Due to the high complexity of the model, also the reconstruction algorithm is likely to show some complexity. In [52] a reconstruction technique is proposed which uses five consecutive stages for the reconstruction. In the first stage, a pixel-by-pixel reconstruction is performed for the interior fatty fibroglandular region, with the skin region being (at this stage of the algorithm typically still incorrectly) estimated and fixed. Once a pixel-based reconstruction has been achieved, an initial shape for the fibroglandular region (the background being then fatty tissue) is extracted from it, which then, in the succeeding stages, is evolved jointly with the interior profiles, the skin region, and a possible tumor region until the final reconstruction is achieved. An important feature of the algorithm is that in different stages of the algorithm, different combinations of the unknowns (level set

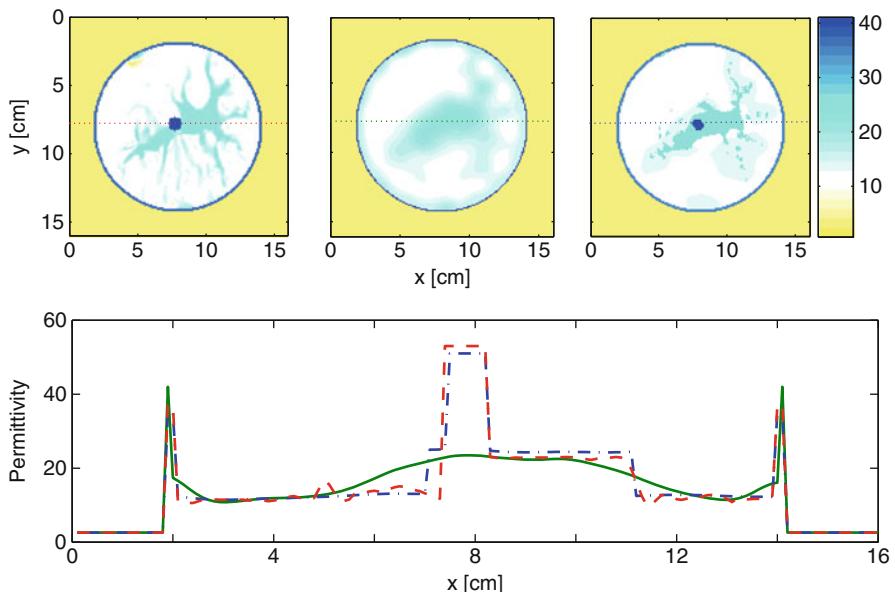

Fig. 11 First breast model of Fig. 1 with a disk-shaped tumor of diameter 8 mm situated deeply inside the breast. *Top left:* reference permittivity profile (true tumor permittivity value $\varepsilon_s^{\text{tum}} = 53$). *Top center:* the result at the end of stage I (pixel-by-pixel reconstruction). *Top right:* final reconstruction of level set-based structural inversion scheme (reconstructed permittivity value $\varepsilon_s^{\text{reconst}} = 50$). *Bottom:* cross section through the correct tumor for constant y coordinate (the *dashed line* represents the true permittivity profile, the *solid line* the pixel-by-pixel result, and the *dash-dotted line* the structural inversion result). For more details, see [52]

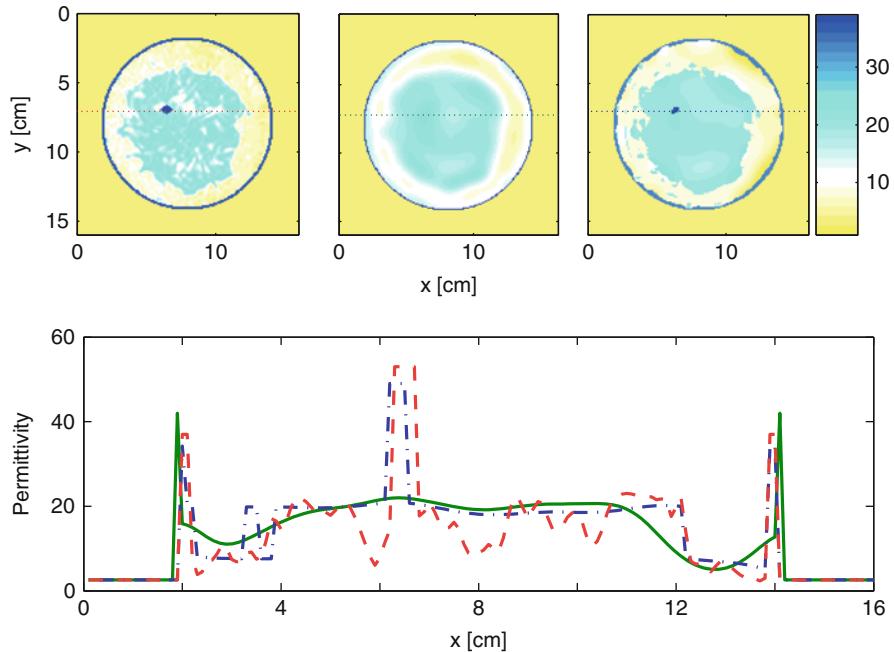

Fig. 12 Second breast model of Fig. 1 with a large fibroglandular tissue and a disk-shaped tumor of 6 mm diameter. The images are arranged as in Fig. 11. The real static permittivity of the tumor is $\epsilon_{\text{st}}^{\text{tumor}} = 52$ and the reconstructed one is $\epsilon_{\text{st}}^{\text{reconst}} = 49$. See also the animated movie provided in [52] which shows the shape evolution for this example

functions and interior parameter profiles) are evolved. For more details regarding the reconstruction algorithm, refer to [52].

Here, the pixel-by-pixel reconstructions of stage I of the algorithm and the final reconstructions using the complex breast model and a level set evolution are presented for the three breast models introduced in Fig. 1 and compared with each other in the cases where a small tumor is present. See Figs. 11–13. The upper left image of each figure shows the real breast, the central upper image shows the pixel-by-pixel reconstruction with our basic reconstruction scheme, and the upper right image shows the level set-based reconstruction using the complex breast model explained in section “Example 1: Microwave Breast Screening.” The bottom images show cross sections through a horizontal line indicated in the upper row images and passing through the tumor locations for the three images.

The data are created on a different grid than the one used for the reconstruction. The corresponding signal-to-noise ratio is 26 dB. Forty antennas are used as sources and as receivers, which are situated equidistantly around the breast. Microwave frequencies of 1, 2, 3, 4, and 5 GHz are used for the illumination of the breast.

Even though the pixel-by-pixel reconstruction scheme is not optimized here, a general problem of pixel-based reconstruction can be identified immediately from

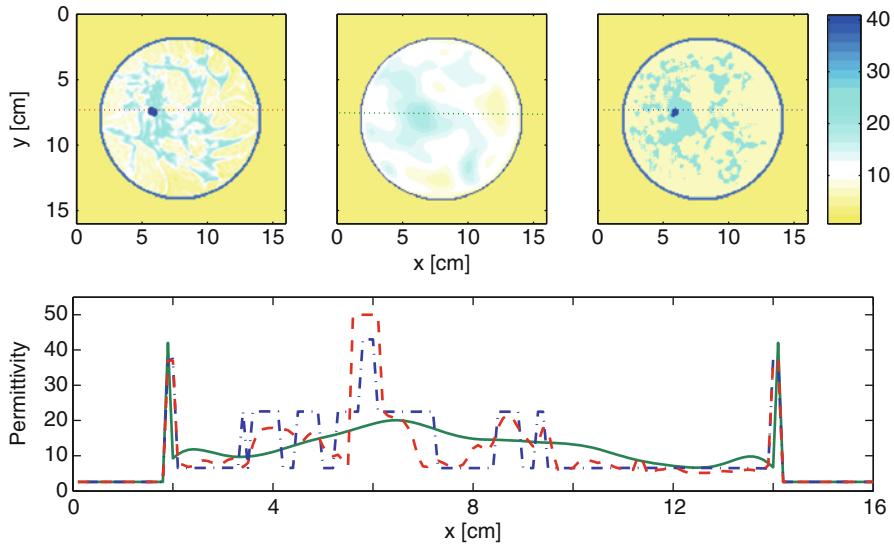

Fig. 13 Third breast model of Fig. 1 with a region of fibroglandular tissue intermixed with adipose tissue. The hidden tumor is an ellipsoid of $5 \times 6 \text{ mm}$ (lengths of principle axes). The images are displayed as in Fig. 11. The real static permittivity value of the tumor is $\epsilon_{st}^{\text{tumor}} = 50$ and the reconstructed one is $\epsilon_{st}^{\text{reconst}} = 42$. For more details, see [52]

the presented examples. The reconstructions tend to be oversmoothed, and the small tumor can hardly be identified from the pixel-based reconstruction. By no means it is possible to give any reliable estimate from these pixel-based reconstructions for the contrast of the interior tumor values to the fibroglandular or fatty tissue values of static relative permittivity. True, the level set reconstruction scheme takes advantage of the fact that it closely follows the correct model for breast tissue. On the other hand, this information is typically available (at least approximately) in breast screening applications, such that better estimates of the tumor characteristics can be expected when using such a level set-based complex breast model. This is confirmed in the three reconstructions shown in the upper right images of Figs. 11–13. For more details on this reconstruction scheme in microwave breast screening, and for an animated movie showing the image evolution, see [52].

Case Study: History Matching in Petroleum Engineering

Figure 14 shows the situation described in section “Example 2: History Matching in Petroleum Engineering” of history matching from production data. The image is composed of one zone of overall (approximately) bilinear behavior (a trend) and another zone where the permeability is smoothly varying without any clearly identifiable trend. The reconstruction follows this model and evolves simultaneously

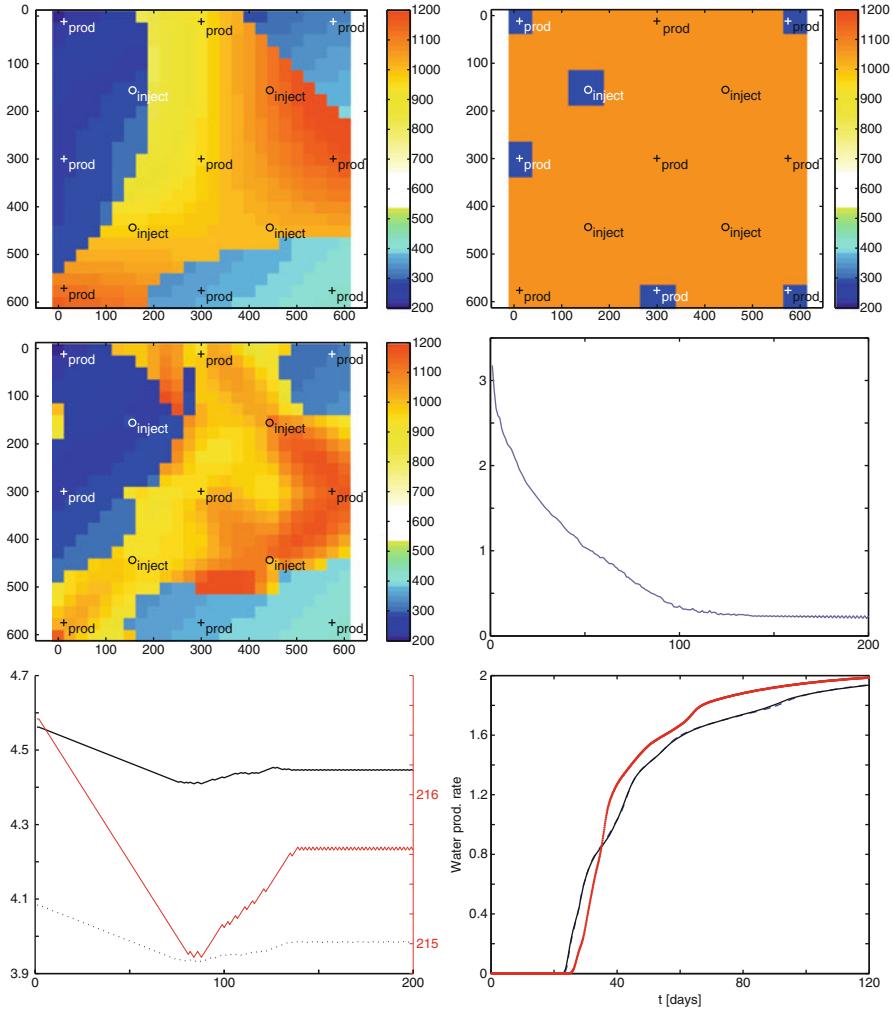

Fig. 14 Case study: history matching in reservoir engineering from production data. *Left column from top to bottom:* reference model, final reconstruction, and evolution of parameter values β_1 , β_2 , β_3 of the bilinear trend model; *right column from top to bottom:* initial guess, evolution of the least squares data misfit and the initial (red solid), final (black dashed), and reference (black solid) total water production rate in m^3/s (i.e., the true and estimated measurements). The complete evolution as an animated file and more details on the reconstruction scheme can be found in [35]

the region boundaries (i.e., the describing level set function), the three expansion parameters of the bilinear profile in the sandstone lithofacie, as well as the smoothly varying interior permeability profile in the shale region. The initial guess (upper right image of the figure) is obtained from well-log measurements. The true image is displayed in the upper left image of the figure and the final reconstruction in

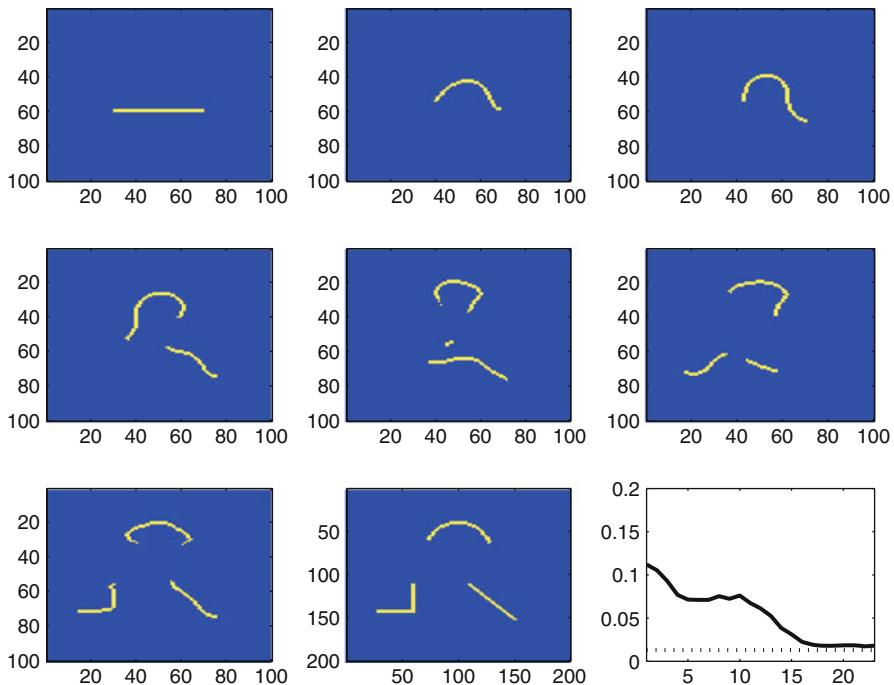

Fig. 15 Case study: crack reconstruction by an evolution of a thin shape. *Top row from left to right:* initial guess, reconstruction after 1 and 2 iterations. *Middle row:* after 5, 10, and 20 iterations. *Bottom row:* final reconstruction after 25 iterations, real crack distribution, and evolution of least squares data misfit with iteration index. The noise level is indicated in the *bottom right* image by a *horizontal dotted line*. One iteration amounts to successive application of the updates corresponding to the data of each source position in a single-step fashion

the center left image. The center right image shows the evolution of the data misfit cost during the joint evolution of all model unknowns, the lower left image shows the evolution of the three model parameters for the bilinear model in one of the regions, and the lower right image shows the initial, true, and final production rate profile over production time averaged over all boreholes (the data). A classical pixel-based reconstruction scheme typically is not able to use different models for the parameter profiles in the different regions and simultaneously reconstruct the sharp region interfaces. For more details on this reconstruction scheme for history matching in reservoir engineering, including animated movies for additional numerical examples, see [35].

Case Study: Reconstruction of Thin Shapes (Cracks)

Figure 15 shows a situation of shape evolution for the reconstruction of thin shapes (cracks) as described in section “Example 3: Crack Detection.” The numerical

model presented in section “A Modification of the Classical Level Set Technique for Describing Cracks or Thin Shapes” is used here, where both level set functions describing the crack are evolved simultaneously driven by the least squares data misfit term. It is seen clearly that also in this specific model, topological changes occur automatically, when marching from a single initial (and somewhat arbitrary) crack candidate (upper left image of the figure) towards the final reconstruction showing three different crack components (bottom left image of the figure). The true situation is displayed in the bottom middle image of the figure, which shows as well three crack components which roughly are at the same location and of similar shape as the reconstructed ones. The evolution of the data misfit cost over artificial evolution time is displayed in the bottom right image of the figure. For more details on this reconstruction scheme and additional numerical experiments, see [4].

Acknowledgments OD thanks Diego Álvarez, Natalia Irishina, Miguel Moscoso and Rossmay Villegas for their collaboration on the exciting topic of level set methods in image reconstruction, and for providing figures which have been included in this chapter. He thanks the Spanish Ministerio de Educacion y Ciencia (Grants FIS2004-22546-E and FIS2007-62673), the European Union (Grant FP6-503259), the French CNRS and Univ. Paris Sud 11, and the Research Councils UK for their support of some of the work which has been presented in this chapter. DL thanks Jean Cea for having introduced him to the fascinating world of shape optimal design, Fadil Santosa for his contribution to his understanding of the linkage between shape optimal design and level set evolutions, and Jean-Paul Zolésio for his precious help on both topics, plus his many insights on topological derivatives.

Cross-References

Readers interested in the material presented in this chapter will also find interesting and relevant additional material in many other chapters of this handbook. Some additional numerical results using level set techniques can be found, for example, in the chapter on EIT. Abstract

The aim of this chapter is to review recent developments in the mathematical and numerical modeling of anomaly detection and multi-physics biomedical imaging. Expansion methods are designed for anomaly detection. They provide robust and accurate reconstruction of the location and of some geometric features of the anomalies, even with moderately noisy data. Asymptotic analysis of the measured data in terms of the size of the unknown anomalies plays a key role in characterizing all the information about the anomaly that can be stably reconstructed from the measured data. In multi-physics imaging approaches, different physical types of waves are combined into one tomographic process to alleviate deficiencies of each separate type of waves while combining their strengths. Multi-physics systems are capable of high-resolution and high-contrast imaging. Asymptotic analysis plays a key role in multi-physics modalities as well.

1 Introduction

Inverse problems in medical imaging are in their most general form ill-posed. They literally have no solution [59, 86]. If, however, in advance one has additional structural information or can supply missing information, then one may be able to determine specific features about what one wishes to image with a satisfactory resolution and accuracy. One such type of information can be that the imaging problem is to find unknown small anomalies with significantly different parameters from those of the surrounding medium. These anomalies may represent potential tumors at an early stage.

Over the last few years, an expansion technique has been developed for the imaging of such anomalies. It has proven useful in dealing with many medical imaging problems. The method relies on deriving asymptotics. Such asymptotics have been investigated in the case of the conductivity equation, the elasticity

equation, the Helmholtz equation, the Maxwell system, the wave equation, the heat equation, and the (modified) Stokes system. A remarkable feature of this method is that it allows a stable and accurate reconstruction of the location and of some geometric features of the anomalies, even with moderately noisy data. This is because the method reduces the set of admissible solutions and the number of unknowns. It can be seen as a kind of regularization in comparison with (nonlinear) iterative approaches.

Another promising technique for efficient imaging is to combine into one tomographic process different physical types of waves. Doing so, one alleviates deficiencies of each separate type of waves while combining their strengths. Again, asymptotic analysis plays a key role in the design of robust and efficient imaging techniques based on this concept of multi-waves. In the last decade or so, work on multi-physics imaging in biomedical applications has come a long way. The motivation is to achieve high-resolution and high-contrast imaging.

The objective of this chapter is threefold: (1) to provide asymptotic expansions for both internal and boundary perturbations that are due to the presence of small anomalies, (2) to apply those asymptotic formulas for the purpose of identifying the location and certain properties of the shape of the anomalies, and (3) to design efficient inversion algorithms in multi-physics modalities.

Applications of the anomaly detection and multi-physics approaches in medical imaging are described in some detail. In particular, the use of asymptotic analysis to improve a multitude of emerging imaging techniques is highlighted. These imaging modalities include electrical impedance tomography, ultrasound imaging, infrared thermography, magnetic resonance elastography, impediography, magneto-acousto-electrical tomography, magneto-acoustic tomography with magnetic induction, and photo-acoustic imaging. They can be divided into three groups: (1) those using boundary or scattering measurements such as electrical impedance tomography, ultrasound, and infrared tomographies; (2) those using internal measurements such as magnetic resonance elastography; and (3) those using boundary measurements obtained from internal perturbations of the medium such as impediography and magneto-acoustic imaging.

As it will be shown in this chapter, modalities from group (1) can only be used for anomaly detection, while those from groups (2) and (3) can provide a stable reconstruction of a distribution of physical parameters.

2 Electrical Impedance Tomography for Anomaly Detection

Physical Principles

Electrical impedance tomography uses low-frequency electric current to probe a body; the method is sensitive to changes in electrical conductivity. By injecting known amounts of current and measuring the resulting electrical potential field at points on the boundary of the body, it is possible to “invert” such data to determine the conductivity or resistivity of the region of the body probed by the

currents. This method can also be used in principle to image changes in dielectric constant at higher frequencies, which is why the method is often called “impedance” tomography rather than “conductivity” or “resistivity” tomography. However, the aspect of the method that is most fully developed to date is the imaging of conductivity/resistivity. Potential applications of electrical impedance tomography include determination of cardiac output, monitoring for pulmonary edema, and in particular screening for breast cancer.

Recently, a commercial system called TS2000 (Mirabel Medical Systems Inc., Austin, TX) has been released for adjunctive clinical uses with X-ray mammography in the diagnostic of breast cancer. The mathematical model of the TransScan can be viewed as a realistic or practical version of the general electrical impedance system. In the TransScan, a patient holds a metallic cylindrical reference electrode, through which a constant voltage of 1–2.5 V, with frequencies spanning 100 Hz–100 KHz, is applied. A scanning probe with a planar array of electrodes, kept at ground potential, is placed on the breast. The voltage difference between the hand and the probe induces a current flow through the breast, from which information about the impedance distribution in the breast can be extracted.

The use of asymptotic analysis yields a rigorous mathematical framework for the TransScan. See [30, 88] for a detailed study of this electrical impedance tomography system.

Mathematical Model

Let Ω be a smooth bounded domain in \mathbb{R}^d , $d = 2$ or 3 and let v_x denote the outward normal to $\partial\Omega$ at x . Suppose that the conductivity of Ω is equal to 1. Let D denote a smooth anomaly inside Ω with conductivity $0 < k \neq 1 < +\infty$. The voltage potential in the presence of the set D of conductivity anomalies is denoted by u . It is the solution to the conductivity problem

$$\begin{cases} \nabla \cdot (\chi(\Omega \setminus \overline{D}) + k\chi(D)) \nabla u = 0 & \text{in } \Omega, \\ \frac{\partial u}{\partial v} \Big|_{\partial\Omega} = g \quad \left(g \in L^2(\partial\Omega), \int_{\partial\Omega} g \, d\sigma = 0 \right), \\ \int_{\partial\Omega} u \, d\sigma = 0, \end{cases} \quad (1)$$

where $\chi(D)$ is the characteristic function of D .

The background voltage potential U in the absence of any anomaly satisfies

$$\begin{cases} \Delta U = 0 & \text{in } \Omega, \\ \frac{\partial U}{\partial v} \Big|_{\partial\Omega} = g, \\ \int_{\partial\Omega} U \, d\sigma = 0. \end{cases} \quad (2)$$

Let $N(x, z)$ be the Neumann function for $-\Delta$ in Ω corresponding to a Dirac mass at z . That is, N is the solution to

$$\begin{cases} -\Delta_x N(x, z) = \delta_z & \text{in } \Omega, \\ \frac{\partial N}{\partial v_x} \Big|_{\partial\Omega} = -\frac{1}{|\partial\Omega|}, \int_{\partial\Omega} N(x, z) d\sigma(x) = 0 & \text{for } z \in \Omega. \end{cases} \quad (3)$$

Note that the Neumann function $N(x, z)$ is defined as a function of $x \in \overline{\Omega}$ for each fixed $z \in \Omega$.

For B a smooth bounded domain in \mathbb{R}^d and $0 < k \neq 1 < +\infty$ a conductivity parameter, let $\hat{v} = \hat{v}(B, k)$ be the solution to

$$\begin{cases} \Delta \hat{v} = 0 & \text{in } \mathbb{R}^d \setminus \overline{B}, \\ \Delta \hat{v} = 0 & \text{in } B, \\ \hat{v}|_- - \hat{v}|_+ = 0 & \text{on } \partial B, \\ k \frac{\partial \hat{v}}{\partial v} \Big|_- - \frac{\partial \hat{v}}{\partial v} \Big|_+ = 0 & \text{on } \partial B, \\ \hat{v}(\xi) - \xi \rightarrow 0 & \text{as } |\xi| \rightarrow +\infty. \end{cases} \quad (4)$$

Here, one denotes

$$v|_{\pm}(\xi) := \lim_{t \rightarrow 0^+} v(\xi \pm t v_\xi), \quad \xi \in \partial B,$$

and

$$\frac{\partial v}{\partial v_\xi} \Big|_{\pm}(\xi) := \lim_{t \rightarrow 0^+} \langle \nabla v(\xi \pm t v_\xi), v_\xi \rangle, \quad \xi \in \partial B,$$

if the limits exist, where v_ξ is the outward unit normal to ∂B at ξ and \langle , \rangle is the scalar product in \mathbb{R}^d . For ease of notation, the dot will be sometimes used for the scalar product in \mathbb{R}^d .

Recall that \hat{v} plays the role of the first-order corrector in the theory of homogenization [79].

Asymptotic Analysis of the Voltage Perturbations

In this section, an asymptotic expansion of the voltage potentials in the presence of a diametrically small anomaly with conductivity different from the background conductivity is provided.

The following theorem gives asymptotic formulas for both boundary and internal perturbations of the voltage potential that are due to the presence of a conductivity anomaly.

Theorem 1 (Voltage perturbations). Suppose that $D = \delta B + z$, δ being the characteristic size of D , and let u be the solution of (1), where $0 < k \neq 1 < +\infty$. Denote by U the background solution, that is, the solution of (2).

- (i) The following asymptotic expansion of the voltage potential on $\partial\Omega$ holds for $d = 2, 3$:

$$u(x) \approx U(x) - \delta^d \nabla U(z) M(k, B) \nabla_z N(x, z). \quad (5)$$

Here, $N(x, z)$ is the Neumann function, that is, the solution to (3), and $M(k, B) = (m_{pq})_{p,q=1}^d$ is the polarization tensor given by

$$M(k, B) := (k - 1) \int_B \nabla \hat{v}(\xi) d\xi, \quad (6)$$

where \hat{v} is the solution to (1).

- (ii) Let w be a smooth harmonic function in Ω . The weighted boundary measurements $I_w[U]$ satisfies

$$I_w[U] := \int_{\partial\Omega} (u - U)(x) \frac{\partial w}{\partial \nu}(x) d\sigma(x) \approx -\delta^d \nabla U(z) \cdot M(k, B) \nabla w(z). \quad (7)$$

- (iii) The following inner asymptotic formula holds:

$$u(x) \approx U(z) + \delta \hat{v} \left(\frac{x - z}{\delta} \right) \cdot \nabla U(z) \quad \text{for } x \text{ near } z. \quad (8)$$

The inner asymptotic expansion (8) uniquely characterizes the shape and the conductivity of the anomaly. In fact, suppose for two Lipschitz domains B and B' and two conductivities k and k' that $\hat{v}(B, k) = \hat{v}(B', k')$ in a domain englobing B and B' , then using the jump conditions satisfied by $\hat{v}(B, k)$ and $\hat{v}(B', k')$, one can easily prove that $B = B'$ and $k = k'$.

The asymptotic expansion (5) expresses the fact that the conductivity anomaly can be modeled by a dipole far away from z . It does not hold uniformly in Ω . It shows that, from an imaging point of view, the location z and the polarization tensor M of the anomaly are the only quantities that can be determined from boundary measurements of the voltage potential, assuming that the noise level is of order δ^{d+1} . It is then important to precisely characterize the polarization tensor and derive some of its properties, such as symmetry, positivity, and isoperimetric inequalities satisfied by its elements, in order to develop efficient algorithms for reconstructing conductivity anomalies of small volume.

Some important properties of the polarization tensor are listed in the next theorem.

Theorem 2 (Properties of the polarization tensor). *For $0 < k \neq 1 < +\infty$, let $M = M(k, B) = (m_{pq})_{p,q=1}^d$ be the polarization tensor associated with the bounded domain B in \mathbb{R}^d and the conductivity k . Then*

- (i) *M is symmetric.*
- (ii) *If $k > 1$, then M is positive definite, and it is negative definite if $0 < k < 1$.*
- (iii) *The following isoperimetric inequalities for the polarization tensor*

$$\begin{cases} \frac{1}{k-1} \operatorname{trace}(M) \leq \left(d - 1 + \frac{1}{k}\right) |B|, \\ (k-1) \operatorname{trace}(M^{-1}) \leq \frac{d-1+k}{|B|}, \end{cases} \quad (9)$$

hold, where trace denotes the trace of a matrix and $|B|$ is the volume of B .

The polarization tensor M can be explicitly computed for disks and ellipses in the plane and balls and ellipsoids in three-dimensional space. See [25, pp. 81–89]. The formula of the polarization tensor for ellipses will be useful here. Let B be an ellipse whose semiaxes are on the x_1 - and x_2 -axes and of lengths a and b , respectively. Then, $M(k, B)$ takes the form

$$M(k, B) = (k-1)|B| \begin{pmatrix} \frac{a+b}{a+kb} & 0 \\ 0 & \frac{a+b}{b+ka} \end{pmatrix}. \quad (10)$$

Formula (5) shows that from boundary measurements, one can always represent and visualize an arbitrary-shaped anomaly by means of an equivalent ellipse of center z with the same polarization tensor. Further, it is impossible to extract the conductivity from the polarization tensor. The information contained in the polarization tensor is a mixture of the conductivity and the volume. A small anomaly with high conductivity and a larger anomaly with lower conductivity can have the same polarization tensor.

The bounds (9) are known as the Hashin–Shtrikman bounds. By making use of these bounds, size and thickness estimations of B can be obtained. An inclusion whose trace of the associated polarization tensor is close to the upper bound must be infinitely thin [40].

Numerical Methods for Anomaly Detection

In this section, one applies the asymptotic formula (5) for the purpose of identifying the location and certain properties of the shape of the conductivity anomalies. Two simple fundamental algorithms that take advantage of the smallness of the anom-

lies are singled out: projection-type algorithms and multiple signal classification (MUSIC)-type algorithms. These algorithms are fast, stable, and efficient.

Detection of a Single Anomaly: A Projection-Type Algorithm

One briefly discusses a simple algorithm for detecting a single anomaly. The reader can refer to [31, 73] for further details. The projection-type location search algorithm makes use of constant current sources. One wants to apply a special type of current that makes ∇U constant in D . The injection current $g = a \cdot v$ for a fixed unit vector $a \in \mathbb{R}^d$ yields $\nabla U = a$ in Ω .

Assume for the sake of simplicity that $d = 2$ and D is a disk. Set

$$w(y) = -(1/2\pi) \log |x - y| \quad \text{for } x \in \mathbb{R}^2 \setminus \overline{\Omega}, y \in \Omega .$$

Since w is harmonic in Ω , then from (7) to (10), it follows that

$$I_w[U] \approx \frac{(k-1)|D|}{\pi(k+1)} \frac{(x-z) \cdot a}{|x-z|^2} , \quad x \in \mathbb{R}^2 \setminus \overline{\Omega} . \quad (11)$$

The first step for the reconstruction procedure is to locate the anomaly. The location search algorithm is as follows. Take two observation lines Σ_1 and Σ_2 contained in $\mathbb{R}^2 \setminus \overline{\Omega}$ given by

$$\begin{aligned} \Sigma_1 &:= \text{a line parallel to } a, \\ \Sigma_2 &:= \text{a line normal to } a. \end{aligned}$$

Find two points $P_i \in \Sigma_i, i = 1, 2$, so that

$$I_w[U](P_1) = 0, \quad I_w[U](P_2) = \max_{x \in \Sigma_2} |I_w[U](x)| .$$

From (11), one can see that the intersecting point P of the two lines

$$\Pi_1(P_1) := \{x \mid a \cdot (x - P_1) = 0\}, \quad (12)$$

$$\Pi_2(P_2) := \{x \mid (x - P_2) \text{ is parallel to } a\} \quad (13)$$

is close to the center z of the anomaly $D : |P - z| = O(\delta^2)$.

Once one locates the anomaly, the factor $|D|(k-1)/(k+1)$ can be estimated. As it has been said before, this information is a mixture of the conductivity and the volume. A small anomaly with high conductivity and larger anomaly with lower conductivity can have the same polarization tensor.

An arbitrary-shaped anomaly can be represented and visualized by means of an ellipse or an ellipsoid with the same polarization tensor. See Fig. 1.

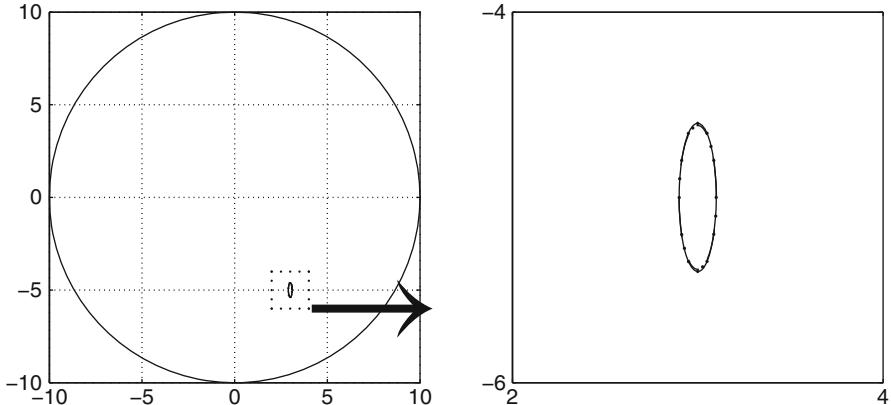

Fig. 1 Detection of the location and the polarization tensor of a small arbitrary-shaped anomaly by a projection-type algorithm. The shape of the anomaly is approximated by an ellipse with the same polarization tensor

We refer the reader to [57] for a discussion on the limits of the applicability of the projection-type location search algorithm and the derivation of a second efficient method, called the effective dipole method.

Detection of Multiple Anomalies: A MUSIC-Type Algorithm

Consider m well-separated anomalies $D_s = \delta B_s + z_s$ (these are a fixed distance apart), with conductivities k_s , $s = 1, \dots, m$. Suppose for the sake of simplicity that all the domains B_s are disks. Let $y_l \in \mathbb{R}^2 \setminus \Omega$ for $l = 1, \dots, n$ denote the source points. Set

$$U_{y_l} = w_{y_l} := -(1/2\pi) \log |x - y_l| \quad \text{for } x \in \Omega, \quad l = 1, \dots, n.$$

The MUSIC-type location search algorithm for detecting multiple anomalies is as follows. For $n \in \mathbb{N}$ sufficiently large, define the response matrix $A = (A_{ll'})_{l,l'=1}^n$ by

$$A_{ll'} = I_{w_{y_l}}[U_{y_{l'}}] := \int_{\partial\Omega} (u - U_{y_{l'}})(x) \frac{\partial w_{y_l}}{\partial \nu}(x) d\sigma(x).$$

Expansion (7) yields

$$A_{ll'} \approx - \sum_{s=1}^m \frac{2(k_s - 1)|D_s|}{k_s + 1} \nabla U_{y_{l'}}(z_s) \nabla U_{y_l}(z_s).$$

Introduce

$$g(x) = (U_{y_1}(x), \dots, U_{y_n}(x))^*,$$

where v^* denotes the transpose of the vector v .

Lemma 1 (MUSIC characterization of the range of the response matrix). *There exists $n_0 > dm$ such that for any $n > n_0$, the following characterization of the location of the anomalies in terms of the range of the matrix A holds:*

$$g(x) \in \text{Range}(A) \text{ if and only if } x \in \{z_1, \dots, z_m\}. \quad (14)$$

The MUSIC-type algorithm to determine the location of the anomalies is as follows. Let $P_{\text{noise}} = I - P$, where P is the orthogonal projection onto the range of A . Given any point $x \in \Omega$, form the vector $g(x)$. The point x coincides with the location of an anomaly if and only if $P_{\text{noise}}g(x) = 0$. Thus, one can form an image of the anomalies by plotting, at each point x , the cost function

$$W_{\text{MU}}(x) = \frac{1}{\|P_{\text{noise}}g(x)\|}.$$

The resulting plot will have large peaks at the locations of the anomalies.

Once one locates the anomalies, the factors $|D_s|(k_s - 1)/(k_s + 1)$ can be estimated from the significant singular values of A .

Bibliography and Open Questions

Part (i) in Theorem 1 was proven in [21, 44, 51]. The proof in [21] is based on a decomposition formula of the solution into a harmonic part and a refraction part first derived in [61]. Part (iii) is from [28]. The Hashin–Shtrikman bounds for the polarization tensor were proved in [43, 77]. The projection algorithm was introduced in [31, 73]. The MUSIC algorithm was originally developed for source separation in signal theory [94]. The MUSIC-type algorithm for locating small conductivity anomalies from the response matrix was first developed in [38]. The strong relation between MUSIC and linear sampling methods was clarified in [16]. The results of this section can be generalized to the detection of anisotropic anomalies [60].

As it has been said before, it is impossible to extract separately from the detected polarization tensor information about the material property and the size of the anomaly. However, if the measurement system is very sensitive, then making use of higher-order polarization tensors yields such information. See [25] for the notion of the higher-order polarization tensors.

One of the most challenging problems in anomaly detection using electrical impedance tomography is that in practical measurements, one usually lacks exact knowledge of the boundary of the background domain. Because of this, the numerical reconstruction from the measured data is done using a model domain that represents the best guess for the true domain. However, it has been noticed that an inaccurate model of the boundary causes severe errors for the reconstructions. An elegant and original solution toward eliminating the error caused by an incorrectly modeled boundary has been proposed and implemented numerically in [69]. As nicely shown in [67], another promising approach is to use multifrequency data.

The anomaly can be detected from a weighted frequency difference of the measured boundary voltage perturbations. Moreover, this method eliminates the need for numerically simulated background measurements at the absence of the conductivity anomaly. See [58, 67].

3 Ultrasound Imaging for Anomaly Detection

Physical Principles

Ultrasound imaging is a noninvasive, easily portable, and relatively inexpensive diagnostic modality which finds extensive clinical use. The major applications of ultrasound include many aspects of obstetrics and gynecology involving the assessment of fetal health, intra-abdominal imaging of the liver and kidney, and the detection of compromised blood flow in veins and arteries.

Operating typically at frequencies between 1 and 10 MHz, ultrasound imaging produces images via the backscattering of mechanical energy from interfaces between tissues and small structures within tissue. It has high spatial resolution, particularly at high frequencies, and involves no ionizing radiation. The weaknesses of the technique include the relatively poor soft tissue contrast and the fact that gas and bone impede the passage of ultrasound waves, meaning that certain organs cannot easily be imaged. However, ultrasound imaging is a valuable technique for anomaly detection. It can be done in the time domain and the frequency domain.

Mathematical models for acoustical soundings of biological media involve the Helmholtz equation in the frequency domain and the scalar wave equation in the time domain.

Asymptotic Formulas in the Frequency Domain

Let k and ρ be positive constants. With the notation of section “Asymptotic Analysis of the Voltage Perturbations,” ρ is the compressibility of the anomaly D and k is its volumetric mass density. The scalar acoustic pressure u generated by the Neumann data g in the presence of the anomaly D is the solution to the Helmholtz equation:

$$\begin{cases} \nabla \cdot (\chi(\Omega \setminus \overline{D}) + k\chi(D)) \nabla u + \omega^2(\chi(\Omega \setminus \overline{D}) + \rho\chi(D))u = 0 & \text{in } \Omega, \\ \frac{\partial u}{\partial \nu} = g & \text{on } \partial\Omega, \end{cases} \quad (15)$$

while the background solution U satisfies

$$\begin{cases} \Delta U + \omega^2 U = 0 & \text{in } \Omega, \\ \frac{\partial U}{\partial \nu} = g & \text{on } \partial\Omega. \end{cases} \quad (16)$$

Here, ω is the operating frequency. A relevant boundary data g is the normal derivative of a plane wave $e^{i\omega x \cdot \theta}$, with the wavelength $\lambda := 2\pi/\omega$, traveling in the direction of the unit vector θ .

Introduce the Neumann function for $-(\Delta + \omega^2)$ in Ω corresponding to a Dirac mass at z . That is, N_ω is the solution to

$$\begin{cases} -(\Delta_x + \omega^2) N_\omega(x, z) = \delta_z & \text{in } \Omega, \\ \frac{\partial N}{\partial v_x} |_{\partial\Omega} = 0 & \text{on } \partial\Omega. \end{cases} \quad (17)$$

Assuming that ω^2 is not an eigenvalue for the operator $-\Delta$ in $L^2(\Omega)$ with homogeneous Neumann boundary conditions, one can prove, using the theory of relatively compact operators, existence and uniqueness of a solution to (15) at least for δ small enough [95]. Moreover, the following asymptotic formula holds.

Theorem 3 (Pressure perturbations). *Let u be the solution of (15) and let U be the background solution. Suppose that $D = \delta B + z$, with $0 < (k, \rho) \neq (1, 1) < +\infty$. Suppose that $\omega\delta \ll 1$.*

(i) *For any $x \in \partial\Omega$,*

$$u(x) \approx U(x) - \delta^d (\nabla U(z) \cdot M(k, B) \nabla_z N_\omega(x, z) + \omega^2(\rho - 1)|B|U(z)N_\omega(x, z)), \quad (18)$$

where $M(k, B)$ is the polarization tensor associated with B and k .

(ii) *Let w be a smooth function such that $(\Delta + \omega^2)w = 0$ in Ω . The weighted boundary measurements $I_w[U, \omega]$ satisfy*

$$\begin{aligned} I_w[U, \omega] &:= \int_{\partial\Omega} (u - U)(x) \frac{\partial w}{\partial v}(x) d\sigma(x) \\ &\approx -\delta^d (\nabla U(z) \cdot M(k, B) \nabla w(z) + \omega^2(\rho - 1)|B|U(z)w(z)). \end{aligned} \quad (19)$$

(iii) *The following inner asymptotic formula holds:*

$$u(x) \approx U(z) + \delta \hat{v} \left(\frac{x - z}{\delta} \right) \cdot \nabla U(z) \quad \text{for } x \text{ near } z, \quad (20)$$

where \hat{v} is the solution to (1).

Compared to the conductivity equation, the only extra difficulty in establishing asymptotic formulas for the Helmholtz equation (15) as the size of the acoustic anomaly goes to zero is that the equations inside and outside the anomaly are not the same.

Asymptotic Formulas in the Time Domain

Suppose that $\rho = 1$. Consider the initial boundary value problem for the (scalar) wave equation

$$\begin{cases} \partial_t^2 u - \nabla \cdot (\chi(\Omega \setminus \bar{D}) + k\chi(D)) \nabla u = 0 & \text{in } \Omega_T, \\ u(x, 0) = u_0(x), \quad \partial_t u(x, 0) = u_1(x) & \text{for } x \in \Omega, \\ \frac{\partial u}{\partial \nu} = g & \text{on } \partial\Omega_T, \end{cases} \quad (21)$$

where $T < +\infty$ is a final observation time, $\Omega_T = \Omega \times]0, T[$, and $\partial\Omega_T = \partial\Omega \times]0, T[$. The initial data $u_0, u_1 \in \mathcal{C}^\infty(\bar{\Omega})$ and the Neumann boundary data $g \in \mathcal{C}^\infty(0, T; \mathcal{C}^\infty(\partial\Omega))$ are subject to compatibility conditions.

Define the background solution U to be the solution of the wave equation in the absence of any anomalies. Thus, U satisfies

$$\begin{cases} \partial_t^2 U - \Delta U = 0 & \text{in } \Omega_T, \\ U(x, 0) = u_0(x), \quad \partial_t U(x, 0) = u_1(x) & \text{for } x \in \Omega, \\ \frac{\partial U}{\partial \nu} = g & \text{on } \partial\Omega_T. \end{cases}$$

For $\rho > 0$, define the operator P_ρ on tempered distributions by

$$P_\rho[\psi](x, t) = \int_{|\omega| \leq \rho} e^{-\sqrt{-1}\omega t} \hat{\psi}(x, \omega) d\omega, \quad (22)$$

where $\hat{\psi}(x, \omega)$ denotes the Fourier transform of $\psi(x, t)$ in the t -variable. Clearly, the operator P_ρ truncates the high-frequency component of ψ .

The following asymptotic expansion holds as $\delta \rightarrow 0$.

Theorem 4 (Perturbations of weighted boundary measurements). *Let $w \in \mathcal{C}^\infty(\bar{\Omega}_T)$ satisfy $(\partial_t^2 - \Delta)w(x, t) = 0$ in Ω_T with $\partial_t w(x, T) = w(x, T) = 0$ for $x \in \Omega$. Suppose that $\rho \ll 1/\delta$. Define the weighted boundary measurements*

$$I_w[U, T] := \int_{\partial\Omega_T} P_\rho[u - U](x, t) \frac{\partial w}{\partial \nu}(x, t) d\sigma(x) dt.$$

Then, for any fixed $T > \text{diam}(\Omega)$, the following asymptotic expansion for $I_w[U, T]$ holds as $\delta \rightarrow 0$:

$$I_w[U, T] \approx \delta^d \int_0^T \nabla P_\rho[U](z, t) M(k, B) \nabla w(z, t) dt, \quad (23)$$

where $M(k, B)$ is defined by (6).

Expansion (23) is a weighted expansion. Pointwise expansions similar to those in Theorem 1 which is for the steady-state model can also be obtained.

Let $y \in \mathbb{R}^3$ be such that $|y - z| \gg \delta$. Choose

$$U(x, t) := U_y(x, t) := \frac{\delta_{t=|x-y|}}{4\pi|x-y|} \quad \text{for } x \neq y. \quad (24)$$

It is easy to check that U_y is the outgoing Green function to the wave equation:

$$(\partial_t^2 - \Delta) U_y(x, t) = \delta_{x=y} \delta_{t=0} \quad \text{in } \mathbb{R}^3 \times]0, +\infty[.$$

Moreover, U_y satisfies the initial conditions: $U_y(x, 0) = \partial_t U_y(x, 0) = 0$ for $x \neq y$. Consider now for the sake of simplicity the wave equation in the whole three-dimensional space with appropriate initial conditions:

$$\begin{cases} \partial_t^2 u - \nabla \cdot (\chi(\mathbb{R}^3 \setminus \overline{D}) + k\chi(D)) \nabla u = \delta_{x=y} \delta_{t=0} & \text{in } \mathbb{R}^3 \times]0, +\infty[, \\ u(x, 0) = 0, \quad \partial_t u(x, 0) = 0 & \text{for } x \in \mathbb{R}^3, x \neq y. \end{cases} \quad (25)$$

The following theorem holds.

Theorem 5 (Pointwise perturbations). *Let u be the solution to (25). Set U_y to be the background solution. Suppose that $\rho \ll 1/\delta$.*

(i) *The following outer expansion holds*

$$P_\rho[u - U_y](x, t) \approx -\delta^3 \int_{\mathbb{R}} \nabla P_\rho[U_z](x, t - \tau) \cdot M(k, B) \nabla P_\rho[U_y](z, \tau) d\tau, \quad (26)$$

for x away from z , where $M(k, B)$ is defined by (6) and U_y and U_z by (24).

(ii) *The following inner approximation holds:*

$$P_\rho[u - U_y](x, t) \approx \delta \hat{v} \left(\frac{x - z}{\delta} \right) \cdot \nabla P_\rho[U_y](x, t) \quad \text{for } x \text{ near } z, \quad (27)$$

where \hat{v} is given by (4) and U_y by (24).

Formula (26) shows that the perturbation due to the anomaly is in the time domain a wave front emitted by a dipolar source located at point z .

Taking the Fourier transform of (26) in the time variable yields the expansions given in Theorem 3 for the perturbations resulting from the presence of a small anomaly for solutions to the Helmholtz equation at low frequencies (at large wavelengths compared to the size of the anomaly).

Numerical Methods

MUSIC-Type Imaging at a Single Frequency

Consider m well-separated anomalies $D_s = \delta B_s + z_s, s = 1, \dots, m$. The compressibility and volumetric mass density of D_s are denoted by ρ_s and k_s , respectively. Suppose as before that all the domains B_s are disks. Let $(\theta_1, \dots, \theta_n)$ be n unit vectors in \mathbb{R}^d . For arbitrary $\theta \in \{\theta_1, \dots, \theta_n\}$, one assumes that one is in the possession of the boundary data u when the object Ω is illuminated with the plane wave $U(x) = e^{i\omega\theta \cdot x}$. Therefore, taking $w(x) = e^{-i\omega\theta' \cdot x}$ for $\theta' \in \{\theta_1, \dots, \theta_n\}$ shows that one is in possession of

$$\sum_{s=1}^m |D_s| \left(2 \frac{(k_s - 1)}{k_s + 1} \theta \cdot \theta' + (\rho_s - 1) \right) e^{i\omega(\theta - \theta') \cdot z_s},$$

for $\theta, \theta' \in \{\theta_1, \dots, \theta_n\}$. Define the response matrix $A = (A_{ll'})_{l,l'=1}^n \in \mathbb{C}^{n \times n}$ by

$$A_{ll'} = \sum_{s=1}^m |D_s| \left(2 \frac{(k_s - 1)}{k_s + 1} \theta_l \cdot \theta_{l'} + (\rho_s - 1) \right) e^{i\omega(\theta_l - \theta_{l'}) \cdot z_s}, \quad l, l' = 1, \dots, n.$$

Introduce

$$g(x) = ((1, \theta_1)^* e^{i\omega\theta_1 \cdot x}, \dots, (1, \theta_n)^* e^{i\omega\theta_n \cdot x})^*.$$

Analogously to Lemma 1, one has the following characterization of the location of the anomalies in terms of the range of the matrix A .

Lemma 2 (MUSIC characterization of the range of the response matrix). *There exists $n_0 \in \mathbb{N}, n_0 > (d + 1)m$, such that for any $n \geq n_0$, the following statement holds:*

$g^j(x) \in \text{Range}(A)$ if and only if $x \in \{z_1, \dots, z_m\}$ for $j = 1, \dots, d + 1$,

where $g^j(x)$ is the j th column of $g(x)$.

The MUSIC algorithm can now be used as before to determine the location of the anomalies. Let $P_{\text{noise}} = I - P$, where P is the orthogonal projection onto the range of A . The imaging functional

$$W_{\text{MU}}(x) := \frac{1}{\sum_{j=1}^{d+1} \|P_{\text{noise}} g^j(x)\|}$$

has large peaks only at the locations of the anomalies. See Fig. 2.

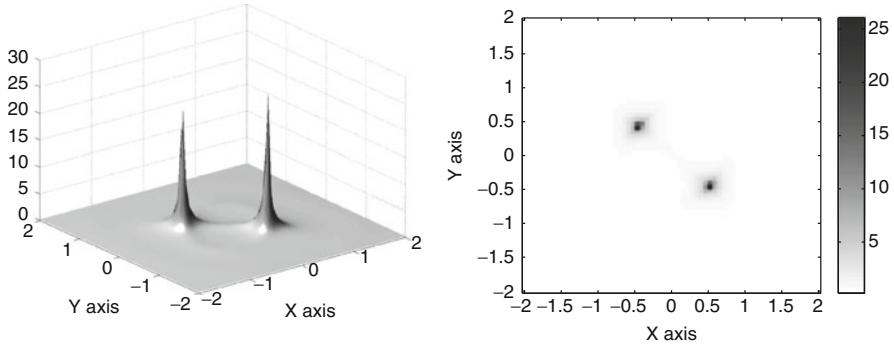

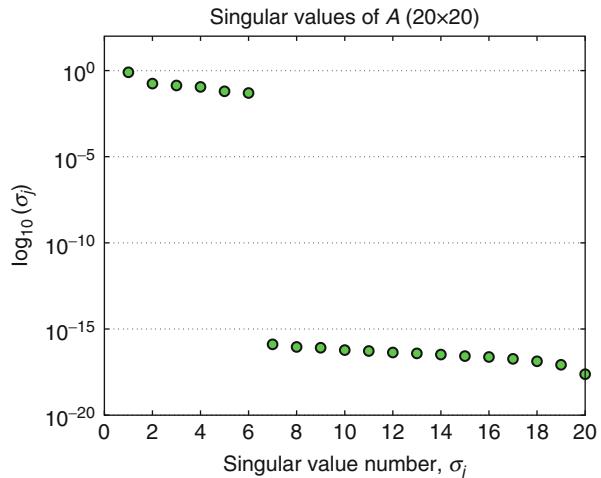

Fig. 2 MUSIC-type reconstruction from the singular value decomposition of A represented in Fig. 3

Fig. 3 Singular value decomposition of the response matrix A corresponding to two well-separated anomalies of general shape for $n = 20$, using a standard log scale. Six singular values emerge from the 14 others in the noise subspace

The significant singular vectors of A can be computed by the singular value decomposition. The number of significant singular values determines the number of anomalies. If, for example, $k_s \neq 1$ and $\rho_s \neq 1$ for all $s = 1, \dots, m$, then there are exactly $(d + 1)m$ significant singular values of A and the rest are zero or close to zero. See Fig. 3. The significant singular values of A can be used to estimate $\frac{(k_s-1)}{k_s+1}|D_s|$ and $(\rho_s - 1)|D_s|$.

Backpropagation-Type Imaging at a Single Frequency

A backpropagation imaging functional at a single frequency ω is given by

$$W_{\text{BP}}(x) := \frac{1}{n} \sum_{l=1}^n e^{-2i\omega\theta_l \cdot x} I_{w_l}[U_l],$$

where $U_l(x) = w_l(x) = e^{i\omega\theta_l \cdot x}$ for $\theta_l \in \{\theta_1, \dots, \theta_n\}$. Suppose that $(\theta_1, \dots, \theta_n)$ are equidistant points on the unit sphere S^{d-1} . For sufficiently large n , since

$$\frac{1}{n} \sum_{l=1}^n e^{i2\omega\theta_l \cdot x} \approx \begin{cases} j_0(2\omega|x|) & \text{for } d = 3, \\ J_0(2\omega|x|) & \text{for } d = 2, \end{cases}$$

where j_0 is the spherical Bessel function of order zero and J_0 is the Bessel function of the first kind and of order zero, it follows that

$$W_{\text{BP}}(x) \approx \sum_{s=1}^m |D_s| \left(2 \frac{(k_s - 1)}{k_s + 1} + (\rho_s - 1) \right) \times \begin{cases} j_0(2\omega|x - z_s|) & \text{for } d = 3, \\ J_0(2\omega|x - z_s|) & \text{for } d = 2. \end{cases}$$

An analogy between the backpropagation and MUSIC-type imaging can be established. Suppose that $k_s = 1$ for $s = 1, \dots, m$. One can see that

$$W_{\text{MU}}(x) \propto \frac{1}{|D_s|(\rho_s - 1) - W_{\text{BP}}(x)}$$

for x near z_s [9].

Kirchhoff-Type Imaging Using a Broad Range of Frequencies

Let $y_l \in \mathbb{R}^2 \setminus \Omega$ for $l = 1, \dots, n$ denote an array of source points. Set

$$w_{y_l}(x) = \frac{i}{4} H_0^{(1)}(\omega|x - y_l|) \quad \text{and} \quad U_{y_{l'}}(x) = \frac{i}{4} H_0^{(1)}(\omega|x - y_{l'}|),$$

where $H_0^{(1)}$ is the Hankel function of first kind and order zero. Using the asymptotic form of the Hankel function, one finds that for $\omega|x - y| \gg 1$,

$$\frac{i}{4} H_0^{(1)}(\omega|x - y|) \approx \frac{1}{2\sqrt{2\pi}} \frac{e^{i\pi/4}}{\sqrt{\omega|x - y|}} e^{i\omega|x - y|},$$

and

$$\frac{i}{4} \nabla H_0^{(1)}(\omega|x - y|) \approx \frac{1}{2\sqrt{2\pi}} \left(\frac{i\omega(x - y)}{|x - y|} \right) \frac{e^{i\pi/4}}{\sqrt{\omega|x - y|}} e^{i\omega|x - y|}.$$

Assume a high-frequency regime with $\omega L \gg 1$ for L the distance from the array center point to the locations $z_s, s = 1, \dots, m$. It follows that

$$I_{w_l}[U_{l'}, \omega] \propto$$

$$\sum_{s=1}^m |D_s| \left(-2 \frac{k_s - 1}{k_s + 1} \frac{(z_s - y_l) \cdot (z_s - y_{l'})}{|z_s - y_l| |z_s - y_{l'}|} + (\rho_s - 1) \right) e^{i\omega(|z_s - y_l| + |z_s - y_{l'}|)}.$$

Introduce the response matrix $A(\omega) = (A_{ll'}(\omega))$ by

$$A_{ll'}(\omega) := I_{wl}[U_{l'}, \omega]$$

and the illumination vector

$$g(x, \omega) := \left(\left(1, \frac{x - y_1}{|x - y_1|} \right)^* e^{i\omega|x-y_1|}, \dots, \left(1, \frac{x - y_n}{|x - y_n|} \right)^* e^{i\omega|x-y_n|} \right)^*.$$

In the case of measurements at multiple frequencies (ω_j) , we construct the weighted Kirchhoff imaging functional as

$$W_{KI}(x) = \frac{1}{J} \sum_{\omega_j, j=1, \dots, J} \sum_l (g(x, \omega_j), u_l(\omega_j)) (g(x, \omega_j), \bar{v}_l(\omega_j)),$$

where $(a, b) = \bar{a} \cdot b$, J is the number of frequencies, and u_l and v_l are, respectively, the left and right singular vectors of A . As for W_{MU} , W_{KI} is written in terms of the singular-value decompositions of the response matrices $A(\omega_j)$.

Time-Reversal Imaging

Unlike the three previous imaging methods, the one in this section is in time domain. It is based on time reversal.

The main idea of time reversal is to take advantage of the reversibility of the wave equation in a non-dissipative unknown medium in order to back propagate signals to the sources that emitted them. In the context of anomaly detection, one measures the perturbation of the wave on a closed surface surrounding the anomaly and retransmits it through the background medium in a time-reversed chronology. Then the perturbation will travel back to the location of the anomaly. One can show that the time-reversal perturbation focuses on the location z of the anomaly with a focal spot size limited to one-half the wavelength which is in agreement with the Rayleigh resolution limit.

In mathematical terms, suppose that one is able to measure the perturbation $u - U_y$ and its normal derivative at any point x on a sphere S englobing the anomaly D and for a large time t_0 . The time-reversal operation is described by the transform $t \mapsto t_0 - t$. Both the perturbation and its normal derivative on S are time reversed and emitted from S . Then a time-reversed perturbation propagates inside the volume surrounded by S .

To detect the anomaly from measurements of the wavefield $u - U_y$ away from the anomaly, one can use a time-reversal technique. Taking into account the definition of the outgoing fundamental solution (24) to the wave equation, spatial reciprocity, and time-reversal invariance of the wave equation, one defines the time-reversal imaging functional W_{TR} by

$$W_{\text{TR}}(x, t) = \int_{\mathbb{R}} \int_S \left[U_x(x', t-s) \frac{\partial P_\rho[u - U_y]}{\partial v}(x', t_0 - s) \right. \\ \left. - \frac{\partial U_x}{\partial v}(x', t-s) P_\rho[u - U_y](x', t_0 - s) \right] d\sigma(x') ds, \quad (28)$$

where

$$U_x(x', t-\tau) = \frac{\delta(t-\tau-|x-x'|)}{4\pi|x-x'|}.$$

The imaging functional W_{TR} corresponds to propagating inside the volume surrounded by S , the time-reversed perturbation $P_\rho[u - U_y]$, and its normal derivative on S . Theorem 5 shows that

$$P_\rho[u - U_y](x, t) \approx -\delta^3 \int_{\mathbb{R}} \nabla P_\rho[U_z](x, t-\tau) \cdot m(z, \tau) d\tau,$$

where

$$m(z, \tau) = M(k, B) \nabla P_\rho[U_y](z, \tau). \quad (29)$$

Therefore, since

$$\int_{\mathbb{R}} \int_S \left[U_x(x', t-s) \frac{\partial P_\rho[U_z]}{\partial v}(x', t_0 - s - \tau) \right. \\ \left. - \frac{\partial U_x}{\partial v}(x', t-s) P_\rho[U_z](x', t_0 - s - \tau) \right] d\sigma(x') ds \\ = P_\rho[U_z](x, t_0 - \tau - t) - P_\rho[U_z](x, t - t_0 + \tau), \quad (30)$$

one obtains the approximation

$$W_{\text{TR}}(x, t) \approx -\delta^3 \int_{\mathbb{R}} m(z, \tau) \cdot \nabla_z [P_\rho[U_z](x, t_0 - \tau - t) - P_\rho[U_z](x, t - t_0 + \tau)] d\tau,$$

which can be interpreted as the superposition of incoming and outgoing waves, centered on the location z of the anomaly. Since

$$P_\rho[U_y](x, \tau) = \frac{\sin \rho(\tau - |x - y|)}{2\pi(\tau - |x - y|)|x - y|},$$

$m(z, \tau)$ is concentrated at the travel time $\tau = T = |z - y|$. It then follows that

$$W_{\text{TR}}(x, t) \approx -\delta^3 m(z, T) \cdot \nabla_z [P_\rho[U_z](x, t_0 - T - t) - P_\rho[U_z](x, t - t_0 + T)]. \quad (31)$$

The imaging functional W_{TR} is clearly the sum of incoming and outgoing polarized spherical waves.

Approximation (31) has an important physical interpretation. By changing the origin of time, T can be set to 0 without loss of generality. Then by taking a Fourier transform of (31) over the time variable t , one obtains that

$$\hat{W}_{\text{TR}}(x, \omega) \propto \delta^3 m(z, T) \cdot \nabla j_0(\omega|x - z|),$$

where ω is the wave number. This shows that the time-reversal perturbation W_{TR} focuses on the location z of the anomaly with a focal spot size limited to one-half the wavelength.

An identity parallel to (30) can be derived in the frequency domain. In fact, one has

$$\begin{aligned} \int_S \left[\hat{U}_x(x') \frac{\partial \widehat{\bar{U}}_z}{\partial v}(x') - \frac{\partial \hat{U}_x}{\partial v}(x') \widehat{\bar{U}}_z(x') \right] d\sigma(x') &= 2i \Im m \hat{U}_z(x) \\ &\propto j_0(\omega|x - z|), \end{aligned} \quad (32)$$

which shows that in the frequency domain, W_{TR} coincides with W_{BP} .

Bibliography and Open Questions

The initial boundary-value problems for the wave equation in the presence of anomalies of small volume have been considered in [5, 24]. Theorem 5 is from [12]. In [12], a time-reversal approach was also designed for locating the anomaly from the outer expansion (26). The physics literature on time reversal is quite rich. One refers, for instance, to [48] and the references therein. See [93] for clinical applications of time reversal. Many interesting mathematical works have dealt with different aspects of time-reversal phenomena: see, for instance, [33] for time reversal in the time domain, [45–47, 82] for time reversal in the frequency domain, and [37, 50] for time reversal in random media.

The MUSIC-type algorithm for locating small acoustic or electromagnetic anomalies from the multi-static response matrix at a fixed frequency was developed in [18]. See also [18–20], where a variety of numerical results was presented to highlight its potential and its limitation. It is worth mentioning that the MUSIC-type algorithm is related to time reversal [82, 87].

MUSIC and Kirchhoff imaging functionals can be extended to the time domain in order to detect the anomaly and its polarization tensor from (dynamical) boundary measurements [24].

The inner expansion in Theorem 5 can be used to design an efficient optimization algorithm for reconstructing the shape and the physical parameter of an anomaly from the near-field perturbations of the wavefield, which can be used in radiation force imaging.

In radiation force imaging, one uses the acoustic radiation force of an ultrasonic focused beam to remotely generate mechanical vibrations in organs. A spatiotemporal sequence of the propagation of the induced transient wave can be acquired, leading to a quantitative estimation of the physical parameters of the anomaly. See, for instance, [35, 36].

The proposed location search algorithms using transient wave or broad-range multifrequency boundary measurements can be extended to the case with limited-view measurements. Using the geometrical control method [34], one can still exploit those algorithms and perform imaging with essentially the same resolution using partial data as using complete data, provided that the geometric optics condition holds.

An identity similar to (32) can be derived in an inhomogeneous medium, which shows that the sharper the behavior of the imaginary part of the Green function around the location of the anomaly is, the higher is the resolution. It would be quite challenging to explicitly see how this behavior depends on the heterogeneity of the surrounding medium. This would yield super-resolved ultrasound imaging systems.

4 Infrared Thermal Imaging

Physical Principles

Infrared thermal imaging is becoming a common screening modality in the area of breast cancer. By carefully examining the aspects of temperature and blood vessels of the breasts in thermal images, signs of possible cancer or precancerous cell growth may be detected up to 10 years prior to being discovered using any other procedure. This provides the earliest detection of cancer possible.

Because of thermal imaging's extreme sensitivity, these temperature variations and vascular changes may be among the earliest signs of breast cancer and/or a precancerous state of the breast. An abnormal infrared image of the breast is an important marker of high risk for developing breast cancer. See [3, 83].

Asymptotic Analysis of Temperature Perturbations

Suppose that the background Ω is homogeneous with thermal conductivity 1 and that the anomaly $D = \delta B + z$ has thermal conductivity $0 < k \neq 1 < +\infty$. In this section, one considers the following transmission problem for the heat equation:

$$\begin{cases} \partial_t u - \nabla \cdot (\chi(\Omega \setminus \overline{D}) + k\chi(D)) \nabla u = 0 & \text{in } \Omega_T, \\ u(x, 0) = u_0(x) & \text{for } x \in \Omega, \\ \frac{\partial u}{\partial \nu} = g & \text{on } \partial\Omega_T, \end{cases} \quad (33)$$

where the Neumann boundary data g and the initial data u_0 are subject to a compatibility condition. Let U be the background solution defined as the solution of

$$\begin{cases} \partial_t U - \Delta U = 0 & \text{in } \Omega_T, \\ U(x, 0) = u_0(x) & \text{for } x \in \Omega, \\ \frac{\partial U}{\partial \nu} = g & \text{on } \partial \Omega_T. \end{cases}$$

The following asymptotic expansion holds as $\delta \rightarrow 0$.

Theorem 6 (Perturbations of weighted boundary measurements). *Let $w \in C^\infty(\overline{\Omega}_T)$ be a solution to the adjoint problem, namely, satisfy $(\partial_t + \Delta)w(x, t) = 0$ in Ω_T with $w(x, T) = 0$ for $x \in \Omega$. Define the weighted boundary measurements*

$$I_w[U, T] := \int_{\partial \Omega_T} (u - U)(x, t) \frac{\partial w}{\partial \nu}(x, t) d\sigma(x) dt.$$

Then, for any fixed $T > 0$, the following asymptotic expansion for $I_w[U, T]$ holds as $\delta \rightarrow 0$:

$$I_w[U, T] \approx -\delta^d \int_0^T \nabla U(z, t) \cdot M(k, B) \nabla w(z, t) dt, \quad (34)$$

where $M(k, B)$ is defined by (6).

Note that (34) holds for any fixed positive final time T , while (23) holds only for $T > \text{diam}(\Omega)$. This difference comes from the finite speed propagation property for the wave equation compared to the infinite one for the heat equation.

Consider now the background solution to be the Green function of the heat equation at y :

$$U(x, t) := U_y(x, t) := \begin{cases} \frac{e^{-\frac{|x-y|^2}{4t}}}{(4\pi t)^{d/2}} & \text{for } t > 0, \\ 0 & \text{for } t < 0. \end{cases} \quad (35)$$

Let u be the solution to the following heat equation with an appropriate initial condition:

$$\begin{cases} \partial_t u - \nabla \cdot (\chi(\mathbb{R}^d \setminus \overline{D}) + k\chi(D)) \nabla u = 0 & \text{in } \mathbb{R}^d \times]0, +\infty[, \\ u(x, 0) = U_y(x, 0) & \text{for } x \in \mathbb{R}^d. \end{cases} \quad (36)$$

Proceeding as in the derivation of (26), one can prove that $\delta u(x, t) := u - U$ is approximated by

$$-(k-1) \int_0^t \frac{1}{(4\pi(t-\tau))^{d/2}} \int_{\partial D} e^{-\frac{|x-x'|^2}{4(t-\tau)}} \frac{\partial \hat{v}}{\partial \nu} \Big|_{\left(\frac{x'-z}{\delta}\right)} \cdot \nabla U_y(x', \tau) d\sigma(x') d\tau, \quad (37)$$

for x near z . Therefore, analogously to Theorem 5, the following pointwise expansion follows from the approximation (37).

Theorem 7 (Pointwise perturbations). *Let $y \in \mathbb{R}^d$ be such that $|y - z| \gg \delta$. Let u be the solution to (36). The following expansion holds*

$$(u - U)(x, t) \approx -\delta^d \int_0^t \nabla U_z(x, t-\tau) M(k, B) \nabla U_y(z, \tau) d\tau \quad \text{for } |x-z| \gg O(\delta), \quad (38)$$

where $M(k, B)$ is defined by (6) and U_y and U_z by (35).

When comparing (38) and (26), one should point out that for the heat equation the perturbation due to the anomaly is accumulated over time.

An asymptotic formalism for the realistic half-space model for thermal imaging, well suited for the design of anomaly reconstruction algorithms, has been developed in [29].

Numerical Methods

In this section, the formula (34) is applied (with an appropriate choice of test functions w and background solutions U) for the purpose of identifying the location of the anomaly D . The first algorithm makes use of constant heat flux, and, not surprisingly, it is limited in its ability to effectively locate multiple anomalies.

Using many heat sources, one then describes an efficient method to locate multiple anomalies and illustrate its feasibility. For the sake of simplicity, only the two-dimensional case will be considered.

Detection of a Single Anomaly

For $y \in \mathbb{R}^2 \setminus \overline{\Omega}$, let

$$w(x, t) = w_y(x, t) := \frac{1}{4\pi(T-t)} e^{-\frac{|x-y|^2}{4(T-t)}}. \quad (39)$$

The function w satisfies $(\partial_t + \Delta)w = 0$ in Ω_T and the final condition $w|_{t=T} = 0$ in Ω .

Suppose that there is only one anomaly $D = z + \delta B$ with thermal conductivity k . For simplicity, assume that B is a disk. Choose the background solution $U(x, t)$ to be a harmonic (time-independent) function in Ω_T . One computes

$$\nabla w_y(z, t) = \frac{y - z}{8\pi(T-t)^2} e^{-\frac{|z-y|^2}{4(T-t)}},$$

$$M(k, B)\nabla w_y(z, t) = \frac{(k-1)|B|}{k+1} \frac{y-z}{4\pi(T-t)^2} e^{-\frac{|z-y|^2}{4(T-t)}},$$

and

$$\int_0^T M(k, B)\nabla w_y(z, t) dt = \frac{(k-1)|B|}{k+1} \frac{y-z}{4\pi} \int_0^T \frac{e^{-\frac{|z-y|^2}{4(T-t)}}}{(T-t)^2} dt.$$

But

$$\frac{d}{dt} e^{-\frac{|z-y|^2}{4(T-t)}} = \frac{-|z-y|^2}{4} \frac{e^{-\frac{|z-y|^2}{4(T-t)}}}{(T-t)^2}$$

and therefore

$$\int_0^T M(k, B)\nabla w_y(z, t) dt = \frac{(k-1)|B|}{k+1} \frac{y-z}{\pi|z-y|^2} e^{-\frac{|z-y|^2}{4(T-t)}}.$$

Then the asymptotic expansion (34) yields

$$I_w[U, T](y) \approx \delta^2 \frac{k-1}{k+1} |B| \frac{\nabla U(z) \cdot (y-z)}{\pi|y-z|^2} e^{-\frac{|y-z|^2}{4T}}. \quad (40)$$

Now, one is in a position to present the projection-type location search algorithm for detecting a single anomaly. Prescribe the initial condition $u_0(x) = a \cdot x$ for some fixed unit constant vector a and choose $g = a \cdot v$ as an applied time-independent heat flux on $\partial\Omega_T$, where a is taken to be a coordinate unit vector. Take two observation lines Σ_1 and Σ_2 contained in $\mathbb{R}^2 \setminus \overline{\Omega}$ such that

$$\Sigma_1 := \text{a line parallel to } a, \quad \Sigma_2 := \text{a line normal to } a.$$

Next, find two points $P_i \in \Sigma_i (i = 1, 2)$ so that $I_w(T)(P_1) = 0$ and

$$I_w(T)(P_2) = \begin{cases} \min_{x \in \Sigma_2} I_w(T)(x) & \text{if } k-1 < 0, \\ \max_{x \in \Sigma_2} I_w(T)(x) & \text{if } k-1 > 0. \end{cases}$$

Finally, draw the corresponding lines $\Pi_1(P_1)$ and $\Pi_2(P_2)$ given by (12). Then the intersecting point P of $\Pi_1(P_1) \cap \Pi_2(P_2)$ is close to the anomaly $D : |P - z| = O(\delta |\log \delta|)$ for δ small enough.

Detection of Multiple Anomalies: A MUSIC-Type Algorithm

Consider m well-separated anomalies $D_s = \delta B_s + z_s$, $s = 1, \dots, m$, whose heat conductivity is k_s . Choose

$$U(x, t) = U_{y'}(x, t) := \frac{1}{4\pi t} e^{-\frac{|x-y'|^2}{4t}} \quad \text{for } y' \in \mathbb{R}^2 \setminus \overline{\Omega}$$

or, equivalently, g to be the heat flux corresponding to a heat source placed at the point source y' and the initial condition $u_0(x) = 0$ in Ω , to obtain that

$$\begin{aligned} I_w[U, T] &\approx -\delta^2 \sum_{s=1}^m \frac{(1-k_s)}{64\pi^2} (y' - z_s) M^{(s)}(y - z_s) \\ &\quad \times \int_0^T \frac{1}{t^2(T-t)^2} \exp\left(-\frac{|y-z_s|^2}{4(T-t)} - \frac{|y'-z_s|^2}{4t}\right) dt, \end{aligned}$$

where w is given by (39) and $M^{(s)}$ is the polarization tensor of D_s .

Suppose for the sake of simplicity that all the domains B_s are disks. Then it follows from (10) that $M^{(s)} = m^{(s)} I_2$, where $m^{(s)} = 2(k_s - 1)|B_s|/(k_s + 1)$ and I_2 is the 2×2 identity matrix. Let $y_l \in \mathbb{R}^2 \setminus \overline{\Omega}$ for $l \in \mathbb{N}$ be the source points. One assumes that the countable set $\{y_l\}_{l \in \mathbb{N}}$ has the property that any analytic function which vanishes in $\{y_l\}_{l \in \mathbb{N}}$ vanishes identically.

The MUSIC-type location search algorithm for detecting multiple anomalies is as follows. For $n \in \mathbb{N}$ sufficiently large, define the matrix $A = [A_{ll'}]_{l,l'=1}^n$ by

$$\begin{aligned} A_{ll'} &:= -\delta^2 \sum_{s=1}^m \frac{(1-k_s)}{64\pi^2} m^{(s)} (y_{l'} - z_s) \cdot (y_l - z_s) \\ &\quad \times \int_0^T \frac{1}{t^2(T-t)^2} \exp\left(-\frac{|y_l-z_s|^2}{4(T-t)} - \frac{|y_{l'}-z_s|^2}{4t}\right) dt. \end{aligned}$$

For $z \in \Omega$, one decomposes the symmetric real matrix C defined by

$$C := \left[\int_0^T \frac{1}{t^2(T-t)^2} \exp\left(-\frac{|y_l-z|^2}{4(T-t)} - \frac{|y_{l'}-z|^2}{4t}\right) dt \right]_{l,l'=1,\dots,n}$$

as follows:

$$C = \sum_{l=1}^p v_l(z) v_l(z)^* \tag{41}$$

for some $p \leq n$, where $v_l \in \mathbb{R}^n$ and v_l^* denotes the transpose of v_l . Define the vector $g_z^{(l)} \in \mathbb{R}^{n \times 2}$ for $z \in \Omega$ by

$$g_z^{(l)} = ((y_1 - z)v_{l1}(z), \dots, (y_n - z)v_{ln}(z))^*, \quad l = 1, \dots, p. \quad (42)$$

Here, v_{l1}, \dots, v_{ln} are the components of the vector v_l , $l = 1, \dots, p$. Let $y_l = (y_{lx}, y_{ly})$ for $l = 1, \dots, n$, $z = (z_x, z_y)$, and $z_s = (z_{sx}, z_{sy})$. One also introduces

$$g_{zx}^{(l)} = ((y_{1x} - z_x)v_{l1}(z), \dots, (y_{nx} - z_x)v_{ln}(z))^*$$

and

$$g_{zy}^{(l)} = ((y_{1y} - z_y)v_{l1}(z), \dots, (y_{ny} - z_y)v_{ln}(z))^*.$$

Lemma 3 (MUSIC characterization of the range of the response matrix). *The following characterization of the location of the anomalies in terms of the range of the matrix A holds:*

$$g_{zx}^{(l)} \text{ and } g_{zy}^{(l)} \in \text{Range}(A) \quad \forall l \in \{1, \dots, p\} \quad \text{if and only if} \quad z \in \{z_1, \dots, z_m\}. \quad (43)$$

Note that the smallest number n which is sufficient to efficiently recover the anomalies depends on the (unknown) number m . This is the main reason for taking n sufficiently large. As for the electrical impedance imaging, the MUSIC-type algorithm for the thermal imaging is as follows. Compute P_{noise} , the projection onto the noise space, by the singular value decomposition of the matrix A . Compute the vectors v_l by (41). Form an image of the locations, z_1, \dots, z_m , by plotting, at each point z , the quantity $\|g_z^{(l)} \cdot a\| / \|P_{\text{noise}}(g_z^{(l)} \cdot a)\|$ for $l = 1, \dots, p$, where $g_z^{(l)}$ is given by (42) and a is a unit constant vector. The resulting plot will have large peaks at the locations of z_s , $s = 1, \dots, m$.

The next two figures (Figs. 4 and 5) show MUSIC-type reconstructions of two anomalies without and with noise.

In Fig. 4, one sees clearly the presence of two anomalies. However, the one on the right, which is also deeper, is not as well rendered as the one on the left.

Bibliography and Open Questions

Thermal imaging of small anomalies has been considered in [17]. See also [29], where a realistic half-space model for thermal imaging was considered and accurate and robust reconstruction algorithms are designed.

It is worth mentioning that the inner expansions derived for the heat equation can be used to improve reconstruction in ultrasonic temperature imaging. The idea behind ultrasonic temperature imaging hinges on measuring local temperature near anomalies. The aim is to reconstruct anomalies with higher spatial and contrast resolution as compared to those obtained from boundary measurements alone. Further numerical investigations on this emerging topic are required.

5 Impedigraphy

Physical Principles

Since all the present electrical impedance tomography technologies are only practically applicable in feature extraction of anomalies, improving electrical impedance tomography calls for innovative measurement techniques that incorporate structural information. A very promising direction of research is the recent magnetic resonance imaging technique, called current density imaging, which measures the

internal current density distribution. See the breakthrough work by Seo and his group described, for instance, in [65, 66, 89]. However, this technique has a number of disadvantages, among which the lack of portability and a potentially long imaging time. Moreover, it uses an expensive magnetic resonance imaging scanner.

Impediography is another mathematical direction for future electrical impedance tomography research in view of biomedical applications. It keeps the most important merits of electrical impedance tomography (real-time imaging, low cost, portability). It is based on the simultaneous measurement of an electric current and of acoustic vibrations induced by ultrasound waves. Its intrinsic resolution depends on the size of the focal spot of the acoustic perturbation, and thus, it may provide high-resolution images.

The core idea of impediography is to couple electric measurements to localized elastic perturbations. A body (a domain $\Omega \subset \mathbb{R}^2$) is electrically probed: one or several currents are imposed on the surface and the induced potentials are measured on the boundary. At the same time, a circular region of a few millimeters in the interior of Ω is mechanically excited by ultrasonic waves, which dilate this region. The measurements are made as the focus of the ultrasounds scans the entire domain. Several sets of measurements can be obtained by varying amplitudes of the ultrasound waves and the applied currents.

Within each disk of (small) volume, the conductivity is assumed to be constant per volume unit. At a point $x \in \Omega$, within a disk D of volume V_D , the electrical conductivity γ is defined in terms of a density ρ as $\gamma(x) = \rho(x)V_D$.

The ultrasonic waves induce a small elastic deformation of the disk D . If this deformation is isotropic, the material points of D occupy a volume V_D^P in the perturbed configuration, which at first order is equal to

$$V_D^P = V_D \left(1 + 2\frac{\Delta r}{r}\right),$$

where r is the radius of the disk D and Δr is the variation of the radius due to the elastic perturbation. As Δr is proportional to the amplitude of the ultrasonic wave, one obtains a proportional change of the deformation. Using two different ultrasonic waves with different amplitudes but with the same spot, it is therefore easy to compute the ratio V_D^P/V_D . As a consequence, the perturbed electrical conductivity γ^P satisfies

$$\forall x \in \Omega, \quad \gamma^P(x) = \rho(x)V_D^P = \gamma(x)\eta(x),$$

where $\eta(x) = V_D^P/V_D$ is a known function. One makes the following realistic assumptions: (1) the ultrasonic wave expands the zone it impacts and changes its conductivity, $\forall x \in \Omega, \eta(x) > 1$, and (2) the perturbation is not too small, $\eta(x) - 1 \gg V_D$.

Mathematical Model

Let u be the voltage potential induced by a current g , in the absence of ultrasonic perturbations. It is given by

$$\begin{cases} \nabla \cdot (\gamma(x) \nabla u) = 0 \text{ in } \Omega, \\ \gamma \frac{\partial u}{\partial \nu} = g \text{ on } \partial\Omega, \end{cases} \quad (44)$$

with the convention that $\int_{\partial\Omega} u = 0$. One supposes that the conductivity γ of the region close to the boundary of the domain is known, so that ultrasonic probing is limited to interior points. One denotes the region (open set) by Ω_1 .

Let u_δ be the voltage potential induced by a current g , in the presence of ultrasonic perturbations localized in a disk-shaped domain $D := z + \delta B$ of volume $|D| = O(\delta^2)$. The voltage potential u_δ is a solution to

$$\begin{cases} \nabla \cdot (\gamma_\delta(x) \nabla u_\delta(x)) = 0 \text{ in } \Omega, \\ \gamma \frac{\partial u_\delta}{\partial \nu} = g \text{ on } \partial\Omega, \end{cases} \quad (45)$$

with the notation

$$\gamma_\delta(x) = \gamma(x) [1 + \chi(D)(x) (\eta(x) - 1)],$$

where $\chi(D)$ is the characteristic function of the domain D .

As the zone deformed by the ultrasound wave is small, one can view it as a small-volume perturbation of the background conductivity γ and seek an asymptotic expansion of the boundary values of $u_\delta - u$. The method of small-volume expansions shows that comparing u_δ and u on $\partial\Omega$ provides information about the conductivity. Indeed, one can prove that

$$\begin{aligned} \int_{\partial\Omega} (u_\delta - u) g \, d\sigma &= \int_D \gamma(x) \frac{(\eta(x) - 1)^2}{\eta(x) + 1} \nabla u \cdot \nabla u \, dx + o(|D|) \\ &= \gamma(z) |\nabla u(z)|^2 \int_D \frac{(\eta(x) - 1)^2}{\eta(x) + 1} \, dx + o(|D|). \end{aligned}$$

Note that because of assumption (2) at the end of the previous section, it follows that

$$\int_D \frac{(\eta(x) - 1)^2}{\eta(x) + 1} \, dx \geq C |D|$$

for some positive constant C . Therefore, one has

$$\gamma(z) |\nabla u(z)|^2 = \mathcal{E}(z) + o(1), \quad (46)$$

where the function $\mathcal{E}(z)$ is defined by

$$\mathcal{E}(z) = \left(\int_D \frac{(\eta(x) - 1)^2}{\eta(x) + 1} dx \right)^{-1} \int_{\partial\Omega} (u_\delta - u) g d\sigma. \quad (47)$$

By scanning the interior of the body with ultrasound waves, given an applied current g , one then obtains data from which one can compute the electrical energy

$$\mathcal{E}(z) := \gamma(z) |\nabla u(z)|^2$$

in an interior subregion of Ω . The new inverse problem is now to reconstruct γ , knowing \mathcal{E} .

Substitution Algorithm

The use of \mathcal{E} leads one to transform (44), having two unknowns γ and u with highly nonlinear dependency on γ , into the following nonlinear PDE (the 0-Laplacian)

$$\begin{cases} \nabla_x \cdot \left(\frac{\mathcal{E}}{|\nabla u|^2} \nabla u \right) = 0 & \text{in } \Omega, \\ \frac{\mathcal{E}}{|\nabla u|^2} \frac{\partial u}{\partial \nu} = g & \text{on } \partial\Omega. \end{cases} \quad (48)$$

It is worth emphasizing that \mathcal{E} is a known function, constructed from the measured data (47). Consequently, all the parameters entering in (48) are known. Thus, the ill-posed inverse problem in electrical impedance tomography is converted into a less-complicated direct problem (48).

The E-substitution algorithm, which will be explained below, uses two currents g_1 and g_2 . One chooses this pair of current patterns to have $\nabla u_1 \times \nabla u_2 \neq 0$ for all $x \in \Omega$, where $u_i, i = 1, 2$, is the solution to (44). One refers to [66] and the references therein for an evidence of the possibility of such a choice. The E-substitution algorithm is based on an approximation of a linearized version of problem (48).

Suppose that γ is a small perturbation of conductivity profile $\gamma_0 : \gamma = \gamma_0 + \delta\gamma$. Let u_0 and $u = u_0 + \delta u$ denote the potentials corresponding to γ_0 and γ with the same Neumann boundary data g . It is easily seen that δu satisfies $\nabla \cdot (\gamma \nabla \delta u) = -\nabla \cdot (\delta\gamma \nabla u_0)$ in Ω with the homogeneous Dirichlet boundary condition. Moreover, from

$$\mathcal{E} = (\gamma_0 + \delta\gamma)|\nabla(u_0 + \delta u)|^2 \approx \gamma_0|\nabla u_0|^2 + \delta\gamma|\nabla u_0|^2 + 2\gamma_0\nabla u_0 \cdot \nabla \delta u,$$

after neglecting the terms $\delta\gamma\nabla u_0 \cdot \nabla \delta u$ and $\delta\gamma|\nabla \delta u|^2$, it follows that

$$\delta\gamma \approx \frac{\mathcal{E}}{|\nabla u_0|^2} - \gamma_0 - 2\gamma_0 \frac{\nabla \delta u \cdot \nabla u_0}{|\nabla u_0|^2}.$$

The E-substitution algorithm is as follows. One starts from an initial guess for the conductivity γ and solves the corresponding Dirichlet conductivity problem

$$\begin{cases} \nabla \cdot (\gamma \nabla u_0) = 0 & \text{in } \Omega, \\ u_0 = \psi & \text{on } \partial\Omega. \end{cases}$$

The data ψ is the Dirichlet data measured as a response to the current g (say $g = g_1$) in the absence of elastic deformation. The discrepancy between the data and the guessed solution is

$$\epsilon_0 := \frac{\mathcal{E}}{|\nabla u_0|^2} - \gamma. \quad (49)$$

One then introduces a corrector, δu , computed as the solution to

$$\begin{cases} \nabla \cdot (\gamma \nabla \delta u) = -\nabla \cdot (\epsilon_0 \nabla u_0) & \text{in } \Omega, \\ \delta u = 0 & \text{on } \partial\Omega, \end{cases}$$

and updates the conductivity

$$\gamma := \frac{\mathcal{E} - 2\gamma \nabla \delta u \cdot \nabla u_0}{|\nabla u_0|^2}.$$

One iteratively updates the conductivity, alternating directions of currents (i.e., with $g = g_2$).

Consider a disk-shaped domain Ω , which contains three anomalies, an ellipse, an L-shaped domain, and a triangle. See Fig. 6.

Figure 7 shows the result of the reconstruction when measurements with very accurate precision for two directions of currents are available.

In the case of incomplete data, that is, if \mathcal{E} is only known on a subset Ω' of the domain, one can follow an optimal control approach. See [39].

Bibliography and Open Questions

Impediography was proposed in [8], and the substitution algorithm proposed there. An optimal control approach for solving the inverse problem in impediography has

Fig. 6 Conductivity distribution

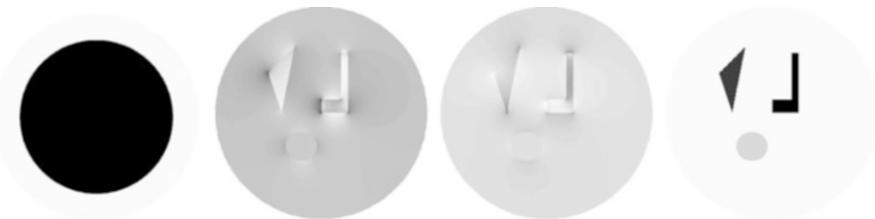

Fig. 7 Reconstruction test. From *left* to *right*, the initial guess, the collected data \mathcal{E} for two directions of currents, and the reconstructed conductivity

been described in [39]. The inversion was considered as a minimization problem, and it was performed in two or three dimensions.

As pointed out in [71], the success of impediography depends on the feasibility of focusing ultrasound waves at an arbitrary point inside the body. Such a focusing, however, is quite tricky to achieve in practice. See, for instance, [85]. A method to extract the measurements corresponding to well-focused beams from the data obtained with unfocused waves has been proposed in [71].

An interesting problem is to study the sensitivity of the inversion methods to limitations on the intensities of the applied voltages, as electrical safety regulations limit the amount of the total current that patients can sustain. Another interesting problem is to reconstruct anisotropic conductivity distributions and to see whether or not impediography allows one to remove the obstruction to unique identifiability of the conductivity by electrical impedance tomography. In electrical impedance tomography, it is known that any change of variables of the background conductor that leaves the boundary fixed gives rise to a new anisotropic conductivity with the same boundary measurements [68].

6 Magneto-Acoustic Imaging

In magneto-acoustic imaging, a probe signal such as an acoustic wave or an electric current (or voltage) is applied to a biological tissue placed in a magnetic field. The probe signal produces, by the Lorentz force, an induced signal that is a function of the local electrical conductivity of the biological tissue. If the probe signal is an acoustic wave, then the induced signal is an electric current and the Lorentz force causes a local current density.

Induced boundary currents or pressure which are proportional to the local electrical conductivity can be measured to reconstruct the conductivity distribution with the spatial resolution of the ultrasound. The induced signal is detected, and an image of the local electrical conductivity of the specimen is generated based on the detected induced signal. The first method is referred as magneto-acousto-electrical tomography and the second one as magneto-acoustic tomography with magnetic induction.

Magneto-Acousto-Electrical Tomography

Physical Principles

In magneto-acousto-electrical imaging, an acoustic wave is applied to a biological tissue placed in a magnetic field. The probe signal produces by the Lorentz force an electric current that is a function of the local electrical conductivity of the biological tissue [80]. The mathematical basis for this magneto-acoustic imaging approach is provided, and an efficient algorithm for solving the inverse problem is proposed which is quite similar to the one designed for impediography.

Mathematical Model

Denote by $\gamma(x)$ the unknown conductivity, and let the voltage potential v be the solution to the conductivity problem

$$\begin{cases} \nabla \cdot \gamma \nabla v = 0 & \text{in } \Omega, \\ v = g & \text{on } \partial\Omega. \end{cases} \quad (50)$$

Suppose that the conductivity γ is a known constant on a neighborhood of the boundary $\partial\Omega$ and let γ_* denote $\gamma|_{\partial\Omega}$.

In magneto-acoustic imaging, ultrasonic waves are focused on regions of small diameter inside a body placed on a static magnetic field. The oscillation of each small region results in frictional forces being applied to the ions, making them move. In the presence of a magnetic field, the ions experience a Lorentz force. This

gives rise to a localized current density within the medium. The current density is proportional to the local electrical conductivity [80]. In practice, the ultrasounds impact a spherical or ellipsoidal zone, of a few millimeters in diameter. The induced current density should thus be sensitive to conductivity variations at the millimeter scale, which is the precision required for breast cancer diagnostics.

Let $z \in \Omega$ and D be a small impact zone around the point z . The created current by the Lorentz force density is given by

$$\mathbf{J}_z(x) = c\chi(D)(x)\gamma(x)\mathbf{e}, \quad (51)$$

for some constant c and a constant unit vector \mathbf{e} , both of which are independent of z . With the induced current \mathbf{J}_z , the new voltage potential, denoted by u_z , satisfies

$$\begin{cases} \nabla \cdot (\gamma \nabla u_z + \mathbf{J}_z) = 0 & \text{in } \Omega, \\ u_z = g & \text{on } \partial\Omega. \end{cases}$$

According to (51), the induced electrical potential $w_z := v - u_z$ satisfies the conductivity equation:

$$\begin{cases} \nabla \cdot \gamma \nabla w_z = c \nabla \cdot (\chi(D)\gamma \mathbf{e}) & \text{for } x \in \Omega, \\ w_z(x) = 0 & \text{for } x \in \partial\Omega. \end{cases} \quad (52)$$

The inverse problem for the magneto-acousto-electrical imaging is to reconstruct the conductivity profile γ from boundary measurements of $\frac{\partial u_z}{\partial v}|_{\partial\Omega}$ or equivalently $\frac{\partial w_z}{\partial v}|_{\partial\Omega}$ for $z \in \Omega$.

Substitution Algorithm

Since γ is assumed to be constant in D and $|D|$ is small, one obtains using Green's identity

$$\int_{\partial\Omega} \gamma_* \frac{\partial w_z}{\partial v} g d\sigma \approx -c|D| \nabla(\gamma v)(z) \cdot \mathbf{e}. \quad (53)$$

The relation (53) shows that, by scanning the interior of the body with ultrasound waves, $c \nabla(\gamma v)(z) \cdot \mathbf{e}$ can be computed from the boundary measurements $\frac{\partial w_z}{\partial v}|_{\partial\Omega}$ in Ω . If one can rotate the subject, then $c \nabla(\gamma v)(z)$ for any z in Ω can be reconstructed. In practice, the constant c is not known. But, since γv and $\partial(\gamma v)/\partial v$ on the boundary of Ω are known, one can recover c and γv from $c \nabla(\gamma v)$ in a constructive way [11].

The new inverse problem is now to reconstruct the contrast profile γ , knowing

$$\mathcal{E}(z) := \gamma(z)v(z) \quad (54)$$

for a given boundary potential g , where v is the solution to (50).

In view of (54), v satisfies

$$\begin{cases} \nabla \cdot \frac{\mathcal{E}}{v} \nabla v = 0 & \text{in } \Omega, \\ v = g & \text{on } \partial\Omega. \end{cases} \quad (55)$$

If one solves (55) for v , then (54) yields the conductivity contrast γ . Note that to be able to solve (55), one needs to know the coefficient $\mathcal{E}(z)$ for all z , which amounts to scanning all the points $z \in \Omega$ by the ultrasonic beam.

Observe that solving (55) is quite easy mathematically: if one puts $w = \ln v$, then w is the solution to

$$\begin{cases} \nabla \cdot \mathcal{E} \nabla w = 0 & \text{in } \Omega, \\ w = \ln g & \text{on } \partial\Omega, \end{cases} \quad (56)$$

as long as $g > 0$. Thus, if one solves (56) for w , then $v := e^w$ is the solution to (55). However, taking an exponent may amplify the error which already exists in the computed data \mathcal{E} . In order to avoid this numerical instability, one solves (55) iteratively. To do so, one can adopt an iterative scheme similar to the one proposed in the previous section.

Start with γ_0 and let v_0 be the solution of

$$\begin{cases} \nabla \cdot \gamma_0 \nabla v_0 = 0 & \text{in } \Omega, \\ v_0 = g & \text{on } \partial\Omega. \end{cases} \quad (57)$$

According to (54), the updates, $\gamma_0 + \delta\gamma$ and $v_0 + \delta v$, should satisfy

$$\gamma_0 + \delta\gamma = \frac{\mathcal{E}}{v_0 + \delta v}, \quad (58)$$

where

$$\begin{cases} \nabla \cdot (\gamma_0 + \delta\gamma) \nabla (v_0 + \delta v) = 0 & \text{in } \Omega, \\ \delta v = 0 & \text{on } \partial\Omega, \end{cases}$$

or equivalently

$$\begin{cases} \nabla \cdot \gamma_0 \nabla \delta v + \nabla \cdot \delta\gamma \nabla v_0 = 0 & \text{in } \Omega, \\ \delta v = 0 & \text{on } \partial\Omega. \end{cases} \quad (59)$$

One then linearizes (58) to have

$$\gamma_0 + \delta\gamma = \frac{\mathcal{E}}{v_0(1 + \delta v/v_0)} \approx \frac{\mathcal{E}}{v_0} \left(1 - \frac{\delta v}{v_0} \right). \quad (60)$$

Fig. 8 Reconstruction test. From *left* to *right*, the conductivity distribution, the initial guess, and the reconstructed conductivity after three iterations

Thus,

$$\delta\gamma = -\frac{\mathcal{E}\delta v}{v_0^2} - \delta, \quad \delta = -\frac{\mathcal{E}}{v_0} + \gamma_0. \quad (61)$$

One then finds δv by solving

$$\begin{cases} \nabla \cdot \gamma_0 \nabla \delta v - \nabla \cdot \left(\frac{\mathcal{E} \nabla v_0}{v_0^2} \delta v \right) = \nabla \cdot \delta \nabla v_0 & \text{in } \Omega, \\ \delta v = 0 & \text{on } \partial\Omega. \end{cases} \quad (62)$$

Figure 8 shows the result of the reconstruction when very accurate measurements for two Dirichlet boundary conditions, $g = g_1, g_2$, are available.

In the case of incomplete data, that is, if \mathcal{E} is only known on a subset ω of the domain, one can follow an optimal control approach. See [11].

Magneto-Acoustic Imaging with Magnetic Induction

Physical Principles

In the magneto-acoustic tomography with magnetic induction, pulsed magnetic stimulation by the ultrasound beam is imposed on an object placed in a static magnetic field. The magnetic stimulation can be considered as an ideal pulsed distribution over time. The magnetically induced eddy current is then subject to a Lorentz force. This in turn creates a pressure wave that can be detected using an ultrasound hydrophone [80]. The magneto-acoustic tomography with magnetic induction uses this acoustic pressure wave to reconstruct the conductivity distribution of the sample as the focus of the ultrasound beam scans the entire domain.

Mathematical Model

Let γ be the conductivity distribution of the object as before. Denoting the constant magnetic field as B_0 and the magnetically induced current density distribution as $\mathbf{J}_z(x)$ with z indicating the location of the magnetic stimulation, the Lorentz force is given by

$$\mathbf{J}_z(x) \times B_0 \delta_{t=0} = c \chi(D)(x) \gamma(x) \mathbf{e} \delta_{t=0},$$

where D is the impact zone which is a small neighborhood of z as before, and c is a constant independent of z and x . Then the wave equation governing the pressure distribution p_z can be written as

$$\frac{\partial^2 p_z}{\partial t^2} - c_s^2 \Delta p_z = 0, \quad x \in \Omega, \quad t \in]0, T[, \quad (63)$$

for some final observation time T , where c_s is the acoustic speed in Ω . The pressure satisfies the Dirichlet boundary condition

$$p_z = 0 \quad \text{on } \partial\Omega \times]0, T[\quad (64)$$

and the initial conditions

$$p_z|_{t=0} = 0 \quad \text{and} \quad \left. \frac{\partial p_z}{\partial t} \right|_{t=0} = -c \nabla \cdot (\chi(D) \gamma \mathbf{e}) \quad \text{in } \Omega. \quad (65)$$

The inverse problem for the magneto-acoustic tomography with magnetic induction is to determine the conductivity distribution γ in Ω from boundary measurements of $\frac{\partial p_z}{\partial v}$ on $\partial\Omega \times]0, T[$ for all $z \in \Omega$. Suppose that T is large enough so that

$$T > \frac{\text{diam}(\Omega)}{c_s}, \quad (66)$$

which says that the observation time is long enough for the wave initiated at z to reach the boundary $\partial\Omega$.

Reconstruction Algorithm

The algorithms for the magneto-acoustic tomography with magnetic induction available in the literature are limited to unbounded media. They use the spherical Radon transform inversion. However, the pressure field is significantly affected by the acoustic boundary conditions at the tissue-air interface, where the pressure must vanish. Thus, one cannot base magneto-acoustic imaging on pressure measurements made over a free surface. Instead, one can use the following algorithm.

Let w satisfy

$$\frac{\partial^2 w}{\partial t^2} - c_s^2 \Delta w = 0 \quad \text{in } \Omega \times]0, T[, \quad (67)$$

with the final conditions

$$w|_{t=T} = \frac{\partial w}{\partial t} \Big|_{t=T} = 0 \quad \text{in } \Omega. \quad (68)$$

Since γ is constant on D , one can prove that the following identity holds:

$$\int_0^T \int_{\partial\Omega} \frac{\partial p_z}{\partial \nu}(x, t) w(x, t) d\sigma(x) dt = \frac{c}{c_s^2} \gamma(z) \int_D \mathbf{e} \cdot \nabla w(x, 0) dx. \quad (69)$$

Suppose that $d = 3$. For $y \in \mathbb{R}^3 \setminus \overline{\Omega}$, define the probe function

$$w_y(x, t) := \frac{\delta \left(t + \tau - \frac{|x-y|}{c_s} \right)}{4\pi|x-y|} \quad \text{in } \Omega \times]0, T[, \quad (70)$$

where $\tau := \frac{|y-z|}{c_s}$. The function w_y is a Green's function corresponding to retarded potentials. Choosing w_y as a test function in (69) yields the new identity

$$c\gamma(z) = \frac{c_s^2}{\int_D \mathbf{e} \cdot \nabla w_y(x, 0) dx} \int_0^T \int_{\partial\Omega} \frac{\partial p_z}{\partial \nu}(x, t) w_y(x, t) d\sigma(x) dt. \quad (71)$$

The quantity $\int_D \mathbf{e} \cdot \nabla w_y(x, 0) dx$ can be explicitly computed. In particular, if the source point y is such that $z - y$ is parallel to \mathbf{e} and D is a sphere of radius r (and center z), then

$$c\gamma(z) = -\frac{c_s}{\frac{r^2}{2|z-y|^2} - \frac{r^4}{4|z-y|^4}} \int_0^T \int_{\partial\Omega} \frac{\partial p_z}{\partial \nu}(x, t) w_y(x, t) d\sigma(x) dt, \quad (72)$$

provided that γ is constant on D . But since r is sufficiently small, one obtains

$$c\gamma(z) \approx -\frac{2c_s|z-y|^2}{r^2} \int_0^T \int_{\partial\Omega} \frac{\partial p_z}{\partial \nu}(x, t) w_y(x, t) d\sigma(x) dt. \quad (73)$$

Formula (73) can be used to effectively compute the conductivity contrast in Ω with a resolution of order the size of the ultrasound beam. It is worth emphasizing that unlike magneto-acousto-electrical imaging, in magneto-acoustic tomography with magnetic induction, it suffices to excite the local spot at z in order to obtain the value $c\gamma(z)$, as clearly shown by (73).

Bibliography and Open Questions

The feasibility of magneto-acoustic imaging has been demonstrated in [54, 75, 76]. The mathematical and numerical modeling described in this section is from [11]. As it will be shown in Sect. 8, the approach for the magneto-acoustic tomography with magnetic induction can be used in photo-acoustic imaging.

It would be interesting to prove the convergence of the proposed iterative scheme for magneto-acousto-electrical tomography. Another important problem is to design an efficient inversion algorithm for magneto-acoustic tomography with magnetic induction when the acoustic speed fluctuates randomly.

7 Magnetic Resonance Elastography

Physical Principles

Extensive work has been carried out in the past decade to image, by inducing motion, the elastic properties of human soft tissues. This wide application field, called elasticity imaging or elastography, is based on the initial idea that shear elasticity can be correlated with the pathological state of tissues. Several techniques arose according to the type of mechanical excitation chosen (static compression, monochromatic, or transient vibration) and the way these excitations are generated (externally or internally). Different imaging modalities can be used to estimate the resulting tissue displacements.

Magnetic resonance elastography (MRE) is a new way of realizing the idea of elastography. It can directly visualize and quantitatively measure the displacement field in tissues subject to harmonic mechanical excitation at low frequencies. A phase-contrast magnetic resonance imaging technique is used to spatially map and measure the complete three-dimensional displacement patterns. From this data, local quantitative values of shear modulus can be calculated, and images that depict tissue elasticity or stiffness can be generated. The inverse problem for magnetic resonance elastography is to determine the shape and the elastic parameters of an elastic anomaly from internal measurements of the displacement field. In most cases, the most significant elastic parameter is the stiffness coefficient.

In biological media, the compression modulus is four to six orders higher than the shear modulus. One can prove that, as the compression modulus goes to $+\infty$, the Lamé system converges to the modified Stokes system. By reducing the elasticity system to a modified Stokes system, one removes the compression modulus from consideration.

Mathematical Model

Consider the modified Stokes system, i.e., the problem of determining \mathbf{v} and q in a domain Ω from the conditions:

$$\begin{cases} (\Delta + \kappa^2) \mathbf{v} - \nabla q = 0, \\ \nabla \cdot \mathbf{v} = 0, \\ \mathbf{v}|_{\partial\Omega} = \mathbf{g}. \end{cases} \quad (74)$$

Problem (74) governs elastic wave propagation in nearly incompressible homogeneous media.

Let $(G_{il})_{i,l=1}^d$ be the Dirichlet Green function for the operator in (74), i.e., for $y \in \Omega$,

$$\begin{cases} (\Delta_x + \kappa^2) G_{il}(x, y) - \frac{\partial F_i(x - y)}{\partial x_l} = \delta_{il} \delta_y(x) & \text{in } \Omega, \\ \sum_{l=1}^d \frac{\partial}{\partial x_l} G_{il}(x, y) = 0 & \text{in } \Omega, \\ G_{il}(x, y) = 0 & \text{on } \partial\Omega. \end{cases} \quad (75)$$

Denote by $(\mathbf{e}_1, \dots, \mathbf{e}_d)$ an orthonormal basis of \mathbb{R}^d . Let $d(\xi) := (1/d) \sum_k \xi_k \mathbf{e}_k$ and $\hat{\mathbf{v}}_{pq}$, for $p, q = 1, \dots, d$, be the solution to

$$\begin{cases} \mu \Delta \hat{\mathbf{v}}_{pq} + \nabla \hat{p} = 0 & \text{in } \mathbb{R}^d \setminus \overline{B}, \\ \tilde{\mu} \Delta \hat{\mathbf{v}}_{pq} + \nabla \hat{p} = 0 & \text{in } B, \\ \hat{\mathbf{v}}_{pq}|_- - \hat{\mathbf{v}}_{pq}|_+ = 0 & \text{on } \partial B, \\ \left(\hat{p} \mathbf{N} + \tilde{\mu} \frac{\partial \hat{\mathbf{v}}_{pq}}{\partial \mathbf{N}} \right)|_- - \left(\hat{p} \mathbf{N} + \mu \frac{\partial \hat{\mathbf{v}}_{pq}}{\partial \mathbf{N}} \right)|_+ = 0 & \text{on } \partial B, \\ \nabla \cdot \hat{\mathbf{v}}_{pq} = 0 & \text{in } \mathbb{R}^d, \\ \hat{\mathbf{v}}_{pq}(\xi) \rightarrow \xi_p \mathbf{e}_q - \delta_{pq} d(\xi) & \text{as } |\xi| \rightarrow \infty, \\ \hat{p}(\xi) \rightarrow 0 & \text{as } |\xi| \rightarrow +\infty. \end{cases} \quad (76)$$

Here, $\partial \mathbf{v} / \partial \mathbf{N} = (\nabla \mathbf{v} + (\nabla \mathbf{v})^*) \cdot \mathbf{N}$ and $(\nabla \mathbf{v})^*$ denotes the transpose of the matrix $\nabla \mathbf{v}$.

Define the viscous moment tensor $(V_{ijpq})_{i,j,p,q=1,\dots,d}$ by

$$V_{ijpq} := (\tilde{\mu} - \mu) \int_B \nabla \hat{\mathbf{v}}_{pq} \cdot (\nabla(\xi_i \mathbf{e}_j) + \nabla(\xi_j \mathbf{e}_i)^*) d\xi. \quad (77)$$

Consider an elastic anomaly D inside a nearly compressible medium Ω . The anomaly D has a shear modulus $\tilde{\mu}$ different from that of Ω , μ . The displacement field \mathbf{u} solves the following transmission problem for the modified Stokes problem:

$$\begin{cases} (\mu\Delta + \omega^2)\mathbf{u} + \nabla p = 0 & \text{in } \Omega \setminus \overline{D}, \\ (\tilde{\mu}\Delta + \omega^2)\mathbf{u} + \nabla p = 0 & \text{in } D, \\ \mathbf{u}|_- = \mathbf{u}|_+ & \text{on } \partial D, \\ (p|_+ - p|_-)\mathbf{N} + \mu \frac{\partial \mathbf{u}}{\partial \mathbf{N}}|_+ - \tilde{\mu} \frac{\partial \mathbf{u}}{\partial \mathbf{N}}|_- = 0 & \text{on } \partial D, \\ \nabla \cdot \mathbf{u} = 0 & \text{in } \Omega, \\ \mathbf{u} = \mathbf{g} & \text{on } \partial \Omega, \\ \int_{\Omega} p = 0, \end{cases} \quad (78)$$

where $\mathbf{g} \in L^2(\partial\Omega)$ satisfies the compatibility condition $\int_{\partial\Omega} \mathbf{g} \cdot \mathbf{N} = 0$.

The inverse problem consists of reconstructing $\tilde{\mu}$ and the shape of the inclusion D from internal measurements of \mathbf{u} .

Asymptotic Analysis of Displacement Fields

Let (\mathbf{U}, q) denote the background solution to the modified Stokes system in the absence of any anomalies, that is, the solution to

$$\begin{cases} (\mu\Delta + \omega^2)\mathbf{U} + \nabla q = 0 & \text{in } \Omega, \\ \nabla \cdot \mathbf{U} = 0 & \text{in } \Omega, \\ \mathbf{U} = \mathbf{g} & \text{on } \partial\Omega, \\ \int_{\Omega} q = 0. \end{cases} \quad (79)$$

The following asymptotic expansions hold.

Theorem 8 (Expansions of the displacement field). Suppose that $D = \delta B + z$, and let \mathbf{u} be the solution of (78), where $0 < \tilde{\mu} \neq \mu < +\infty$.

(i) The following inner expansion holds:

$$\mathbf{u}(x) \approx \mathbf{U}(z) + \delta \sum_{p,q=1}^d \partial_q \mathbf{U}(z)_p \hat{\mathbf{v}}_{pq} \left(\frac{x-z}{\delta} \right) \quad \text{for } x \text{ near } z, \quad (80)$$

where $\hat{\mathbf{v}}_{pq}$ is defined by (76).

(ii) Let (V_{ijpq}) be the viscous moment tensor defined by (77). The following outer expansion holds uniformly for $x \in \partial\Omega$:

$$(\mathbf{u} - \mathbf{U})(x) \approx \delta^d \left[\sum_{i,j,p,q,\ell=1}^d \mathbf{e}_\ell \partial_j G_{\ell i}(x,z) \partial_q \mathbf{U}(z)_p V_{ijpq} \right], \quad (81)$$

where V_{ijpq} is given by (77), and the Green function $(G_{il})_{i,l=1}^d$ is defined by (75) with $\kappa^2 = \omega^2/\mu$, μ being the shear modulus of the background medium.

The notion of a viscous moment tensor extends the notion of a polarization tensor to quasi-incompressible elasticity. The viscous moment tensor, V , characterizes all the information about the elastic anomaly that can be learned from the leading-order term of the outer expansion (81). It can be explicitly computed for disks and ellipses in the plane and balls and ellipsoids in three-dimensional space. If B is a two-dimensional disk, then

$$V = 4|B|\mu \frac{(\tilde{\mu} - \mu)}{\tilde{\mu} + \mu} P,$$

where $P = (P_{ijpq})$ is the orthogonal projection from the space of symmetric matrices onto the space of symmetric matrices of trace zero, i.e.,

$$P_{ijpq} = \frac{1}{2} (\delta_{ip}\delta_{jq} + \delta_{iq}\delta_{jp}) - \frac{1}{d}\delta_{ij}\delta_{pq}.$$

If B is an ellipse of the form

$$\frac{x_1^2}{a^2} + \frac{x_2^2}{b^2} = 1, \quad a \geq b > 0, \quad (82)$$

then the viscous moment tensor for B is given by

$$\begin{cases} V_{1111} = V_{2222} = -V_{1122} = -V_{2211} = |B| \frac{2\mu(\tilde{\mu} - \mu)}{\mu + \tilde{\mu} - (\tilde{\mu} - \mu)m^2}, \\ V_{1212} = V_{2112} = V_{1221} = V_{2121} = |B| \frac{2\mu(\tilde{\mu} - \mu)}{\mu + \tilde{\mu} + (\tilde{\mu} - \mu)m^2}, \\ \text{the remaining terms are zero,} \end{cases} \quad (83)$$

where $m = (a - b)/(a + b)$.

If B is a ball in three dimensions, the viscous moment tensor associated with B and an arbitrary $\tilde{\mu}$ is given by

$$\begin{cases} V_{iiii} = \frac{20\mu|B|}{3} \frac{\tilde{\mu} - \mu}{2\tilde{\mu} + 3\mu}, & V_{iijj} = -\frac{10\mu|B|}{3} \frac{\tilde{\mu} - \mu}{2\tilde{\mu} + 3\mu} \quad (i \neq j), \\ V_{ijij} = V_{ijji} = 5\mu|B| \frac{\tilde{\mu} - \mu}{2\tilde{\mu} + 3\mu}, & (i \neq j), \\ \text{the remaining terms are zero.} \end{cases} \quad (84)$$

Theorem 9 (Properties of the viscous moment tensor). *For $0 < \tilde{\mu} \neq \mu < +\infty$, let $V = (V_{ijpq})_{i,p,q=1}^d$ be the viscous moment tensor associated with the bounded domain B in \mathbb{R}^d and the pair of shear modulus $(\tilde{\mu}, \mu)$. Then*

(i) *For $i, j, p, q = 1, \dots, d$,*

$$V_{ijpq} = V_{jipq}, \quad V_{ijpq} = V_{ijqp}, \quad V_{ijpq} = V_{pqij}. \quad (85)$$

(ii) *One has*

$$\sum_p V_{ijpp} = 0 \quad \text{for all } i, j \quad \text{and} \quad \sum_i V_{iipq} = 0 \quad \text{for all } p, q,$$

or equivalently, $V = PVP$.

- (iii) *The tensor V is positive (negative, resp.) definite on the space of symmetric matrices of trace zero if $\tilde{\mu} > \mu$ ($\tilde{\mu} < \mu$, resp.).*
- (iv) *The tensor $(1/(2\mu))V$ satisfies the following bounds:*

$$\text{Tr}\left(\frac{1}{2\mu}V\right) \leq |B|\left(\frac{\tilde{\mu}}{\mu} - 1\right)\left((d-1)\frac{\mu}{\tilde{\mu}} + \frac{d(d-1)}{2}\right), \quad (86)$$

$$\text{Tr}\left(\frac{1}{2\mu}V\right)^{-1} \leq \frac{1}{|B|\left(\frac{\tilde{\mu}}{\mu} - 1\right)}\left((d-1)\frac{\tilde{\mu}}{\mu} + \frac{d(d-1)}{2}\right), \quad (87)$$

where for $C = (C_{ijpq})$, $\text{Tr}(C) := \sum_{i,j=1}^d C_{ijij}$.

Note that the viscous moment tensor, V , is a four tensor and can be regarded, because of its symmetry, as a linear transformation on the space of symmetric matrices. Note also that, in view of Theorem 2, the right-hand sides of (86) and (87) are exactly in the two-dimensional case ($d = 2$) the Hashin–Shtrikman bounds (9) for the polarization tensor associated with the same domain B and the conductivity contrast $k = \tilde{\mu}/\mu$.

Numerical Methods

Let \mathbf{u} be the solution to the modified Stokes system (78). The inverse problem in the magnetic resonance elastography is to reconstruct the shape and the shear modulus of the anomaly D from internal measurements of \mathbf{u} .

Based on the inner asymptotic expansion (80) of $\delta\mathbf{u}$ ($:= \mathbf{u} - \mathbf{U}$) of the perturbations in the displacement field that are due to the presence of the anomaly, a reconstruction method of binary level set type can be designed.

The first step for the reconstruction procedure is to locate the anomaly. This can be done using the outer expansion of $\delta\mathbf{u}$, i.e., an expansion far away from the elastic anomaly.

Suppose that z is reconstructed. Since the representation $D = z + \delta B$ is not unique, one can fix δ . One uses a binary level set representation f of the scaled domain B :

$$f(x) = \begin{cases} 1, & x \in B, \\ -1, & x \in \mathbb{R}^3 \setminus \overline{B}. \end{cases} \quad (88)$$

Let

$$2h(x) = \tilde{\mu} \left(f \left(\frac{x-z}{\delta} \right) + 1 \right) - \mu \left(f \left(\frac{x-z}{\delta} \right) - 1 \right) \quad (89)$$

and let β be a regularization parameter. Then the second step is to fix a window W (containing z) and solve the following constrained minimization problem

$$\begin{aligned} \min_{\tilde{\mu}, f} L(f, \tilde{\mu}) = & \frac{1}{2} \left\| \delta\mathbf{u}(x) - \delta \sum_{p,q=1}^d \partial_q \mathbf{U}(z)_p \hat{\mathbf{v}}_{pq} \left(\frac{x-z}{\delta} \right) + \nabla \mathbf{U}(z)(x-z) \right\|_{L^2(W)}^2 \\ & + \beta \int_W |\nabla h(x)| dx, \end{aligned} \quad (90)$$

subject to (76). Here, $\int_W |\nabla h| dx$ is the total variation of the shear modulus and $|\nabla h|$ is understood as a measure:

$$\int_W |\nabla h| = \sup \left\{ \int_W h \nabla \cdot \mathbf{v} dx, \quad \mathbf{v} \in \mathcal{C}_0^1(W) \text{ and } |\mathbf{v}| \leq 1 \text{ in } W \right\}.$$

This regularization indirectly controls both the length of the level curves and the jumps in the coefficients.

The local character of the method is due to the decay of

$$\delta \sum_{p,q=1}^d \partial_q \mathbf{U}(z)_p \hat{\mathbf{v}}_{pq} \left(\frac{\cdot - z}{\delta} \right) - \nabla \mathbf{U}(z)(\cdot - z)$$

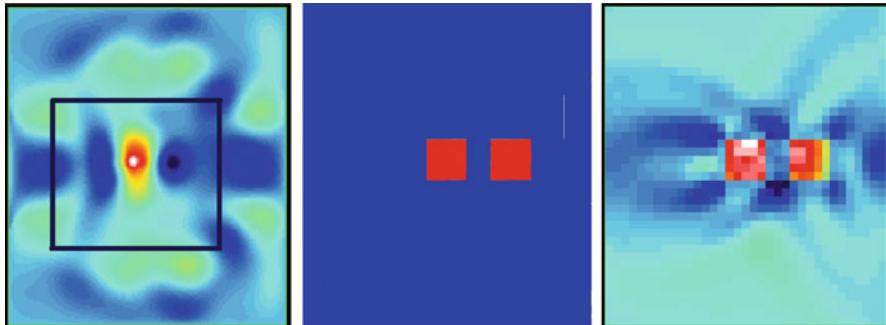

Fig. 9 Reconstruction using the data on the whole domain on the *left*, a zoom on the anomaly in the *middle*, and on the *right* the reconstruction limited on the subregion defined by the boxed region on the *left*

away from z . This is one of the main features of the method. In the presence of noise, because of a trade-off between accuracy and stability, one has to choose carefully the size of W . As it has been shown in [13], the size of W should not be too small in order to preserve some stability and not too big so that one can gain some accuracy. See Fig. 9.

The minimization problem (90) corresponds to a minimization with respect to $\tilde{\mu}$ followed by a step of minimization with respect to f . The minimization steps are over the set of $\tilde{\mu}$ and f and can be performed using a gradient-based method with a line search. Of importance are the optimal bounds satisfied by the viscous moment tensor V . One should check at each step whether the bounds (86) and (87) on V are satisfied or not. In the case where they are not, one has to restate the value of $\tilde{\mu}$. Another way to deal with (86) and (87) is to introduce them into the minimization problem (90) as a constraint. Set $\alpha = \text{Tr}(V)$ and $\beta = \text{Tr}(V^{-1})$ and suppose for simplicity that $\tilde{\mu} > \mu$. Then, (86) and (87) can be rewritten (when $d = 3$) as follows:

$$\begin{cases} \alpha \leq 2(\tilde{\mu} - \mu) \left(3 + \frac{2\mu}{\tilde{\mu}} \right) |D|, \\ \frac{2\mu(\tilde{\mu} - \mu)}{3\mu + 2\tilde{\mu}} |D| \leq \beta^{-1}. \end{cases} \quad (91)$$

Bibliography and Open Questions

Magnetic resonance elastography was first proposed in [81]. The results provided on this technique are from [14]. Theorem 8 and the results on the viscous moment tensor in Theorem 9 are from [15].

In general, the elastic parameters of biological tissues show anisotropic properties, that is, the local value of elasticity is different in the different spatial directions [91] and also viscous properties. It would be very interesting to extend the algorithm described in this section for detecting the shape of an elastic anomaly and the viscosity and the anisotropy in its shear modulus. The study of the dependence of the shear modulus as a function of the frequency is also important [90].

8 Photo-Acoustic Imaging of Small Absorbers

Physical Principles

In photo-acoustic imaging, optical energy absorption causes thermoelastic expansion of the tissue, which in turn leads to propagation of a pressure wave. This signal is measured by transducers distributed on the boundary of the object, which is in turn used for imaging optical properties of the object. The significance of photo-acoustic imaging is to provide images of optical contrasts (based on the optical absorption) with the resolution of ultrasound.

In pure optical imaging, optical scattering in soft tissues degrades spatial resolution significantly with depth. As for electrical impedance tomography, even though pure optical imaging is very sensitive to optical absorption, it can only provide a spatial resolution of the order of 1 cm at centimeter depths. As discussed before, pure conventional ultrasound imaging is based on the detection of the mechanical properties (acoustic impedance) in biological soft tissues. It can provide good spatial resolution because of its millimetric wavelength and weak scattering at megahertz frequencies.

If the medium is acoustically homogeneous and has the same acoustic properties as the free space, then the boundary of the object plays no role and the optical properties of the medium can be extracted from the measurements of the pressure wave by inverting a spherical Radon transform.

In the more realistic situation, where a boundary condition has to be imposed on the pressure field, such an inversion formula does not hold. Using asymptotic analysis, one can develop an efficient approach for reconstructing absorbing regions and absorbing energy density inside a bounded domain from boundary data. One can also reconstruct the optical absorption coefficient. In general, it is not possible to infer physiological parameters from the absorbing energy density. It is the optical absorption coefficient distribution that directly correlates with tissue structural and functional information such as blood oxygenation.

Mathematical Model

Let $D_l, l = 1, \dots, m$, be m absorbing domains inside the nonabsorbing background-bounded medium $\Omega \subset \mathbb{R}^d, d = 2$ or 3 . In an acoustically homogeneous medium, the photo-acoustic effect is described by the following equation:

$$\frac{\partial^2 p}{\partial t^2}(x, t) - c_s^2 \Delta p(x, t) = \gamma \frac{\partial H}{\partial t}(x, t), \quad x \in \Omega, \quad t \in \mathbb{R}, \quad (92)$$

where c_s is the acoustic speed in Ω , γ the dimensionless Grüneisen coefficient in Ω , and $H(x, t)$ a heat source function (absorbed energy per unit time per unit volume).

Assuming the stress-confinement condition, the source term can be modeled as $\gamma H(x, t) = \delta(t)A(x)$, where the absorbed optical energy density times the Grüneisen coefficient $A = \sum_{l=1}^m A_l \chi(D_l)$ and A_l are constants. Under this assumption, the pressure in an acoustically homogeneous medium obeys the following wave equation:

$$\frac{\partial^2 p}{\partial t^2}(x, t) - c_s^2 \Delta p(x, t) = 0, \quad x \in \Omega, \quad t \in]0, T[,$$

for some final observation time T . The pressure satisfies the Dirichlet boundary condition

$$p = 0 \quad \text{on } \partial\Omega \times]0, T[$$

and the initial conditions

$$p|_{t=0} = \sum_{l=1}^m \chi(D_l) A_l \quad \text{and} \quad \left. \frac{\partial p}{\partial t} \right|_{t=0} = 0 \quad \text{in } \Omega.$$

Suppose that T satisfies (66). The inverse problem in photo-acoustic imaging is to determine the supports of nonzero optical absorption ($D_l, l = 1, \dots, m$) in Ω and $A(x)$ from boundary measurements of $\frac{\partial p}{\partial v}$ on $\partial\Omega \times]0, T[$.

Reconstruction Algorithms

Analogously to (71), the following identity holds:

$$\frac{1}{c_s^2} \sum_{l=1}^m A_l \int_D \partial_t w_y(x, 0; \tau) dx = \int_0^T \int_{\partial\Omega} \frac{\partial p}{\partial v}(x, t) w_y(x, t; \tau) d\sigma(x) dt, \quad (93)$$

where the probe function w_y is given by (70).

Determination of Location

Suppose for simplicity that there is only one absorbing object ($m = 1$) which is denoted by $D (= z + \delta B)$. Identity (93) shows that the imaging functional

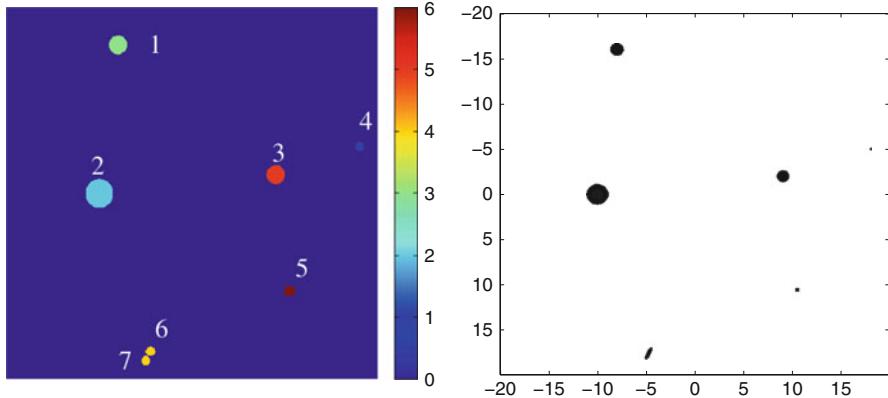

Fig. 10 Real configuration of the medium on the *left* – there are seven optical anomalies of various size and absorption. Reconstructed configuration on the *right* – anomalies 6 and 7 are reconstructed as a single anomaly

$$W(\tau, y) := \int_0^T \int_{\partial\Omega} \frac{\partial p}{\partial v}(x, t) w_y(x, t; \tau) d\sigma(x) dt \quad (94)$$

is nonzero only on the interval $\tau_a, \tau_e]$, where $\tau_a = \text{dist}(y, D)/c_s$ is the first τ for which the sphere of center y and radius τ hits D and τ_e is the last τ for which such sphere hits D . This gives a simple way to detect the location (by changing the source point y and taking intersection of spheres). The functional $W(\tau, y)$ can be used to probe the medium as a function of τ and y . For fixed y , it is a one-dimensional function and is related to time reversal in the sense that it is a convolution with a reversed wave.

A result of numerical simulation to validate the location search algorithm is given in Fig. 10.

Estimation of Absorbing Energy

Consider first the three-dimensional case. If D is a sphere with $A(x) = A\chi(D)$, then one has

$$\delta^2 A \approx c_s |z - y| \int_{\tau_a}^{\tau_e} \left| \int_0^T \int_{\partial\Omega} \frac{\partial p}{\partial v}(x, t) w_y(x, t; \tau) d\sigma(x) dt \right| d\tau, \quad (95)$$

which gives an approximation of $\delta^2 A$.

In two dimensions, one should rather consider the probe wave given by

$$w_\theta(x, t; \tau) = \delta \left(t + \tau - \frac{\langle x, \theta \rangle}{c} \right), \quad (96)$$

where θ is a unit vector and τ is a parameter satisfying

$$\tau > \max_{x \in \Omega} \left(\frac{\langle x, \theta \rangle}{c} \right).$$

One can still use the function

$$\tau \mapsto \int_0^T \int_{\partial\Omega} \frac{\partial p}{\partial \nu}(x, t) w_\theta(x, t; \tau) d\sigma(x) dt$$

to probe the medium as a function of τ . This quantity is nonzero on the interval $\left] \tau_a, \tau_e \right[$, where τ_a and τ_e are defined such that planes $\langle x, \theta \rangle = c\tau$ for $\tau = \tau_a$ and τ_e hit D . Changing the direction θ and intersecting stripes gives an efficient way to reconstruct the anomalies.

By exactly the same arguments as in three dimensions, one can show that

$$\delta A \approx \frac{c_s}{4} \int_{\tau_a}^{\tau_e} \left| \int_0^T \int_{\partial\Omega} \frac{\partial p}{\partial \nu}(x, t) w_\theta(x, t; \tau) d\sigma(x) dt \right| d\tau. \quad (97)$$

The above formula can be used to estimate δA .

In the case when there are m inclusions, one first computes for each l the quantity

$$\theta_{l,\text{best}} = \operatorname{argmax}_{\theta \in [0, \pi]} \left(\min_{j \neq l} |\langle z_j - z_l, \theta \rangle| \right)$$

and then, since along the direction $\theta_{l,\text{best}}$, the inclusion D_l is well separated from all the other inclusions, one can use formula (97) to estimate its δA_l .

Reconstruction of the Absorption Coefficient

The density $A(x)$ is related to the optical absorption coefficient distribution $\mu_a(x) = \mu_a \chi(D)$ by the equation $A(x) = \mu_a(x) \Phi(x)$, where Φ is the fluence rate. The function Φ depends on the distribution of scattering and absorption within Ω , as well as the light sources. Based on the diffusion approximation to the transport equation, Φ satisfies

$$\left(\frac{i\omega}{c} + \mu_a(x) - \frac{1}{3} \nabla \cdot \frac{1}{\mu_a(x) + \mu_s(x)} \nabla \right) \Phi(x) = 0 \quad \text{in } \Omega, \quad (98)$$

with the boundary condition

$$\frac{1}{\mu_s} \frac{\partial \Phi}{\partial \nu} = g \quad \text{on } \partial\Omega. \quad (99)$$

Here, g denotes the light source, ω a given frequency, c the speed of light, and μ_s the scattering coefficient. The diffusion approximation holds when $\mu_s \gg \mu_a$.

Suppose that $d = 3$ and μ_s is known a priori. Define Φ_0 by

$$\left(\frac{i\omega}{c} - \frac{1}{3} \nabla \cdot \frac{1}{\mu_s(x)} \nabla \right) \Phi_0(x) = 0 \quad \text{in } \Omega,$$

subject to the boundary condition

$$\frac{1}{\mu_s} \frac{\partial \Phi_0}{\partial \nu} = g \quad \text{on } \partial\Omega.$$

Introduce \hat{N}_B to be the Newton potential given by

$$\hat{N}_B(\xi) := \int_B \Gamma(\xi - y) dy,$$

where $\Gamma := -1/(4\pi|x|)$ is a fundamental solution of the Laplacian in three dimensions.

Let $\alpha := \delta^2 \mu_a \Phi(z) = \delta^2 A$. As shown before, α can be reconstructed from $\frac{\partial p}{\partial \nu}$. To extract $\delta^2 \mu_a$ from α , one uses the following theorem:

Theorem 10 (Fluence rate perturbations). *If B is the unit sphere, then the following expansion holds:*

$$(\Phi - \Phi_0)(z) \approx 3\alpha \mu_s(z) \hat{N}_B(0), \quad (100)$$

from which it follows that the (normalized) absorption coefficient can be approximated by

$$\delta^2 \mu_a \approx \frac{\alpha}{3\alpha \mu_s(z) \hat{N}_B(0) + \Phi_0(z)}. \quad (101)$$

Separating δ from μ_a requires boundary measurements of Φ on $\partial\Omega$. One can use

$$\int_{\partial\Omega} g(\Phi - \Phi_0) d\sigma \approx \mu_a \Phi_0^2(z) |D| \quad (102)$$

to separately recover δ from μ_a .

In the case where μ_s is unknown, an algorithm to extract the absorption coefficient μ_a from absorbed energies obtained at multiple wavelengths was developed in [10]. It assumes that the wavelength dependence of the scattering and absorption coefficients are known. In biological tissues, the wavelength dependence of the scattering often approximates to a power law.

Bibliography and Open Questions

Basic physical principles of the photo-acoustic effect have been described, for instance, in [49, 98]. The results of this section are from [9, 10]. The location search algorithm described in this section can be extended to the case with limited-view measurements. The half-space problem has been considered [96]. In free space, one refers to [1, 2, 4, 55, 56, 70, 84] for uniqueness of the reconstruction and inversion procedures based on the spherical Radon transform. Reconstruction methods with incomplete data have been developed in [97]. Sensitivity analysis of a photo-acoustic wave to the presence of small absorbing objects has been provided in [49].

In connection with photo-acoustic imaging, it is worth mentioning the multi-physics imaging technique proposed in [52], which combines electrical impedance tomography with acoustic tomography. This method makes use of the fact that the absorbed electrical energy causes thermoelastic expansion of the tissue, which leads to propagation of a pressure wave. With the notation of Sect. 5, the induced signal is measured on the boundary of the object and can be used for calculating the absorbed electrical energy, $\mathcal{E} = \gamma |\nabla u|^2$, inside the body, from which the electrical conductivity γ can be reconstructed using, for instance, the substitution algorithm.

As for magneto-acoustic imaging with magnetic induction, it would be very interesting to design a robust inversion algorithm when the acoustic speed fluctuates randomly.

9 Conclusion

In this chapter, applications of asymptotic analysis in emerging medical imaging are outlined. This method leads to very effective and robust reconstruction algorithms in many imaging problems. Of particular interest are emerging multi-physics or hybrid-imaging approaches. These approaches allow one to overcome the severe ill-posedness character of image reconstruction. It would be very interesting to analytically investigate their robustness, with respect to incomplete data, measurement, and medium noises. Another important problem is to take into account the effect of anisotropy, dissipation, or attenuation in biological tissues.

Abstract

The topic of this chapter is devoted to *shape identification problems*, i.e., problems where the shape of an object has to be determined from indirect measurements. In contrast to iterative methods where a sequence of forward problems has to be computed the *sampling methods* avoid the (usually expansive) computation of the forward problems. Instead, a class of test objects (e.g., points) are chosen and a binary criterium is constructed which depends on the measured data only, and which decides whether this test object is inside or outside of the searched for domain. In this chapter, the *factorization method* is explained for the impedance tomography problem with insulating or conducting inclusions, for scattering theory for time harmonic acoustic plane waves in the presence of a perfectly sound–soft obstacle, and for electromagnetic scattering by an inhomogeneous conducting medium. Brief descriptions of related sampling methods, such as the *linear sampling method*, *MUSIC*, the *singular sources method*, and the *probe method* complement this chapter.

1 Introduction

The topic of this chapter is devoted to *shape identification problems*, i.e., problems where the shape of an object has to be determined from indirect measurements. Such a situation typically occurs in problems of *tomography*, in particular electrical impedance tomography or optical tomography. For example, a current through a homogeneous object will in general induce a different potential than the same current through the same object containing an enclosed cavity. In impedance tomography, the task is to determine the shape of the cavity from measurements of the potential on the boundary of the object. For survey articles on this subject, we refer to [18, 54], and chapter ▶ [Electrical Impedance Tomography](#) in this volume.

As a second of these fields, we mention *inverse scattering problems* where one wants to detect – and identify – unknown objects through the use of acoustic, electromagnetic, or elastic waves. Similar to the above, one of the important problems in inverse scattering theory is to determine the shape of the scattering obstacle from field measurements. Applications of inverse scattering problems occur in such diverse areas as medical imaging, material science, nondestructive testing, radar, remote sensing, or seismic exploration. A survey on the state of the art of the mathematical theory and numerical approaches for solving inverse time-harmonic scattering problems until 1998 can be found in the standard monograph [36] (see also chapter ▶ [Inverse Scattering](#) or [83] for an introduction and survey on inverse scattering problems).

Shape identification problems are intrinsically *nonlinear*, i.e., the measured quantities do not depend linearly on the shape. Even the notion of linearity does not make sense since, in general, the set of admissible shapes does not carry a linear structure. Traditional (and still very successful) approaches describe the objects by appropriate parameterizations and compute the parameters by *iterative schemes* as, e.g., Newton-type methods. Newton-type methods are attractive because of their

fast convergence, although they require a good initial guess to converge. Still, these methods are widely used – partly because techniques from shape optimization theory can be used to characterize the required first- or second-order derivatives. We refer to [84, 89] for general references and to [57, 58, 65] for applications in inverse scattering theory.

While classical iterative algorithms use explicit parameterizations of the object, new shape optimization methods have been developed since around 1995 which completely avoid the use of parameterizations and replace the classical Fréchet derivative by a geometrically motivated *topological derivative*, see, e.g., [50] for the application of these methods in the inverse scattering context. Yet these methods have the shortcoming that they are not able to change the number of connectivity components during the algorithm. This has led to the development of *level set methods* which are based on implicit representations of the unknown object involving an “evolution parameter” t . We refer to [25] or chapter ▶ [Level Set Methods for Structural Inversion and Image Reconstruction](#) for recent surveys.

While very successful in many cases, iterative methods for shape identification problems – may they use classical tools as the Fréchet derivative or more recent techniques such as domain derivatives, level curves, or topological derivatives – are computationally very expensive since they require the solution of a direct problem in every step. Furthermore, for many important cases, the convergence theory is still missing. This is due to the fact that these problems are not only nonlinear but also because their linearizations are *improperly posed*. Although there exist many results on the convergence of (regularized) iterative methods for solving nonlinear improperly posed problems (see, e.g., [39, 64] or chapter ▶ [Iterative Solution Methods](#)), the assumptions for convergence are not met in the applications to shape identification problems. (Or, at least, it is unknown whether these assumptions are fulfilled or not.)

These difficulties and disadvantages of iterative schemes gave rise to the development of different classes of *non-iterative* methods which avoid the solution of a sequence of direct problems. We briefly mention *decomposition methods* (according to the notion of [37]) which consist of an analytic continuation step (which is linear but highly improperly posed) and a nonlinear step of finding the boundary of the unknown domain by forcing the boundary condition to hold. We refer to section “[Decomposition Methods](#)” in chapter ▶ [Inverse Scattering](#).

This chapter will focus on a different class of non-iterative methods, the so-called *sampling methods*. The common idea of these methods is the construction of criteria on the known data to decide whether a given test object (a point or a curve or a set) is inside or outside the unknown domain D . Then, a grid of “sampling” points is chosen in a region that is known to contain the unknown domain D , in order to compute the (approximate) characteristic function of D . The different kinds of sampling methods differ in the way of defining the criteria and in the type of test objects.

One of the first methods which falls into this class has been developed by David Colton and one of the authors (A. K.) in 1996 [35], now known as the *linear sampling method*. Its origin goes back to the *dual space method* developed

between 1985 and 1990 (see, e.g., [36]). The numerical implementation of the linear sampling method is extremely simple and fast because sampling is done by points z only. For every sampling point z , one has to compute the field of a point source in z with respect to the background medium (essentially, one has to compute the fundamental solution of the underlying differential operator; if the background is constant, the response is given analytically) and evaluate a series, i.e., a finite sum in practice.

A problem with the linear sampling method from the mathematical point of view is that the computable criterion is only a sufficient condition which is, in general, not necessary. The *factorization method* overcomes this drawback and yields a criterion for z which is both necessary and sufficient. Therefore, this method succeeds to provide a simple formula for the characteristic function of D which can easily be used for numerical computations.

The factorization method consists of three components. First, a “measurement operator” M is factorized in three factors of the form

$$M = AGA^*, \quad (1)$$

where A^* is the dual operator of A with respect to the L^2 topology. Second, the range of A is characterized by the obstacle D , and vice versa. Third, if the operator G satisfies a certain coercivity condition, then the range of A can be determined by the given operator M . This requires some functional analytic results on range identities which we have collected in an appendix.

Combining these three steps yields an explicit characterization of the unknown obstacle D by the measurement operator M .

The outline of this chapter is as follows. First, in Sect. 2, we present the factorization method for two different settings in the impedance tomography context. In the very first setting, we deal with insulating inclusions, and this allows for a very elementary presentation of the method. Afterwards, in Sect. 3, we turn to applications from inverse acoustic and (full 3D) electromagnetic scattering. Finally, we give a brief overview of other sampling type methods in Sect. 4, including the original linear sampling method and MUSIC-type methods.

2 The Factorization Method in Impedance Tomography

We start with the impedance tomography problem. Consider an object that fills a simply connected domain $\Omega \subset \mathbb{R}^n$ with Lipschitz continuous boundary, where $n = 2$ or $n = 3$, respectively. We assume that the object is a homogeneous and isotropic conductor, except for a finite number m of so-called inclusions, given by domains $D_i \subset \Omega$, $i = 1, \dots, m$, with Lipschitz continuous boundaries ∂D_i . We assume that these domains are well separated, i.e., $\overline{D}_i \cap \overline{D}_j = \emptyset$ when $i \neq j$, and that the complement of the closure \overline{D} of $D = \cup_{i=1}^m D_i$ is connected. In impedance tomography, currents are imposed through the boundary of the object,

and the resulting boundary potentials are measured. Linear independent boundary currents yield independent pieces of information, which can be used as input data to determine the unknown shapes and positions of the inclusions.

In practice, at least in most medical applications, the boundary currents have a frequency in the kHz range (5–500 kHz), and the dc approximation with a positive real conductivity σ (or possibly a positive definite tensor) serves as a suitable physical model. Without loss of generality, we can always assume that the homogeneous conductivity of the object equals $\sigma = 1$, whereas $\sigma \neq 1$ within the inclusions.

Below we will consider two specific scenarios. In the first one, we assume that the inclusions are insulating, formally corresponding to the case where $\sigma = 0$. Our analysis of the factorization method for the corresponding inverse problem will be somewhat nonstandard; in particular, we employ a factorization in only two factors instead of three as in (1), but this allows for a most elementary treatment of the method.

Subsequently, we show how to deal with conducting obstacles with a conductivity tensor σ . Of particular interest is the setting where the object under consideration can be modeled as a half space; examples of this sort arise in geophysics, cf. [78], and in medicine, e.g., when a planar device is used for mammography examinations, cf. [92]. Another interesting application for the half-space problem has recently been considered in [17]. We therefore briefly describe the differences that arise in this context (mainly in the theoretical justification of the method).

We conclude our case studies with a setting where the inclusion degenerates to a crack, i.e., an $n - 1$ dimensional smooth manifold within Ω . This application requires some care in the appropriate implementation of the factorization method.

Impedance Tomography in the Presence of Insulating Inclusions

To begin with, we take up the case where Ω is a bounded domain, and the domains $D_i \subset \Omega$, $i = 1, \dots, m$ correspond to insulating inclusions. Within the dc model, the potential u_0 induced by a boundary current f is given by

$$\begin{aligned} \Delta u_0 &= 0 \quad \text{in } \Omega \setminus \overline{D}, \quad \frac{\partial}{\partial \nu} u_0 = 0 \quad \text{on } \partial D, \\ \frac{\partial}{\partial \nu} u_0 &= f \quad \text{on } \partial \Omega, \quad \int_{\partial \Omega} u_0 \, ds = 0, \end{aligned} \tag{2}$$

where the normal vectors ν on $\partial \Omega$ and ∂D are pointing into the exterior of Ω and D , respectively. In order to make the forward problem (2) well posed, we restrict f to be square integrable with vanishing mean on $\partial \Omega$. The corresponding set of admissible boundary currents is

$$L^2_{\diamond}(\partial \Omega) = \left\{ f \in L^2(\partial \Omega) : \int_{\partial \Omega} f \, ds = 0 \right\}. \tag{3}$$

Under these assumptions, problem (2) has a unique (weak) solution

$$u_0 \in H_{\diamond}^1(\Omega \setminus \overline{D}) = \left\{ u \in H^1(\Omega \setminus \overline{D}) : \int_{\partial\Omega} u \, ds = 0 \right\}.$$

The last condition in (2) normalizes this boundary potential to have vanishing mean; without this condition, the solution would only be unique up to additive constants, reflecting the fact that only the voltage, i.e., the difference between the potential at two different points, is a well-defined physical quantity.

Therefore, the **direct problem** is to determine the field u_0 when f and D are given.

The quantity that is measured in impedance tomography is the trace $g_0 = u_0|_{\partial\Omega}$, i.e., the boundary potential. The corresponding measurement operator

$$\Lambda_0 : \begin{cases} L_{\diamond}^2(\partial\Omega) \rightarrow L_{\diamond}^2(\partial\Omega), \\ f \mapsto g_0 = u_0|_{\partial\Omega}, \end{cases} \quad (4)$$

i.e., the so-called *Neumann-Dirichlet operator*, is usually referred to as *absolute data* in impedance tomography.

The **inverse problem** is to determine the shape of D from the measurement operator Λ_0 .

For the factorization method, we employ *relative data*, that is, the difference between the above Neumann-Dirichlet operator and the corresponding one for a completely homogeneous object in Ω . To be precise, let u_1 be the reference solution for the homogeneous object, given the same boundary current $f \in L_{\diamond}^2(\partial\Omega)$,

$$\Delta u_1 = 0 \quad \text{in } \Omega, \quad \frac{\partial}{\partial\nu} u_1 = f \quad \text{on } \partial\Omega, \quad \int_{\partial\Omega} u_1 \, ds = 0, \quad (5)$$

and denote by $\Lambda_1 : f \mapsto g_1 = u_1|_{\partial\Omega}$ the Neumann-Dirichlet map associated with (5). It is the relative data $M = \Lambda_0 - \Lambda_1$ that later enters in (1) to lay the grounds for the setting of the factorization method.

We refer to chapter ▶ [Electrical Impedance Tomography](#) for a more elaborate treatment of the impedance tomography problem, but we will see below that $\Lambda_0 - \Lambda_1$ is a bounded and positive self-adjoint operator. We also do not discuss practical issues such as electrode models that should be incorporated into a realistic problem setting. For the same reason, we do not comment on how to obtain relative data in practice; the generation of accurate reference data is indeed a difficult subject, and some work-arounds have therefore been suggested for this purpose. (We like to highlight one recent approach from [56], where different frequencies are used in the experimental setup to obtain relative data. This approach, however, leads to a different variant of the factorization method than the one that is described here.) Our specification of the impedance tomography problem is thus a purely mathematical one, although it can be shown to be a pretty reasonable approximation of the real case, cf., e.g., [60, 77].

Before we continue, we pause to comment on the nature of the relative data introduced above. Any function h in the range $\mathcal{R}(\Lambda_0 - \Lambda_1)$ of $\Lambda_0 - \Lambda_1$ corresponds to a suitable input current $f \in L^2_{\diamond}(\partial\Omega)$, such that h is the trace of $w = u_0 - u_1 : \Omega \setminus \overline{D} \rightarrow \mathbb{R}$, where u_0 and u_1 are the solutions of (2) and (5), respectively. As u_0 and u_1 are both harmonic in $\Omega \setminus \overline{D}$, the same holds true for w ; on top of that, like u_0 and u_1 , w has finite H^1 norm on $\Omega \setminus \overline{D}$, as well as vanishing mean on $\partial\Omega$. Moreover, w has homogeneous Neumann boundary conditions on $\partial\Omega$, as u_0 and u_1 both satisfy the same Neumann boundary condition. And finally, on ∂D_i , $i = 1, \dots, m$, we have

$$\int_{\partial D_i} \frac{\partial}{\partial \nu} w \, ds = - \int_{\partial D_i} \frac{\partial}{\partial \nu} u_1 \, ds = 0$$

by virtue of Green's formula. Accordingly, the range of $\Lambda_0 - \Lambda_1$ consists of traces of potentials w from

$$\begin{aligned} \mathcal{W} = \left\{ w \in H_{\diamond}^1(\Omega \setminus \overline{D}) : \Delta w = 0, \frac{\partial}{\partial \nu} w = 0 \text{ on } \partial\Omega, \right. \\ \left. \int_{\partial D_i} \frac{\partial}{\partial \nu} w \, ds = 0, i = 1, \dots, m \right\}. \end{aligned} \quad (6)$$

It is well known that harmonic functions have infinite smoothness. Moreover, as the elements of \mathcal{W} have a vanishing Neumann derivative on $\partial\Omega$, the “variation” of w on $\partial\Omega$ can only be caused by their behavior near the boundary of D – unless the boundary of Ω is non-smooth. In other words, the (local) variation of the trace of some function $w \in \mathcal{W}$ is an indicator for the (local) width of the domain $\Omega \setminus \overline{D}$. In fact, as we will show next, it is possible to characterize D completely, if the set of all traces of \mathcal{W} on $\partial\Omega$ were known. (For one insulating inclusion, it is even known that the trace of one single potential $w \in \mathcal{W}$ is enough to identify D , cf., e.g., [16]. For conducting obstacles, with known conductivity, the corresponding uniqueness problem is still open.)

To this end, we introduce the Neumann function $N(\cdot, z)$ associated with the Laplacian in the domain Ω , which is given as the (distributional) solution of the problem

$$\begin{aligned} -\Delta N(x, z) &= \delta(x - z) \quad \text{in } \Omega, & \frac{\partial}{\partial \nu} N(x, z) &= -\frac{1}{|\partial\Omega|} \quad \text{on } \partial\Omega, \\ \int_{\partial\Omega} N(x, z) \, ds(x) &= 0, \end{aligned} \quad (7)$$

where $z \in \Omega$ is kept fixed, and the differential operators act on the x -variable only. To achieve a unique solution, we have normalized $N(\cdot, z)$ to have vanishing mean on $\partial\Omega$. The directional derivative

$$U_z(x) = p \cdot \operatorname{grad}_z N(x, z) \quad (8)$$

with respect to z of N in direction p (of unit length) yields the potential of a dipole source in z with moment p in the presence of an insulated boundary $\partial\Omega$: We refer to U_z as the dipole potential, tacitly assuming the dipole moment to be fixed. (All subsequent results hold true for an arbitrary choice of $p \in \mathbb{R}^n$ with $|p| = 1$, and it appears that there is still space to improve the numerical performance of the method, especially in three-space dimensions, provided that this property is exploited in an optimal way.) We remark that U_z behaves like

$$U_z(x) \sim \begin{cases} \frac{1}{2\pi} \frac{(x-z) \cdot p}{|x-z|^2}, & n = 2, \\ \frac{1}{4\pi} \frac{(x-z) \cdot p}{|x-z|^3}, & n = 3, \end{cases} \quad \text{as } x \rightarrow z, \quad (9)$$

and, in fact, U_z agrees with the right-hand side of (9) up to a harmonic function. This statement holds true for every fixed $z \in \Omega$.

Now we are ready to formulate the characterization of the inclusion D as it has been established by Brühl in his dissertation [21] (see also [22]) and which constitutes the basis for the factorization method.

Theorem 1. *A point $z \in \Omega$ belongs to D , if and only if the trace $\phi_z = U_z|_{\partial\Omega}$ coincides with the trace of some potential $w \in \mathcal{W}$.*

Proof. First, let $z \in D$. Then the dipole potential U_z is harmonic in $\Omega \setminus \{z\}$, i.e., in $\Omega \setminus \overline{D}$ and in a neighborhood of ∂D . Accordingly U_z belongs to $H_{\Delta}^1(\Omega \setminus \overline{D})$. As $N(x, z)$ has the same Neumann boundary data for any $z \in \mathbb{R}^n$, its directional derivative with respect to z has vanishing Neumann data on $\partial\Omega$. Moreover, according to Green's formula,

$$\int_{\partial D_i} \frac{\partial}{\partial \nu} U_z \, ds = 0 \quad (10)$$

for every component D_i of D which does not contain z ; however, as the total flux of U_z across $\partial(\Omega \setminus \overline{D})$ vanishes as well, (10) must also hold true for that component D_i of D which does contain z . Therefore, $U_z \in \mathcal{W}$, and its trace belongs to the corresponding trace space.

Now, let $z \notin \overline{D}$, and assume that the trace ϕ_z of the dipole potential U_z is the trace of a potential $w \in \mathcal{W}$. As we have seen in the first part of this proof, U_z and w thus have the same Cauchy data on $\partial\Omega$, and it follows from the uniqueness of solutions of the Cauchy problem for the Poisson equation that U_z and w coincide in $\Omega \setminus (\overline{D} \cup \{z\})$, where both are harmonic. (It is here where the assumption on the connectedness of $\Omega \setminus \overline{D}$ is needed.) Now, w extends as a harmonic function into the point z and, hence, is bounded near z , whereas U_z is not, cf. (9). This provides the desired contradiction.

In the last case, where z sits on the boundary of D , we can use the same argument as before to show that w and U_z coincide in $\Omega \setminus \overline{D}$. According to (6), U_z must

therefore have a finite H^1 -norm on $\Omega \setminus \overline{D}$, which contradicts the asymptotic behavior (9) near $z \in \partial D$. (This argument requires the Lipschitz continuity of ∂D , because this assumption makes sure that we can find an open-cone $\mathcal{C} \subset \Omega \setminus \overline{D}$ with vertex in z and, hence, that the integral $\int_{\mathcal{C}} |\operatorname{grad} U_z|^2 dx$ is unbounded.) ■

It turns out that the potentials $w = u_0 - u_1$, which provide the given relative data, have additional features that are not captured by the description of the set \mathcal{W} of (6). For example, if the boundaries of the domains D_i are smooth, then the potential u_0 of (2) can be extended by reflection to a certain subset of D , showing that w has a harmonic extension to a larger domain than just $\Omega \setminus \overline{D}$ (see [54]; Appendix). Therefore, the space spanned by the relative data is *smaller* than the trace space of \mathcal{W} in general. Still, there is a means to deduce this trace space from the given relative data – and the appropriate tool is the factorization method.

At this point we deviate from the usual presentation of the factorization method to opt for a more elementary derivation of the main results. Instead of the usual factorization of the data map in three factors as in (1), we follow the approach in [23] and factor the relative data in only two parts, namely,

$$\Lambda_0 - \Lambda_1 = K^* K, \quad (11)$$

where K^* is an appropriate adjoint of the operator K given by

$$K : f \mapsto \begin{cases} u_0 - u_1 & \text{in } \Omega \setminus \overline{D}, \\ c_i - u_1 & \text{in } \overline{D}_i, i = 1, \dots, m, \end{cases} \quad (12)$$

and the real numbers c_i in (12) are the means of the potential u_0 at the boundaries of the insulating inclusions, i.e.,

$$c_i = \frac{1}{|\partial D_i|} \int_{\partial D_i} u_0 ds, \quad i = 1, \dots, m. \quad (13)$$

We claim (see Theorem 2 below for a proof) that K is a continuous operator from $L^2_{\diamond}(\partial\Omega)$ to \mathcal{X} , where

$$\begin{aligned} \mathcal{X} = \{v : \Omega \rightarrow \mathbb{R} : v|_{\Omega \setminus \overline{D}} \in H^1_{\diamond}(\Omega \setminus \overline{D}), v|_D \in H^1(D), \\ \int_{\partial D_i} [v] ds = 0, i = 1, \dots, m\}. \end{aligned} \quad (14)$$

In this definition, again, the subscript \diamond indicates that any $v \in \mathcal{X}$ is required to have vanishing mean on $\partial\Omega$, and

$$[v] = v^+|_{\partial D} - v^-|_{\partial D}$$

denotes the jump of v across the boundary of the inclusion(s), defined in the appropriate trace spaces. Here and below we denote by v^+ and v^- the restriction

of a generic element $v \in \mathcal{X}$ to $\Omega \setminus \overline{D}$ and D , respectively. We equip \mathcal{X} with the inner product

$$\begin{aligned} (v, w)_{\mathcal{X}} &= \int_{\Omega \setminus \partial D} \operatorname{grad} v \cdot \operatorname{grad} w \, dx \\ &= \int_D \operatorname{grad} v^- \cdot \operatorname{grad} w^- \, dx + \int_{\Omega \setminus \overline{D}} \operatorname{grad} v^+ \cdot \operatorname{grad} w^+ \, dx, \end{aligned} \quad (15)$$

which turns \mathcal{X} into a Hilbert space. Take note that $H_{\diamond}^1(\Omega)$, i.e., the set of all functions from $H^1(\Omega)$ with vanishing mean on $\partial\Omega$, is a subset of \mathcal{X} .

Lemma 1. *Let $\mathcal{K} \subset \mathcal{X}$ be the set of all elements $w \in \mathcal{X}$ that are harmonic in $\Omega \setminus \partial D$ and satisfy*

$$\frac{\partial}{\partial \nu} w = 0 \text{ on } \partial\Omega \quad \text{and} \quad \left[\frac{\partial}{\partial \nu} w \right] = 0 \text{ on } \partial D.$$

Then \mathcal{K} is the orthogonal complement of $H_{\diamond}^1(\Omega)$ in \mathcal{X} .

Proof. Using Green's formula for any $v \in H_{\diamond}^1(\Omega)$ and any $w \in \mathcal{X}$ that is harmonic in $\Omega \setminus \partial D$, we obtain

$$\begin{aligned} \int_{\Omega \setminus \partial D} \operatorname{grad} v \cdot \operatorname{grad} w \, dx &= \int_{\partial\Omega} v \frac{\partial w}{\partial \nu} \, ds - \int_{\partial D} v \frac{\partial w^+}{\partial \nu} \, ds + \int_{\partial D} v \frac{\partial w^-}{\partial \nu} \, ds \\ &= \int_{\partial\Omega} v \frac{\partial w}{\partial \nu} \, ds - \int_{\partial D} v \left[\frac{\partial w}{\partial \nu} \right] \, ds, \end{aligned} \quad (16)$$

as v has a well-defined unique trace on ∂D . Now, if we choose $w \in \mathcal{K}$, then both integrals vanish, and hence $w \perp v$ with respect to the scalar product in \mathcal{X} .

Vice versa, pick $w \in \mathcal{X}$ from the orthogonal complement of $H_{\diamond}^1(\Omega)$, and let v be a C^∞ function with compact support in $\Omega \setminus \overline{D}$, then Green's formula yields

$$\begin{aligned} \int_{\Omega \setminus \overline{D}} w \Delta v \, dx &= \int_{\partial\Omega} w \frac{\partial v}{\partial \nu} \, ds - \int_{\partial D} w \frac{\partial v}{\partial \nu} \, ds - \int_{\Omega \setminus \overline{D}} \operatorname{grad} w \cdot \operatorname{grad} v \, dx \\ &= \int_{\partial\Omega} w \frac{\partial v}{\partial \nu} \, ds - \int_{\partial D} w \frac{\partial v}{\partial \nu} \, ds - \int_{\Omega \setminus \partial D} \operatorname{grad} w \cdot \operatorname{grad} v \, dx, \end{aligned}$$

and all three integrals in the bottom line are zero by construction. Thus, w is harmonic in $\Omega \setminus \overline{D}$ according to Weyl's Lemma. The same kind of argument also shows that w is harmonic in D . Accordingly, as above, (16) holds true for any $v \in H_{\diamond}^1(\Omega)$, where now the left-hand side of (16) is zero because of the orthogonality. A standard variational argument then shows that the normal derivative of w on $\partial\Omega$ and the flux of w across ∂D must vanish. ■

We briefly mention that every potential w from \mathcal{W} of (6) has a unique continuation to a potential $w \in \mathcal{K}$, and the restriction of a nontrivial element from \mathcal{K} to $\Omega \setminus \overline{D}$ is a nonzero element from \mathcal{W} . Accordingly, the set of traces on $\partial\Omega$ of potentials from \mathcal{W} and \mathcal{K} , respectively, are the same.

Theorem 2. *The operator $K : L^2_{\diamond}(\partial\Omega) \rightarrow \mathcal{X}$ defined in (12) is bounded, injective, and its range lies dense in the subset \mathcal{K} introduced in Lemma 1. The adjoint operator $K^* : \mathcal{X} \rightarrow L^2_{\diamond}(\partial\Omega)$ satisfies*

$$K^*v = \begin{cases} v|_{\partial\Omega}, & v \in \mathcal{K}, \\ 0, & v \in H^1_{\diamond}(\Omega). \end{cases}$$

In particular, there holds $K^*K = \Lambda_0 - \Lambda_1$, i.e., (11).

Proof. We recall that the two Neumann problems (2) and (5) have well-defined unique solutions u_0 and u_1 in the space $H^1_{\diamond}(\Omega \setminus \overline{D})$ and $H^1_{\diamond}(\Omega)$, respectively, which are given by the corresponding weak formulations

$$\begin{aligned} \int_{\Omega \setminus \overline{D}} \operatorname{grad} u_0 \cdot \operatorname{grad} v_0 dx &= \int_{\partial\Omega} f v_0 ds \quad \text{for every } v_0 \in H^1_{\diamond}(\Omega \setminus \overline{D}), \\ \int_{\Omega} \operatorname{grad} u_1 \cdot \operatorname{grad} v dx &= \int_{\partial\Omega} f v ds \quad \text{for every } v \in H^1_{\diamond}(\Omega). \end{aligned} \tag{17}$$

Moreover, the two solutions depend continuously (in H^1) on the given boundary data $f \in L^2_{\diamond}(\partial\Omega)$. Accordingly, $w = Kf$ is a well-defined element of \mathcal{X} and K a bounded linear operator from $L^2_{\diamond}(\partial\Omega)$ to \mathcal{X} . The jump condition $\int_{\partial D_i} [w] ds = 0$ is a consequence of the definition (13) of c_i and the uniqueness of the trace of u_1 on ∂D .

Now, choose any $f \in L^2_{\diamond}(\partial\Omega)$, and denote by u_0 and u_1 the corresponding solutions of (2) and (5). As in the definition of Kf , we can extend u_0 to a function

$$\hat{u}_0 = \begin{cases} u_0 & \text{in } \Omega \setminus \overline{D}, \\ c_i & \text{in } \overline{D}_i, i = 1, \dots, m, \end{cases}$$

in \mathcal{X} , such that $Kf = \hat{u}_0 - u_1$. First, for $v \in H^1_{\diamond}(\Omega)$, we have

$$\begin{aligned} (Kf, v)_{\mathcal{X}} &= (\hat{u}_0, v)_{\mathcal{X}} - (u_1, v)_{\mathcal{X}} \\ &= \int_{\Omega \setminus \overline{D}} \operatorname{grad} u_0 \cdot \operatorname{grad} v dx - \int_{\Omega} \operatorname{grad} u_1 \cdot \operatorname{grad} v dx = 0 \end{aligned}$$

by virtue of (17), and, hence, $\mathcal{R}(K) \perp H_{\diamond}^1(\Omega)$. It thus follows from Lemma 1 that $\mathcal{R}(K) \subset \mathcal{K}$ and $\mathcal{N}(K^*) = \overline{\mathcal{R}(K)}^\perp \supset H_{\diamond}^1(\Omega)$ and, in particular, that $K^*v = 0$ for every $v \in H_{\diamond}^1(\Omega)$.

Second, for $v \in \mathcal{K}$, we compute

$$(Kf, v)_{\mathcal{X}} = (\hat{u}_0, v)_{\mathcal{X}} - (u_{\mathbb{1}}, v)_{\mathcal{X}} = (\hat{u}_0, v)_{\mathcal{X}},$$

since $u_{\mathbb{1}}$ and v are orthogonal to each other according to Lemma 1. Together with (17) thus follows that

$$(Kf, v)_{\mathcal{X}} = \int_{\Omega \setminus \overline{D}} \operatorname{grad} u_0 \cdot \operatorname{grad} v \, dx = \int_{\partial\Omega} f v \, ds = (f, v)_{L^2(\partial\Omega)},$$

i.e., that $K^*v = v|_{\partial\Omega}$. In particular, for $v = Kf = \hat{u}_0 - u_{\mathbb{1}} \in \mathcal{K}$, we obtain

$$K^*Kf = K^*(\hat{u}_0 - u_{\mathbb{1}}) = (u_0 - u_{\mathbb{1}})|_{\partial D},$$

and, hence, the assertion (11) follows, cf. (4).

Assume now that $\mathcal{R}(K)$ were not dense in \mathcal{K} . Then there is some $0 \neq v \in \mathcal{K} \cap \overline{\mathcal{R}(K)}^\perp = \mathcal{K} \cap \mathcal{N}(K^*)$, and since $0 = K^*v = v|_{\partial\Omega}$, this function v has vanishing Dirichlet boundary values on $\partial\Omega$. Moreover, as v belongs to \mathcal{K} , it is harmonic in $\Omega \setminus \overline{D}$ with vanishing Neumann boundary values on $\partial\Omega$ (see Lemma 1). Thus, $v^+ = v|_{\Omega \setminus \overline{D}} = 0$ because of the unique solvability of the Cauchy problem for harmonic functions. Using Lemma 1 once more, it follows that $v^- = v|_D$ is also harmonic with vanishing Neumann boundary values on ∂D , and, hence, v^- is constant on each D_i , say $v^-|_{D_i} = v_i^-$, $i = 1, \dots, m$. Since $\int_{\partial D_i} [v] \, ds = -v_i^- |\partial D|$ and as v belongs to \mathcal{X} , these constants must all be zero. This is a contradiction to $v \neq 0$, and, hence, $\mathcal{R}(K)$ is dense in \mathcal{K} .

Finally, to show injectivity of K , we assume $Kf = 0$ for some $f \in L_{\diamond}^2(\partial\Omega)$. Then $u_0 = u_{\mathbb{1}}$ in $\Omega \setminus \overline{D}$, and $u_{\mathbb{1}} = c_i$ in D_i , $i = 1, \dots, m$. Since $u_{\mathbb{1}}$ is harmonic in all of the domain Ω , the field must be constant in Ω (principle of unique continuation), and the flux $f = \partial u_{\mathbb{1}} / \partial \nu$ vanishes on $\partial\Omega$. ■

This theorem – together with Lemma 1 – reveals that the range of K^* consists of all traces of potentials $w \in \mathcal{K}$, whereas the range of $\Lambda_0 - \Lambda_{\mathbb{1}}$ only consists of a dense subset of this set. Accordingly, we need to find a way to deduce the range of K^* from the given data to decrypt the information hidden in these traces according to Theorem 1.

To this end we exploit the so-called *Picard criterion*, a formulation of which can be found in the appendix (Theorem 25) for the ease of completeness. The Picard criterion is based on the singular value decomposition of the operator K , which is largely equivalent to the spectral decomposition of the operator $K^*K = \Lambda_0 - \Lambda_{\mathbb{1}}$.

Corollary 1. *The operator $\Lambda_0 - \Lambda_{\mathbb{1}}$ is a compact and self-adjoint operator from $L_{\diamond}^2(\partial\Omega)$ into itself. As such, $L_{\diamond}^2(\partial\Omega)$ has an orthonormal eigenbasis $\{f_j\}$ and*

associated eigenvalues λ_j , such that

$$(\Lambda_0 - \Lambda_1) f_j = \lambda_j f_j, \quad n \in \mathbb{N}. \quad (18)$$

These eigenvalues are positive and converge to zero as $n \rightarrow \infty$. Throughout we shall assume that they are sorted in nonincreasing order.

Proof. That Λ_0 and Λ_1 are compact operators can be seen from the fact that the trace space of $H^1(\Omega \setminus \overline{D})$ on $\partial\Omega$, i.e., $H^{1/2}(\partial\Omega)$, is compactly embedded in $L^2(\partial\Omega)$. Accordingly, the difference operator $\Lambda_0 - \Lambda_1$ is compact as well as self-adjoint, as follows readily from (11). One can thus find an orthonormal eigenbasis of $\Lambda_0 - \Lambda_1$, and the associated eigenvalues converge to zero for $j \rightarrow \infty$. It remains to prove that they are all positive; this follows from (11) and the injectivity of K by Theorem 2. ■

As we have mentioned before, a point $z \in \Omega$ belongs to D , if and only if the trace ϕ_z of U_z is the trace of a potential in \mathcal{K} , i.e., if it belongs to the range of K^* . As we show in the appendix, cf. Corollary 3, this can be tested in the following way.

Theorem 3. Let $\{f_j\}$ and $\{\lambda_j\}$ be the eigenbasis and eigenvalues of $\Lambda_0 - \Lambda_1$. Then, for any point $z \in \Omega$,

$$z \in D \iff \sum_{n=1}^{\infty} \frac{|(\phi_z, f_j)_{L^2(\partial\Omega)}|^2}{\lambda_j} < \infty \quad (19)$$

with $\phi_z = U_z|_{\partial\Omega}$ from (8).

Remark 1. With the notations $1/\infty = 0$ and $\text{sign } \alpha = \begin{cases} \alpha/|\alpha|, & \alpha \neq 0, \\ 0, & \alpha = 0, \end{cases}$ for any $\alpha \in \mathbb{C}$, we note that

$$\chi_D(z) = \text{sign} \left[\sum_j \frac{|(\phi_z, f_j)_{L^2(\partial\Omega)}|^2}{\lambda_j} \right]^{-1}, \quad z \in \Omega,$$

is the characteristic function of D . In particular, this result provides a constructive proof of the uniqueness of the inverse problem.

Conducting Obstacles

Next, we turn to the case of anisotropic conducting obstacles. To this end we assume that for each $x \in \Omega$ the conductivity $\sigma(x)$ is a real, symmetric positive definite $n \times n$ -matrix, measurable and essentially bounded as a function of x and that the associated quadratic form is bounded from below by some positive constant $c > 0$,

i.e.,

$$p \cdot (\sigma(x)p) \geq c \text{ for almost every } x \in \overline{D} \text{ and every } p \in \mathbb{R}^n \text{ with } |p| = 1 \text{ and} \\ \sigma(x) = I \text{ on } \Omega \setminus \overline{D}, \quad (20)$$

where D denotes the obstacles, which are assumed to have the same topological properties as before. Another assumption that seems to be necessary for the validity of the factorization method is that

$$p \cdot (\sigma(x)p) \leq \kappa < 1 \quad \text{for every } p \in \mathbb{R}^n \text{ with } |p| = 1, \text{ and almost every } x \in D, \quad (21)$$

which states that the background conductivity of the object is strictly larger than within the inclusions. Instead of (21), one can alternatively require that the conductivity within the inclusions is strictly larger than in the background, with straightforward modifications of the analysis; however, we will stick to the above assumption for the ease of simplicity. We mention that the assumption that the background conductivity be *strictly* larger (or smaller) than within the object can be relaxed to just being larger (or smaller), for the prize that the outcome of the method, is unspecified for sampling points right on the boundary of the inclusions, cf. [42]. However, it is an open problem whether the factorization method is applicable, if inequality (21) holds in some obstacles, while $p \cdot (\sigma(x)p) \geq \gamma > 1$ in other inclusions; numerically, the method does not seem to deteriorate in this “mixed case.”

With conducting obstacles, the potential corresponding to a boundary current $f \in L^2_\diamond(\partial\Omega)$ is given as the (weak) solution $u \in H^1_\diamond(\Omega)$ of the boundary value problem

$$\operatorname{div}(\sigma \operatorname{grad} u) = 0 \quad \text{in } \Omega, \quad \frac{\partial}{\partial \nu} u = f \quad \text{on } \partial\Omega, \quad \int_{\partial\Omega} u \, ds = 0, \quad (22)$$

which replaces the model (2) from section “Impedance Tomography in the Presence of Insulating Inclusions” above. Accordingly, we denote by Λ the Neumann-Dirichlet map associated with (13), i.e., $\Lambda : f \mapsto g = u|_{\partial\Omega}$.

As before, the corresponding **inverse problem** is to determine the shape of the obstacles D from the relative data $\Lambda - \Lambda_1$. Here, again, Λ_1 corresponds to the “unperturbed” case $\sigma = \sigma_1 = 1$ everywhere in Ω .

We mention that the problem whether not only D but the conductivity σ itself is uniquely determined by these data is completely settled when $n = 2$ – as long as σ is isotropic – cf. [14]. For $n = 3$, this question is still open for general scalar L^∞ – conductivities. Partial answers are known; we refer to chapter ▶ **Electrical Impedance Tomography**. However, the set D is uniquely determined as we will see below in Theorem 7.

Now we proceed to derive a factorization of $\Lambda - \Lambda_1$ in three factors as in (1), i.e.,

$$\Lambda - \Lambda_1 = AGA^*. \quad (23)$$

To this end we imagine the effect of a *virtual source* φ on the boundary of the obstacle D , given that the boundary of the object Ω is insulated. The corresponding potential v is the solution of the boundary value problem

$$\begin{aligned} \Delta v = 0 & \quad \text{in } \Omega \setminus \overline{D}, & -\frac{\partial}{\partial v} v = \varphi & \quad \text{on } \partial D, \\ \frac{\partial}{\partial v} v = 0 & \quad \text{on } \partial \Omega, & \int_{\partial \Omega} v \, ds = 0. \end{aligned} \quad (24)$$

Recall that the normal vector v on ∂D has been fixed to point into the interior of $\Omega \setminus \overline{D}$, and therefore the minus sign in front of the normal derivative on ∂D reflects the fact that φ is considered to be a source and not a sink. We will require that this source has vanishing mean on *each* connected component D_i of D , i.e.,

$$\varphi \in H_*^{-1/2}(\partial D) = \left\{ \varphi \in H^{-1/2}(\partial D) : \int_{\partial D_i} \varphi \, ds = 0, i = 1, \dots, m \right\}, \quad (25)$$

where the integrals have to be interpreted as dual pairings between $H^{-1/2}$ functions and the unit constant from $H^{1/2}$. For later use we remark that the dual space of $H_*^{-1/2}(\partial D)$ can be identified with the subspace

$$H_*^{1/2}(\partial D) = \left\{ \psi \in H^{1/2}(\partial D) : \int_{\partial D_i} \psi \, ds = 0, i = 1, \dots, m \right\} \quad (26)$$

of $H^{1/2}(\partial D)$.

Associated with (24), we define the operator

$$A : \begin{cases} H_*^{-1/2}(\partial D) \rightarrow L^2_\diamond(\partial \Omega), \\ \varphi \mapsto v|_{\partial \Omega}, \end{cases} \quad (27)$$

and remark that the adjoint operator $A^* : L^2_\diamond(\partial \Omega) \rightarrow H_*^{1/2}(\partial D)$ of A is easily seen to map $f \in L^2_\diamond(\partial \Omega)$ onto the trace of the solution u_0 of (2) on the boundary of the obstacle – after an appropriate renormalization of this trace on each component ∂D_i of ∂D . More precisely the following holds

$$(A^* f)(x) = u_0(x) - c_i \quad \text{for } x \in \partial D_i, i = 1, \dots, m, \quad (28)$$

with c_i as in (13).

In order to establish (23), it remains to determine the operator G in the middle. We define G via the weak solution w of the diffraction problem

$$\begin{aligned} \operatorname{div}(\sigma \operatorname{grad} w) &= 0 \quad \text{in } \Omega \setminus \partial D, & \frac{\partial}{\partial \nu} w &= 0 \quad \text{on } \partial \Omega, & \int_{\partial \Omega} w \, ds &= 0, \\ [w]_{\partial D} &= \psi, & [\nu \cdot (\sigma \operatorname{grad} w)]_{\partial D} &= 0, \end{aligned} \tag{29}$$

and the solution w_1 of the corresponding problem with σ replaced by one everywhere. Again, the normal ν on ∂D is pointing into the exterior of D . Note that when $\sigma = 1$ throughout all of Ω , then the corresponding solution w_1 of (29) can be represented as a modified double-layer potential with density ψ and the Neumann function for the Laplacian as kernel, i.e.,

$$w_1(x) = \int_{\partial D} \frac{\partial}{\partial_y \nu} N(x, y) \psi(y) \, ds(y), \quad x \in \Omega \setminus \partial D.$$

For a general conductivity tensor, the weak form of (29) is obtained by integrating the differential equation against any test function $v \in H^1(\Omega)$ and using partial integration, which yields

$$\int_{\Omega \setminus \partial D} \operatorname{grad} w \cdot (\sigma \operatorname{grad} v) \, dx = 0 \quad \text{for every } v \in H^1(\Omega). \tag{30}$$

Now we can make the ansatz $w = w_1 + \hat{w}$ with $\hat{w} \in H^1(\Omega)$ to rewrite this as a standard variational problem in $H^1(\Omega)$. Find $\hat{w} \in H^1(\Omega)$ such that

$$\int_{\Omega} \operatorname{grad} \hat{w} \cdot (\sigma \operatorname{grad} v) \, dx = - \int_{\Omega \setminus \partial D} \operatorname{grad} w_1 \cdot (\sigma \operatorname{grad} v) \, dx$$

for every $v \in H^1(\Omega)$. From this, it follows readily that problem (29) has a unique weak solution in $H^1(\Omega \setminus \partial D)$, provided that $\psi \in H^{1/2}(\partial D)$, i.e., that ψ belongs to the trace space of $H^1(D)$. In accordance with the definition of A^* , however, we will restrict ψ to $H_*^{1/2}(\partial D)$.

The flux of w and w_1 across ∂D is well defined in $H^{-1/2}(\partial D)$, cf., e.g., [45, Thm. 2.5], and there holds

$$\begin{aligned} \int_{\partial D_i} \frac{\partial}{\partial \nu} (w^+ - w_1^+) \, ds &= \int_{\partial D_i} \nu \cdot (\sigma \operatorname{grad} w^-) \, ds - \int_{\partial D_i} \frac{\partial}{\partial \nu} w_1^- \, ds \\ &= \int_{D_i} \operatorname{div}(\sigma \operatorname{grad} w) \, dx - \int_{D_i} \Delta w_1 \, dx = 0. \end{aligned}$$

We can therefore define the bounded operator G in the following way:

$$G : \begin{cases} H_*^{1/2}(\partial D) & \rightarrow & H_*^{-1/2}(\partial D), \\ \psi & \mapsto & \frac{\partial}{\partial \nu} (w^+ - w_1^+) |_{\partial D}. \end{cases} \tag{31}$$

Theorem 4. *With A and G defined as above, the difference $\Lambda - \Lambda_1$ of the two Neumann-Dirichlet operators associated with (22) and (5), respectively, satisfies*

$$\Lambda - \Lambda_1 = AGA^*.$$

Proof. Consider an arbitrary element $f \in L_\diamond^2(\partial\Omega)$ and the corresponding function $\psi = A^*f$, which satisfies

$$\psi|_{\partial D_i} = u_0|_{\partial D_i} - c_i,$$

where u_0 is given by (2), and c_i is as in (13). The function ψ belongs to $H_*^{1/2}(\partial D)$, and it is easy to verify that the associated solution w_1 of (29) – where σ is replaced by one – is given by

$$w_1 = \begin{cases} u_0 - u_1 & \text{in } \Omega \setminus \overline{D}, \\ c_i - u_1 & \text{in } D_i, i = 1, \dots, m, \end{cases}$$

where u_1 is the solution of (5). Similarly, the solution w of (29) is given by

$$w = \begin{cases} u_0 - u & \text{in } \Omega \setminus \overline{D}, \\ c_i - u & \text{in } D_i, i = 1, \dots, m, \end{cases}$$

with u from (22). Accordingly, $w^+ - w_1^+ = u_1^+ - u^+$, and hence,

$$\varphi = GA^*f = \frac{\partial}{\partial v}(u_1^+ - u^+) \Big|_{\partial D}.$$

If we insert this particular source term φ into (24), then we conclude readily that the associated solution v of (24) is given by $v = u^+ - u_1^+$. It thus follows from (27) that

$$AGA^*f = A\varphi = g - g_1 = (\Lambda - \Lambda_1)f$$

as required. ■

At this occasion, we recall that every function $w \in \mathcal{W}$ of (6) has a well-defined normal derivative $\varphi \in H_*^{-1/2}(\partial D)$ at the inner boundary ∂D and, hence, solves the corresponding boundary value problem (24). And vice versa, the solution of (24) for any $\varphi \in H_*^{-1/2}(\partial D)$ belongs to \mathcal{W} . Thus, we can reformulate Theorem 1 as follows.

Theorem 5. *A point $z \in \Omega$ belongs to D , if and only if the trace ϕ_z of the dipole potential U_z in z , defined by (8), belongs to $\mathcal{R}(A)$.*

As in the insulating case, it remains to derive a constructive algorithm to test whether the trace of some dipole potential belongs to $\mathcal{R}(A)$ or not. The next step on

our way towards this goal is an investigation of the functional analytic properties of the operator G . In the following, we will often consider operators acting between a reflexive Banach space X and its dual space X^* . We will denote the action of an element $\ell \in X^*$ on an element $\psi \in X$ by $\langle \ell, \psi \rangle$ and the pair of spaces by $\langle X^*, X \rangle$ in order to indicate that the first argument belongs to X^* and the second to X . A particular example is the Sobolev space $H_*^{1/2}(\partial D)$ with dual space $H_*^{-1/2}(\partial D)$.

Theorem 6. *The operator $G : H_*^{1/2}(\partial D) \rightarrow H_*^{-1/2}(\partial D)$ is self-adjoint (i.e., G coincides with $G^* : H_*^{1/2}(\partial D) \rightarrow H_*^{-1/2}(\partial D)$ if the bi-dual of $H_*^{1/2}(\partial D)$ is identified with itself) and coercive, i.e., there exists $\gamma > 0$ with*

$$\langle G\psi, \psi \rangle \geq \gamma \|\psi\|_{H^{1/2}(\partial D)}^2 \quad \text{for all } \psi \in H_*^{1/2}(\partial D). \quad (32)$$

Here, $\langle \cdot, \cdot \rangle$ denotes the dual pairing in the dual system $\left(H_*^{-1/2}(\partial D), H_*^{1/2}(\partial D) \right)$.

Proof. The proof proceeds in a couple of steps.

- At first we establish the symmetry of G . Take any ψ and $\tilde{\psi}$ from $H_*^{1/2}(\partial D)$, define w and w_1 as in the proof of Theorem 4, and – using $\tilde{\psi}$ instead of ψ in (29) – define \tilde{w} and \tilde{w}_1 accordingly. Then we conclude that

$$\begin{aligned} \langle G\psi, \tilde{\psi} \rangle &= \int_{\partial D} \tilde{\psi} \frac{\partial}{\partial \nu} w^+ ds - \int_{\partial D} \tilde{\psi} \frac{\partial}{\partial \nu} w_1^+ ds \\ &= \int_{\partial D} (\tilde{w}^+ - \tilde{w}^-) \frac{\partial}{\partial \nu} w^+ ds - \int_{\partial D} (\tilde{w}_1^+ - \tilde{w}_1^-) \frac{\partial}{\partial \nu} w_1^+ ds \\ &= \int_{\partial D} \tilde{w}^+ \frac{\partial}{\partial \nu} w^+ ds - \int_{\partial D} \tilde{w}^- (\nu \cdot (\sigma \operatorname{grad} w^-)) ds \\ &\quad - \int_{\partial D} \tilde{w}_1^+ \frac{\partial}{\partial \nu} w_1^+ ds + \int_{\partial D} \tilde{w}_1^- \frac{\partial}{\partial \nu} w_1^- ds. \end{aligned}$$

Now we can use (29) and apply Green's formula in D or $\Omega \setminus \overline{D}$, respectively, in each of these integrals (care has to be taken concerning the orientation of the normal on ∂D), to obtain

$$\begin{aligned} \langle G\psi, \tilde{\psi} \rangle &= - \int_{\Omega \setminus \overline{D}} \operatorname{grad} \tilde{w} \cdot \operatorname{grad} w dx - \int_D \operatorname{grad} \tilde{w} \cdot (\sigma \operatorname{grad} w) dx \\ &\quad + \int_{\Omega \setminus \overline{D}} \operatorname{grad} \tilde{w}_1 \cdot \operatorname{grad} w_1 dx + \int_D \operatorname{grad} \tilde{w}_1 \cdot \operatorname{grad} w_1 dx \\ &= \int_{\Omega \setminus \partial D} \operatorname{grad} \tilde{w}_1 \cdot \operatorname{grad} w_1 dx - \int_{\Omega \setminus \partial D} \operatorname{grad} \tilde{w} \cdot (\sigma \operatorname{grad} w) dx, \end{aligned} \quad (33)$$

from which the symmetry of G is obvious.

2. Turning to the coercivity assertion (32), we fix some $\psi \in H_*^{1/2}(\partial D)$ and employ the weak form (30) of (29) with $v = w - w_{\mathbb{1}} \in H^1(\Omega)$. Starting from (33) with $\psi = \tilde{\psi}$, we thus obtain

$$\begin{aligned}\langle G\psi, \psi \rangle &= \int_{\Omega \setminus \partial D} |\operatorname{grad} w_{\mathbb{1}}|^2 dx - \int_{\Omega \setminus \partial D} \operatorname{grad} w \cdot (\sigma \operatorname{grad} w) dx \\ &= \int_{\Omega \setminus \partial D} |\operatorname{grad} w_{\mathbb{1}}|^2 dx - \int_{\Omega \setminus \partial D} \operatorname{grad} w \cdot (\sigma \operatorname{grad} w) dx \\ &\quad + 2 \int_{\Omega \setminus \partial D} \operatorname{grad} w \cdot (\sigma \operatorname{grad} (w - w_{\mathbb{1}})) dx \\ &= \int_{\Omega \setminus \partial D} |\operatorname{grad} w_{\mathbb{1}}|^2 dx + \int_{\Omega \setminus \partial D} \operatorname{grad} w \cdot (\sigma \operatorname{grad} w) dx \\ &\quad - 2 \int_{\Omega \setminus \partial D} \operatorname{grad} w \cdot (\sigma \operatorname{grad} w_{\mathbb{1}}) dx \\ &= \int_{\Omega \setminus \partial D} \operatorname{grad} w_{\mathbb{1}} \cdot ((1 - \sigma) \operatorname{grad} w_{\mathbb{1}}) dx \\ &\quad + \int_{\Omega \setminus \partial D} \operatorname{grad} (w - w_{\mathbb{1}}) \cdot (\sigma \operatorname{grad} (w - w_{\mathbb{1}})) dx \\ &\geq \int_{\Omega \setminus \partial D} \operatorname{grad} w_{\mathbb{1}} \cdot ((1 - \sigma) \operatorname{grad} w_{\mathbb{1}}) dx.\end{aligned}$$

The integrand of the last integral vanishes in $\Omega \setminus \overline{D}$ and can be bounded in D from below using the restriction (21) on the conductivity. Accordingly we have

$$\langle G\psi, \psi \rangle \geq (1 - \kappa) \int_D |\operatorname{grad} w_{\mathbb{1}}|^2 dx. \quad (34)$$

3. To accomplish the proof of (32), we need to show that

$$\|\operatorname{grad} w_{\mathbb{1}}\|_{L^2(D)} \geq c \|\psi\|_{H^{1/2}(\partial D)} \quad (35)$$

for some constant $c > 0$. Assume the contrary: let $\psi^{(j)} \in H_*^{1/2}(\partial D)$ and the corresponding $w_{\mathbb{1}}^{(j)}$ be such that $\|\psi^{(j)}\|_{H^{1/2}(\partial D)} = 1$ for every j and that $\|\operatorname{grad} w_{\mathbb{1}}^{(j)}\|_{L^2(D)}$ converges to zero as j tends to infinity. Define $\tilde{w}_{\mathbb{1}}^{(j)} \in H^1(\Omega \setminus \partial D)$ as

$$\tilde{w}_{\mathbb{1}}^{(j)} = \begin{cases} w_{\mathbb{1}}^{(j)} & \text{in } \Omega \setminus D, \\ w_{\mathbb{1}}^{(j)} - c_i^{(j)} & \text{in } D_i, i = 1, \dots, m, \end{cases}$$

with

$$c_i^{(j)} = \frac{1}{|\partial D_i|} \int_{\partial D_i} \left(w_{\mathbb{1}}^{(j)} \right)^- ds, \quad i = 1, \dots, m.$$

Then $\tilde{w}_{\mathbb{1}}^{(j)}|_{D_i}$ has vanishing mean on ∂D_i , and $\|\operatorname{grad} \tilde{w}_{\mathbb{1}}^{(j)}\|_{L^2(D_i)} \rightarrow 0$ for every $i = 1, \dots, m$ as $j \rightarrow \infty$. By virtue of the Poincaré inequality, this implies that $\tilde{w}_{\mathbb{1}}^{(j)}$ tends to zero in $H^1(D)$. From (29), thus follows that the normal derivative $\frac{\partial}{\partial v} \tilde{w}_{\mathbb{1}}^{(j)}$ at ∂D (from either side) tends to zero in $H^{-1/2}(\partial D)$ and, hence, that $\tilde{w}_{\mathbb{1}}^{(j)}|_{\Omega \setminus \overline{D}}$ converges in $H^1(\Omega \setminus \overline{D})$ to the solution of the homogeneous Neumann problem, normalized at the outer boundary. In other words, $\tilde{w}_{\mathbb{1}}^{(j)}$ converges to zero in $H^1(D)$ and in $H^1(\Omega \setminus \overline{D})$ as $j \rightarrow \infty$. Recurring to (29) once again, we observe that

$$\psi^{(j)}|_{\partial D_i} + c_i^{(j)} = \left[w_{\mathbb{1}}^{(j)} \right]_{\partial D_i} + c_i^{(j)} = \left[\tilde{w}_{\mathbb{1}}^{(j)} \right]_{\partial D_i}, \quad (36)$$

and since $\psi^{(j)} \in H_*^{1/2}(\partial D)$, it follows by integration over ∂D_i that

$$\begin{aligned} c_i^{(j)} &= \frac{1}{|\partial D_i|} \int_{\partial D_i} \left[\tilde{w}_{\mathbb{1}}^{(j)} \right]_{\partial D_i} ds - \frac{1}{|\partial D_i|} \int_{\partial D_i} \psi^{(j)} ds \\ &= \frac{1}{|\partial D_i|} \int_{\partial D_i} \left[\tilde{w}_{\mathbb{1}}^{(j)} \right]_{\partial D_i} ds \rightarrow 0 \end{aligned}$$

as j runs to infinity. Inserting this into (36), we conclude that

$$\psi^{(j)}|_{\partial D_i} = \left[\tilde{w}_{\mathbb{1}}^{(j)} \right]_{\partial D_i} - c_i^{(j)} \rightarrow 0, \quad j \rightarrow \infty$$

in $H^{1/2}(\partial D_i)$, $i = 1, \dots, m$, but this contradicts $\|\psi^{(j)}\|_{H^{1/2}(\partial D)} = 1$. Therefore, (35) is true for some $c > 0$ and every $\psi \in H_*^{1/2}(\partial D)$, and hence, (32) follows from (34) and (35). ■

By virtue of Theorem 6, all assumptions of Corollary 5 are satisfied for the factorization of the relative data $\Lambda - \Lambda_{\mathbb{1}}$ established in Theorem 5. Therefore, we can now conclude the main result of this section.

Theorem 7. *Let $z \in \Omega$ and ϕ_z be defined as before.*

$$\text{Then: } z \in D \iff \sum_{n=1}^{\infty} \frac{|(\phi_z, f_j)_{L^2(\partial \Omega)}|^2}{\lambda_j} < \infty,$$

where f_j and λ_j are the orthonormal eigenfunctions and eigenvalues of $\Lambda - \Lambda_{\mathbb{1}}$.

Local Data

It is an important feature of the factorization method that it can be easily adapted to applications where the given data correspond to what is called the local Neumann-Dirichlet map Λ^ℓ . This is the map that takes Neumann boundary values supported on some relatively open subset $\Gamma \subset \partial\Omega$ only and returns the corresponding boundary potentials on the very same subset (normalized to have vanishing mean, say). The local Neumann-Dirichlet map occurs whenever part of the boundary is inaccessible to measurements, in which case Γ corresponds to that part of the boundary of Ω where electrodes can be attached. Mathematically, the local Neumann-Dirichlet map can be interpreted as a Galerkin projection

$$\Lambda^\ell = P \Lambda P^* \quad (37)$$

of the full Neumann-Dirichlet map, where

$$P : \begin{cases} L_\diamond^2(\partial\Omega) & \rightarrow L_\diamond^2(\Gamma), \\ g & \mapsto g|_\Gamma - \frac{1}{|\Gamma|} \int_\Gamma g \, ds, \end{cases} \quad (38)$$

and P^* is its L^2 adjoint, i.e.,

$$P^* f = \begin{cases} f & \text{on } \Gamma, \\ 0 & \text{on } \partial D \setminus \Gamma. \end{cases}$$

From Theorem 4 we immediately conclude that if the conductivity distribution satisfies (20) and (21), then the difference of the two local Neumann-Dirichlet maps Λ^ℓ and Λ_1^ℓ can be factorized in the form

$$\Lambda^\ell - \Lambda_1^\ell = (PA)G(PA)^*$$

with A and G as before. Moreover, the coercivity of G allows a constructive way to check whether a given function belongs to $\mathcal{R}(PA)$, considered as an operator from $H_*^{-1/2}(\partial D)$ to $L_\diamond^2(\Gamma)$. Note that it is obvious from Theorem 5 that the function $P\phi_z$ belongs to $\mathcal{R}(PA)$ when $z \in D$; the converse statement requires a little more effort.

Theorem 8. *Let Γ be a relatively open subset of $\partial\Omega$, and let P be the projector defined in (38). Then $z \in D$, if and only if $P\phi_z \in \mathcal{R}(PA)$.*

Proof. According to the definition (27) of A , the test function $P\phi_z$ belongs to $\mathcal{R}(PA)$, if and only if ϕ_z coincides on Γ (up to a constant) with the trace of a solution v of (24). In this case, however, the dipole potential U_z and the function v are both harmonic functions in $\Omega \setminus (\overline{D} \cup \{z\})$ and have the same Cauchy data on Γ (again, up to a constant). Now we choose a connected subset Ω' of $\Omega \setminus (\overline{D} \cup \{z\})$, whose boundary contains a portion of Γ that is also a relatively open subset of $\partial\Omega$. Then U_z

and v coincide up to a constant in Ω' according to Holmgren's theorem and, hence, near all of $\partial\Omega$. This shows that $\phi_z \in \mathcal{R}(A)$, and, hence, the assertion follows from Theorem 5. ■

Accordingly, if Γ is a relatively open subset of $\partial\Omega$, then Theorem 7 also extends readily to the local situation, if the eigenfunctions and eigenvalues of $\Lambda - \Lambda_1$ are replaced by those of $\Lambda^\ell - \Lambda_1^\ell$.

Note that Theorem 8 requires that Γ is a relatively open subset of $\partial\Omega$, and in fact, the factorization method no longer applies for discrete measurements or finitely many boundary currents. Still, this is precisely the situation that is encountered in practice, as data are always finite dimensional. Due to the rapid decay of the eigenvalues of $\Lambda - \Lambda_1$, however, the full relative data can be very well approximated by operators of finite rank, such as those corresponding to real data (see [54] for detailed numerical examples).

Other Generalizations

The Half-Space Problem

The factorization method can also be applied to a related inverse electrostatic problem in full space with near field data, if the same manifold of codimension one is used to generate a source *and* to measure the resulting change of the potential. In fact, this problem which has been studied in [52] and [75] is very similar to the setting for the Helmholtz equation that we will consider in the following section. We also like to refer to [15] where this approach has been applied to some real two-dimensional data.

For quite a few applications, however, the impedance tomography problem is more appropriately modeled in a half space, rather than in the full space or within a bounded domain. For this setting new difficulties arise, as the data (may) live on the entire, unbounded boundary of the surface, which calls for weighted Sobolev spaces for an appropriate theoretical analysis. In the sequel we restrict our attention to three-space dimensions ($n = 3$), as the two-dimensional case needs some additional attention, cf. [55] and at the same time appears to be less interesting from a practical point of view.

We consider the half-space $\Omega = \{x \in \mathbb{R}^3 : v \cdot x < 0\}$, where $v \in \mathbb{R}^3$ is a fixed unit vector, which coincides with the outer normal on the hyperplane $\{x : v \cdot x = 0\}$, which is the boundary of Ω . The main difficulty in the analysis of this problem is that solutions of the corresponding conductivity problem

$$\operatorname{div}(\sigma \operatorname{grad} u) = 0 \quad \text{in } \Omega, \quad \frac{\partial}{\partial v} u = f \quad \text{on } \partial\Omega, \quad (39)$$

need no longer belong to $L^2(\Omega)$; instead, one has to resort to weighted Sobolev spaces, such as

$$\mathcal{U} = \{u \in \mathcal{D}'(\Omega) : (1 + |\cdot|^2)^{-1/2}u \in L^2(\Omega), |\operatorname{grad} u| \in L^2(\Omega)\},$$

to search for a unique solution of (39). If σ is given by (20), then a weak solution $u \in \mathcal{U}$ can be shown to exist provided that f belongs to

$$L^{2,-1}(\partial\Omega) = \{f : (1 + |\cdot|^2)^{1/2}f \in L^2(\partial\Omega)\},$$

in which case the trace of u belongs to the dual space $L^{2,1}(\partial\Omega)$ of $L^{2,-1}(\partial\Omega)$. Note that no normalization of u is required in (39) because solutions in \mathcal{U} are implicitly normalized to vanish at infinity. We refer to [55] for further details about the forward problem.

Within this function space setting, the Neumann-Dirichlet operator is defined in a natural way as an operator $\Lambda : L^{2,-1}(\partial\Omega) \rightarrow L^{2,1}(\partial\Omega)$, and the difference between Λ and Λ_1 (the latter corresponding to the homogeneous half space) admits a factorization (23) as before, where now

$$A : \begin{cases} H_*^{-1/2}(\partial D) & \rightarrow L^{2,1}(\partial\Omega), \\ \varphi & \mapsto v|_{\partial\Omega}, \end{cases}$$

and v solves the same boundary value problem as in (24), except for the missing normalization over the boundary $\partial\Omega$. Furthermore, the self-adjoint operator G is defined as before (with the appropriate definition of a weak solution of (29)) and is coercive again.

We emphasize that the dipole potential (8) for the half space is explicitly known, i.e., we have (up to a negligible multiplicative constant)

$$\phi_z(x) = \frac{(x - z) \cdot p}{|x - z|^3}, \quad x \in \partial\Omega. \quad (40)$$

With these notations, the characterization of the inclusions can be established in much the same way as before (see [55]).

Theorem 9. *A point $z \in \Omega$ belongs to D , if and only if ϕ_z of (40) belongs to $\mathcal{R}(A)$.*

For real applications, the measuring device will only cover a bounded region $\Gamma \subset \partial\Omega$. The corresponding local Neumann-Dirichlet operator Λ^ℓ can then be embedded in the standard L^2 framework from the previous section, and the usual Picard series can be used to implement the range test. For the ease of completeness, we briefly mention that for such local data the test dipole ϕ_z can be replaced by the function

$$\tilde{\phi}_z(x) = \frac{1}{|x - z|}, \quad x \in \Gamma,$$

which is the trace of the corresponding Neumann function (again, up to a multiplicative constant), as the latter has a vanishing normal derivative on the boundary of the half space. We hasten to add, though, that $\tilde{\phi}_z$ must not be used for full data, as it does not belong to $L^{2,1}(\partial\Omega)$. Numerically, however, this modification of the method has no significant benefit.

The Crack Problem

Another case of interest are cracks, i.e., lower-dimensional manifolds of codimension one, that are insulating, say. This setting has important applications in nondestructive testing of materials. Consider a domain $\Omega \subset \mathbb{R}^n$, with $n = 2$ or $n = 3$ again, and the union $\Sigma = \cup_{i=1}^m \Sigma_i \subset \Omega$ of m smooth, bounded manifolds (the insulating cracks), such that $\Sigma_i \cap \Sigma_j = \emptyset$ and $\Omega \setminus \Sigma$ are connected. Given a boundary current $f \in L^2_\diamond(\partial\Omega)$, the induced potential satisfies the model equations

$$\Delta u_0 = 0 \quad \text{in } \Omega \setminus \Sigma, \quad \frac{\partial}{\partial \nu} u_0 = 0 \quad \text{on } \Sigma, \quad \frac{\partial}{\partial \nu} u_0 = f \quad \text{on } \partial\Omega, \quad (41)$$

and the corresponding Neumann–Dirichlet operator is the map that takes f onto the trace of u_0 on $\partial\Omega$:

$$\Lambda : \begin{cases} L^2_\diamond(\partial\Omega) & \rightarrow L^2_\diamond(\partial\Omega), \\ f & \mapsto u_0|_{\partial\Omega}. \end{cases}$$

The crack case can be analyzed in a similar way as in section ‘‘Impedance Tomography in the Presence of Insulating Inclusions’’, cf. [23], using a factorization $\Lambda - \Lambda_1 = K^*K$, where K is almost identical to the operator in (12), except that it maps into $H^1(\Omega \setminus \Sigma)$. There is a more important difference, though. As the crack has no interior points, the range test will always fail with the hitherto used test function ϕ_z , as the dipole singularity of U_z is too strong to belong to $H^1(\Omega \setminus \Sigma)$, even when $z \in \Sigma$. To detect a crack, we therefore need to construct a new test function by integrating the function ϕ_z over z along some ‘‘test arc’’ (in \mathbb{R}^2) or some ‘‘test surface’’ (in \mathbb{R}^3).

The range test can then be implemented by placing linear (planar) test cracks in different sampling points with various orientations (see [23] for numerical reconstructions in two-space dimensions). The amount of work thus grows substantially, as we now have 2 degrees of freedom to sample (a test point and a normal direction) instead of only one in the previous cases. Also, in a numerical realization, test cracks will – at best – only touch the crack tangentially, but in theory this already suffices to ruin the range test. It turns out that in practice the usual implementation with the test function ϕ_z performs as good as the more elaborate but expensive variant described above. As said before, in theory, ϕ_z will never belong to the range of K ; in practice, however, it will ‘‘almost’’ do so, i.e., the Picard series (19) will grow much more slowly in the close neighborhood of the crack.

One-dimensional cracks in three-dimensional objects cannot be reconstructed in this way, because the potential does not ‘‘see’’ inhomogeneities of this size.

However, one can use an asymptotic analysis similar to the derivation of MUSIC-type algorithms that are discussed in section “MUSIC” below. Here we give a brief sketch of an argument provided in [47] and refer to this paper for further details. The basic idea is that realistic “one-dimensional” cracks in a 3D world are not exactly one-dimensional, but better modeled as extremely thin tubular inclusions of small diameter $\delta > 0$. The corresponding relative data $\Lambda_\delta - \Lambda_1$, where Λ_δ is the Neumann-Dirichlet operator associated with the tubular inclusion and Λ_1 is as usual, turn out to satisfy an asymptotic expansion in δ ,

$$\Lambda_\delta - \Lambda_1 = \delta^2 \hat{M} + o(\delta^2),$$

possibly after selecting an appropriate (sub)sequence $\delta_k \rightarrow 0$. The operator \hat{M} that constitutes the dominating term of this expansion admits a factorization similar to (23). In contrast to the MUSIC framework below, this operator has infinite dimensional range. Although the operators of the corresponding factorization are somewhat different from the ones that we have encountered above, the bottom line is the same as for one-dimensional cracks in two-space dimensions. The same integrated test function belongs to the range of the operator A of this factorization, if and only if the corresponding test arc is part of the crack. The singular value decomposition of \hat{M} can be used to evaluate this test, and in practice this singular value decomposition can be approximated by the one of $\Lambda_\delta - \Lambda_1$, i.e., by the given data.

3 The Factorization Method in Inverse Scattering Theory

The second part of this chapter is devoted to the factorization method for problems in inverse scattering theory for time-harmonic waves. The scattering of an incident plane wave by a medium gives rise to a scattered field which is measured “far away” from the medium. The factorization method characterizes the shape of the scattering medium from this far field information. The measurement operator will be the far field operator F which maps the density of the incident Herglotz field to the corresponding far field pattern of the scattered field.

The far field operator F allows a factorization of the form (1) where the operators A and G depend on the specific situation. We will discuss two typical cases and start with the scattering by a sound-soft obstacle D in section “Inverse Acoustic Scattering by a Sound-Soft Obstacle.” This is an example of a nonabsorbing medium which is mathematically reflected by the fact that the far field operator is normal – though not self-adjoint as for the corresponding problem in impedance tomography. It was this example for which the factorization method was developed for the first time in [66]. In section “Inverse Electromagnetic Scattering by an Inhomogeneous Medium,” we will study the scattering of time-harmonic electromagnetic plane waves by an absorbing medium. In this case the corresponding far field operator fails to be normal.

Each case study will start with a short repetition of the corresponding direct problem. Then the inverse problem will be stated, and a factorization of the form

(1) will be derived. As in impedance tomography, a crucial point is to establish in each case a certain coercivity condition for G . In addition, one needs to prove a range identity which describes the range of A via the known – possibly non-normal – data operator F .

Here and throughout the following sections, $S^2 = \{x \in \mathbb{R}^3 : |x| = 1\}$ denotes the unit sphere in \mathbb{R}^3 .

Inverse Acoustic Scattering by a Sound-Soft Obstacle

This section is devoted to the analysis of the factorization method for the most simplest case in scattering theory. We consider the scattering of time-harmonic plane waves by an impenetrable obstacle $D \subset \mathbb{R}^3$ which we model by assuming Dirichlet boundary conditions on the boundary ∂D of D . As before, we assume that D is a finite union $D = \cup_{i=1}^m D_i$ of bounded domains D_i such that $\overline{D}_i \cap \overline{D}_j = \emptyset$ for $i \neq j$. Furthermore, we assume that the boundaries ∂D_i are Lipschitz continuous and that the exterior $\mathbb{R}^3 \setminus \overline{D}$ of \overline{D} is connected. Finally, let $k > 0$ be the wave number and

$$u^i(x) = \exp(ikx \cdot \hat{\theta}), \quad x \in \mathbb{R}^3, \quad (42)$$

be the incident plane wave of direction $\hat{\theta} \in S^2$. The obstacle D gives rise to a scattered field $u^s \in C^2(\mathbb{R}^3 \setminus \overline{D}) \cap C(\mathbb{R}^3 \setminus D)$ which superposes u^i and results in the total field $u = u^i + u^s$ which satisfies the *Helmholtz equation*

$$\Delta u + k^2 u = 0 \quad \text{outside } \overline{D} \quad (43)$$

and the Dirichlet boundary condition

$$u = 0 \quad \text{on } \partial D. \quad (44)$$

The scattered field u^s satisfies the *Sommerfeld radiation condition*

$$\frac{\partial u^s}{\partial r} - iku^s = \mathcal{O}(r^{-2}) \quad \text{for } r = |x| \rightarrow \infty \quad (45)$$

uniformly with respect to $\hat{x} = x/|x| \in S^2$.

The **direct scattering problem** is to determine the scattered field u^s for a given obstacle $D \subset \mathbb{R}^3$, some $\hat{\theta} \in S^2$ and $k > 0$.

For the treatment of this direct problem, we refer to [36] (see also section “Obstacle Scattering” in chapter ▶ [Inverse Scattering](#)). There it is also shown that the scattered field u^s has the asymptotic behavior

$$u^s(x) = \frac{\exp(ik|x|)}{4\pi|x|} u^\infty(\hat{x}) + \mathcal{O}(|x|^{-2}), \quad |x| \rightarrow \infty \quad (46)$$

uniformly with respect to $\hat{x} = x/|x| \in S^2$. The function $u^\infty : S^2 \rightarrow \mathbb{C}$ is analytic and is called the *far field pattern* of u^s . It depends on the wave number k , the direction $\hat{\theta} \in S^2$, and the domain D . Since we will keep $k > 0$ fixed, only the dependence on $\hat{\theta}$ is indicated: $u^\infty = u^\infty(\hat{x}; \hat{\theta})$ for $\hat{x}, \hat{\theta} \in S^2$.

In the **inverse scattering problem**, the far field pattern $u^\infty(\hat{x}; \hat{\theta})$ is known for all $\hat{x}, \hat{\theta} \in S^2$ and some fixed $k > 0$, and the domain D has to be determined. We refer again to [36] or chapter ▶ **Inverse Scattering** for the presentation of the most important properties of this inverse scattering problem. The knowledge of $u^\infty(\hat{x}; \hat{\theta})$ for all $\hat{x}, \hat{\theta} \in S^2$ determines the integral kernel of the *far field operator* F from $L^2(S^2)$ into itself, which is defined by

$$(Fg)(\hat{x}) = \int_{S^2} u^\infty(\hat{x}; \hat{\theta}) g(\hat{\theta}) d\text{s}(\hat{\theta}) \quad \text{for } \hat{x} \in S^2. \quad (47)$$

The far field operator F is compact, normal (i.e., F commutes with its adjoint F^*), and the so-called *scattering operator* $I + \frac{ik}{8\pi^2} F$ is unitary in $L^2(S^2)$.

As in section “Conducting Obstacles,” the first step is to derive a factorization of F in the form (1).

The operator A is the *data-to-pattern operator* which maps $f \in H^{1/2}(\partial D)$ to the far field pattern v^∞ of the radiating (i.e., v satisfies the Sommerfeld radiation condition (45)) solution $v \in H_{loc}^1(\mathbb{R}^3 \setminus \overline{D})$ of

$$\Delta v + k^2 v = 0 \text{ in the exterior of } \overline{D}, \quad v = f \text{ on } \partial D. \quad (48)$$

Here, $H_{loc}^1(\mathbb{R}^3 \setminus \overline{D})$ is the space of functions v with $v|_{B \setminus \overline{D}} \in H^1(B \setminus \overline{D})$ for all balls $B \subset \mathbb{R}^3$. Existence and uniqueness is assured (see, e.g., [80]; Chap. 9).

Theorem 10. Define the operator $A : H^{1/2}(\partial D) \rightarrow L^2(S^2)$ by $Af = v^\infty$ where v^∞ is the far field pattern of the unique radiating solution $v \in H_{loc}^1(\mathbb{R}^3 \setminus \overline{D})$ of (48). Then A is one-to-one with dense range, and the following factorization holds

$$F = -AS^*A^*, \quad (49)$$

where $A^* : L^2(S^2) \rightarrow H^{-1/2}(\partial D)$ is the dual of A , and $S^* : H^{-1/2}(\partial D) \rightarrow H^{1/2}(\partial D)$ is the dual of the single-layer boundary operator $S : H^{-1/2}(\partial D) \rightarrow H^{1/2}(\partial D)$ defined by

$$(S\varphi)(x) = \int_{\partial D} \varphi(y) \Phi(x, y) d\text{s}(y), \quad x \in \partial D. \quad (50)$$

Here, Φ denotes the fundamental solution of the Helmholtz equation, i.e.,

$$\Phi(x, y) = \frac{\exp(ik|x - y|)}{4\pi|x - y|}, \quad x, y \in \mathbb{R}^3, x \neq y, \quad (51)$$

and the explicit definition (50) of this operator makes only sense for smooth functions φ . It has to be extended to functionals $\varphi \in H^{-1/2}(\partial D)$ by a density or duality argument.

Proof. The injectivity of A follows immediately from Rellich's Lemma (see [36] or chapter ▶ Inverse Scattering). The denseness of the range of A can be shown by approximating any $g \in L^2(S^2)$ by a finite sum of spherical harmonics to which the corresponding field can be written down explicitly.

To derive the factorization, define the auxiliary operator $\mathcal{H} : L^2(S^2) \rightarrow H^{1/2}(\partial D)$ by

$$(\mathcal{H}g)(x) = \int_{S^2} g(\hat{\theta}) \exp(i k x \cdot \hat{\theta}) ds(\hat{\theta}) = \int_{S^2} g(\hat{\theta}) u^i(x; \hat{\theta}) ds(\hat{\theta}), \quad x \in \partial D.$$

First we note that $u^\infty(\cdot; \hat{\theta}) = -A u^i(\cdot; \hat{\theta})$ by the definition of A , and thus by the superposition principle, $Fg = -A\mathcal{H}g$ for all $g \in L^2(S^2)$, i.e., $F = -A\mathcal{H}$. We compute the dual $\mathcal{H}^* : H^{-1/2}(\partial D) \rightarrow L^2(S^2)$ as

$$(\mathcal{H}^* \varphi)(\hat{x}) = \int_{\partial D} \varphi(y) \exp(-ik\hat{x} \cdot y) ds(y), \quad \hat{x} \in S^2.$$

The fundamental solution Φ has the asymptotic behavior

$$\Phi(x, y) = \frac{\exp(ik|x|)}{4\pi|x|} \exp(-ik\hat{x} \cdot y) + \mathcal{O}(|x|^{-2}), \quad |x| \rightarrow \infty \quad (52)$$

uniformly with respect to $\hat{x} \in S^2$ and $y \in \partial D$ and thus has the far field pattern $\Phi^\infty(\hat{x}, y) = \exp(-ik\hat{x} \cdot y)$. Therefore, again by superposition, $\mathcal{H}^* \varphi = AS\varphi$, i.e., $\mathcal{H} = S^* A^*$. Substituting this into $F = -A\mathcal{H}$ yields (49). ■

Therefore, F allows a factorization in the form (1) with $G = -S^*$. The most important properties of this operator are collected in the following theorem. (For a proof see, e.g., [73, 80].)

Theorem 11. *Assume that k^2 is not a Dirichlet eigenvalue of $-\Delta$ in D . Then the following holds:*

- *S is an isomorphism from the Sobolev space $H^{-1/2}(\partial D)$ onto $H^{1/2}(\partial D)$.*
- *$\text{Im}\langle \varphi, S\varphi \rangle < 0$ for all $\varphi \in H^{-1/2}(\partial D)$ with $\varphi \neq 0$. Here, $\langle ., . \rangle$ denotes the duality pairing in $\langle H^{-1/2}(\partial D), H^{1/2}(\partial D) \rangle$.*
- *Let S_i be the single-layer boundary operator (50) corresponding to the wave number $k = i$. The operator S_i is self-adjoint and coercive as an operator from $H^{-1/2}(\partial D)$ onto $H^{1/2}(\partial D)$, i.e., there exists $c_0 > 0$ with*

$$\langle \varphi S_i \varphi \rangle \geq c_0 \|\varphi\|_{H^{-1/2}(\partial D)}^2 \quad \text{for all } \varphi \in H^{-1/2}(\partial D). \quad (53)$$

- The difference $S - S_i$ is compact from $H^{-1/2}(\partial D)$ into $H^{-1/2}(\partial D)$.

From this theorem the following coercivity result can be derived.

Assume that k^2 is not a Dirichlet eigenvalue of $-\Delta$ in D . Then there exists $c_1 > 0$ with

$$|\langle \varphi S \varphi \rangle| \geq c_1 \|\varphi\|_{H^{-1/2}(\partial D)}^2 \quad \text{for all } \varphi \in H^{-1/2}(\partial D). \quad (54)$$

This establishes the first step of the factorization method. In the second step, the domain D is characterized by the range of the operator A .

Theorem 12. For any $z \in \mathbb{R}^3$, define the function $\phi_z \in L^2(S^2)$ by

$$\phi_z(\hat{x}) = \exp(-ik\hat{x} \cdot z), \quad \hat{x} \in S^2. \quad (55)$$

Then z belongs to D , if and only if $\phi_z \in \mathcal{R}(A)$.

Proof. Let first $z \in D$. From (52), we conclude that ϕ_z is the far field pattern of $\Phi(\cdot, z)$; thus, $\phi_z = Af$, where $f = \Phi(\cdot, z)|_{\partial D} \in H^{1/2}(\partial D)$.

Let now $z \notin D$ and assume, on the contrary, that $\phi_z = Af$ for some $f \in H^{1/2}(\partial D)$. Let v be as in the definition of Af . Then $\phi_z = v^\infty$. From Rellich's Lemma and unique continuation, we conclude that $\Phi(\cdot, z)$ and v coincide in $\mathbb{R}^3 \setminus (\overline{D} \cup \{z\})$. By the same arguments as in the proof of Theorem 1, this is a contradiction since v is regular and $\Phi(\cdot, z)$ is singular at z . ■

From the factorization (49), we conclude that $\mathcal{R}(F) \subset \mathcal{R}(A)$, and thus

$$\phi_z \in \mathcal{R}(F) \implies z \in D.$$

Therefore, the condition on the left-hand side determines only a subset of D . One can show, cf. [35], that for the case of D , being a ball, the left-hand side is only satisfied for the center of this ball. Nevertheless, the (regularized version) of the test $\phi_z \in \mathcal{R}(F)$ leads to the *Linear Sampling Method*, cf. section “The Linear Sampling Method”.

In the third step of the factorization method, the range $\mathcal{R}(A)$ of A has to be expressed by the known data operator F . This is achieved by a second factorization of F based on the spectral decomposition of the normal operator F . From now on we make the assumption that k^2 is not a Dirichlet eigenvalue of $-\Delta$ in D . Then the far field operator is one-to-one as it follows directly from the factorization (49) and part (a) of Theorem 11.

Since F is compact, normal, and one-to-one, there exists a complete set of orthonormal eigenfunctions $\psi_j \in L^2(S^2)$ with corresponding eigenvalues $\lambda_j \in \mathbb{C}$, $j = 1, 2, 3, \dots$ (see, e.g., [88]). Furthermore, since the operator $I + ik/(8\pi^2)F$ is unitary, the eigenvalues λ_j of F lie on the circle of radius $1/r$ and center i/r

where $r = k/(8\pi^2)$. The spectral theorem for normal operators yields that F has the form

$$F\psi = \sum_{j=1}^{\infty} \lambda_j (\psi, \psi_j)_{L^2(S^2)} \psi_j, \quad \psi \in L^2(S^2). \quad (56)$$

Therefore, F has a second factorization in the form

$$F = (F^* F)^{1/4} G_2 (F^* F)^{1/4}, \quad (57)$$

where the self-adjoint operator $(F^* F)^{1/4} : L^2(S^2) \rightarrow L^2(S^2)$ and the signum $G_2 : L^2(S^2) \rightarrow L^2(S^2)$ of F are given by

$$(F^* F)^{1/4} \psi = \sum_{j=1}^{\infty} \sqrt{|\lambda_j|} (\psi, \psi_j)_{L^2(S^2)} \psi_j, \quad \psi \in L^2(S^2), \quad (58)$$

$$G_2 \psi = \sum_{j=1}^{\infty} \frac{\lambda_j}{|\lambda_j|} (\psi, \psi_j)_{L^2(S^2)} \psi_j, \quad \psi \in L^2(S^2). \quad (59)$$

Also this operator G_2 satisfies a coercivity condition of the form (54).

Theorem 13. *Assume that k^2 is not a Dirichlet eigenvalue of $-\Delta$ in D . Then there exists $c_2 > 0$ with*

$$|(G_2 \psi, \psi)_{L^2(S^2)}| \geq c_2 \|\psi\|_{L^2(S^2)}^2 \quad \text{for all } \psi \in L^2(S^2). \quad (60)$$

Proof. It is sufficient to prove (60) for $\psi \in L^2(S^2)$ of the form $\psi = \sum_j c_j \psi_j$ with $\|\psi\|_{L^2(S^2)}^2 = \sum_j |c_j|^2 = 1$. With the abbreviation $s_j = \lambda_j/|\lambda_j|$, it is

$$|(G_2 \psi, \psi)_{L^2(S^2)}| = \left| \left(\sum_{j=1}^{\infty} s_j c_j \psi_j, \sum_{j=1}^{\infty} c_j \psi_j \right)_{L^2(S^2)} \right| = \left| \sum_{j=1}^{\infty} s_j |c_j|^2 \right|.$$

The complex number $\sum_{j=1}^{\infty} s_j |c_j|^2$ belongs to the closure of the convex hull $\mathcal{C} = \text{conv} \{s_j : j \in \mathbb{N}\} \subset \mathbb{C}$ of the complex numbers s_j . We conclude that

$$|(G_2 \psi, \psi)_{L^2(S^2)}| \geq \inf \{|z| : z \in \mathcal{C}\}$$

for all $\psi \in L^2(S^2)$ with $\|\psi\|_{L^2(S^2)} = 1$. From the facts that λ_j lie on the circle with center i/r passing through the origin and that λ_j tends to zero as j tends to infinity, we conclude that the only accumulation points of the sequence $\{s_j\}$ can be $+1$ or -1 . From the factorization (49) and Theorem 11, it can be shown (see the proof of Theorem 1.23 of [73]) that indeed 1 is the only accumulation point, i.e., $s_j \rightarrow 1$ as

j tends to infinity. Therefore, the set \mathcal{C} is contained in the part of the upper half disk which is above the line $l = \{\hat{s} + (1-t)1 : t \in \mathbb{R}\}$ passing through \hat{s} and 1. Here, \hat{s} is the point in $\{s_j : j \in \mathbb{N}\}$ with the smallest real part. Therefore, the distance of the origin to this convex hull \mathcal{C} is positive, i.e., there exists c_2 with (60).

From Theorem 10 and Eq. (57), the scattering operator F can be written as

$$F = AG_1A^* = (F^*F)^{1/4}G_2(F^*F)^{1/4}, \quad (61)$$

where we have set $G_1 = -S^*$. Both of the operators G_j , $j = 1, 2$ are coercive in the sense of (54) and (60), respectively. By the range identity of Corollary 4, the ranges of A and $(F^*F)^{1/4}$ coincide. The combination of this result and Theorem 12 yields the main result of this section. (To derive the second equivalence of (62), Theorem 25 of Picard has been applied.)

Theorem 14. *Assume that k^2 is not a Dirichlet eigenvalue of $-\Delta$ in D . For any $z \in \mathbb{R}^3$, define again $\phi_z \in L^2(S^2)$ by (55), i.e.,*

$$\phi_z(\hat{x}) := \exp(-ik\hat{x} \cdot z), \quad \hat{x} \in S^2.$$

Then

$$z \in D \iff \phi_z \in \mathcal{R}((F^*F)^{1/4}) \iff \sum_j \frac{|(\phi_z, \psi_j)_{L^2(S^2)}|^2}{|\lambda_j|} < \infty. \quad (62)$$

Here, $\lambda_j \in \mathbb{C}$ are the eigenvalues of the normal operator F with corresponding normalized eigenfunctions $\psi_j \in L^2(S^2)$.

Formula (62) provides a simple and fast technique to visualize the object D by plotting the inverse of the series on the right-hand side. In practice, this will be a finite sum instead of a series, but the value of the finite sum is much larger for points z outside than for points inside of D . We refer to the original paper [66] for some typical plots.

Remark 2. It is illuminating to compare the presentation in this section with the one for impedance tomography from section ‘‘Conducting Obstacles’’. The relative potential $u - u_1$ considered there corresponds to the scattered wave $u^s = u - u^i$, i.e., the total field minus the incoming field; the incoming field is the potential that is induced by the excitation if the background is homogeneous, whereas the total field is the corresponding solution in the presence of the scatterer.

In both cases, the operator that maps the excitation onto the associated ‘‘relative data’’ can be factorized in three operators: the one that is applied first, i.e., A^* , maps the excitation/the incoming field onto the boundary of the obstacle(s), the operator A that is applied last, maps appropriate boundary data on the obstacle onto the ‘‘outgoing field,’’ and its measured data. Accordingly, the operator in the middle encodes the ‘‘refraction’’ at the obstacle(s).

As such, we can view the factorization from impedance tomography as a generalization of Huygens' principle to the diffusion problem (22), although the time causality from scattering theory has no apparent physical analog in stationary diffusion processes.

Inverse Electromagnetic Scattering by an Inhomogeneous Medium

This section is devoted to the analysis of the factorization method for the inverse scattering of electromagnetic time-harmonic plane waves by an inhomogeneous nonmagnetic and conducting medium. Let $k = \omega\sqrt{\varepsilon_0\mu_0} > 0$ be the *wave number* with angular frequency ω , electric permittivity ε_0 , and magnetic permeability μ_0 in vacuum. The incident plane wave has the form

$$H^i(x) = p \exp(ik\hat{\theta} \cdot x), \quad E^i(x) = -\frac{1}{i\omega\varepsilon_0} \operatorname{curl} H^i(x), \quad (63)$$

for some polarization vector $p \in \mathbb{C}^3$ and some direction $\hat{\theta} \in S^2$ such that $p \cdot \hat{\theta} = 0$. This pair satisfies the time-harmonic Maxwell system in vacuum, i.e.,

$$\operatorname{curl} E^i - i\omega\mu_0 H^i = 0 \quad \text{in } \mathbb{R}^3, \quad (64)$$

$$\operatorname{curl} H^i + i\omega\varepsilon_0 E^i = 0 \quad \text{in } \mathbb{R}^3. \quad (65)$$

This incident wave is scattered by a medium with space-dependent electric permittivity $\varepsilon = \varepsilon(x)$ and conductivity $\sigma = \sigma(x)$. We assume that the magnetic permeability μ is constant and equal to the permeability μ_0 of vacuum. Furthermore, we assume that $\varepsilon \equiv \varepsilon_0$ and $\sigma \equiv 0$ outside of some bounded domain. The total fields are superpositions of the incident and scattered fields, i.e., $E = E^i + E^s$ and $H = H^i + H^s$ and satisfy the Maxwell system

$$\operatorname{curl} E - i\omega\mu_0 H = 0 \quad \text{in } \mathbb{R}^3, \quad (66)$$

$$\operatorname{curl} H + i\omega\varepsilon E = \sigma E \quad \text{in } \mathbb{R}^3. \quad (67)$$

Also, the tangential components of E and H are continuous on interfaces where σ or ε are discontinuous. Finally, the scattered fields have to be radiating, i.e., satisfy the *Silver-Müller radiation condition*

$$\sqrt{\mu_0}H^s(x) \times \hat{x} - \sqrt{\varepsilon_0}E^s(x) = \mathcal{O}\left(\frac{1}{|x|^2}\right) \quad \text{as } |x| \rightarrow \infty \quad (68)$$

uniformly w.r.t. $\hat{x} = x/|x| \in S^2$. The complex-valued *relative electric permittivity* ε_r is defined by

$$\varepsilon_r(x) = \frac{\varepsilon(x)}{\varepsilon_0} + i\frac{\sigma(x)}{\omega\varepsilon_0}. \quad (69)$$

Note that $\varepsilon_r \equiv 1$ outside of some bounded domain. Equation (67) can then be written in the form

$$\operatorname{curl} H + i\omega\varepsilon_0\varepsilon_r E = 0 \quad \text{in } \mathbb{R}^3. \quad (70)$$

It is preferable to work with the magnetic field H only. This is motivated by the fact that the magnetic field is divergence free as seen from (66) and the fact that $\operatorname{div} \operatorname{curl} = 0$. In general, this is not the case for the electric field E . Eliminating the electric field E from the system (66) and (70) leads to

$$\operatorname{curl} \left[\frac{1}{\varepsilon_r} \operatorname{curl} H \right] - k^2 H = 0 \quad \text{in } \mathbb{R}^3. \quad (71)$$

The incident field H^i satisfies

$$\operatorname{curl}^2 H^i - k^2 H^i = 0 \quad \text{in } \mathbb{R}^3. \quad (72)$$

Subtracting both equations yields

$$\operatorname{curl} \left[\frac{1}{\varepsilon_r} \operatorname{curl} H^s \right] - k^2 H^s = \operatorname{curl} [q \operatorname{curl} H^i] \quad \text{in } \mathbb{R}^3, \quad (73)$$

where the contrast q is defined by $q = 1 - 1/\varepsilon_r$. The Silver-Müller radiation condition turns into

$$\operatorname{curl} H^s(x) \times \hat{x} - ikH^s(x) = \mathcal{O}\left(\frac{1}{|x|^2}\right), \quad |x| \rightarrow \infty. \quad (74)$$

The continuity of the tangential components of E and H translates into analogous requirements for H^s and $\operatorname{curl} H^s$.

It will be necessary to allow more general source terms on the right-hand side of (73). In particular, we will consider the problem to determine a radiating solution $v \in H_{loc}(\operatorname{curl}, \mathbb{R}^3)$ of

$$\operatorname{curl} \left[\frac{1}{\varepsilon_r} \operatorname{curl} v \right] - k^2 v = \operatorname{curl} f \quad \text{in } \mathbb{R}^3 \quad (75)$$

for given $f \in L^2(\mathbb{R}^3)^3$ with compact support. (For any open set D the space $L^2(D)^3$ denotes the space of vector functions $v : D \rightarrow \mathbb{C}^3$ such that all components are in $L^2(D)$.) The solutions v of (75) as well as of (71) and (73) have to be understood in the variational sense, i.e., $v \in H_{loc}(\operatorname{curl}, \mathbb{R}^3)$ satisfies

$$\int_{\mathbb{R}^3} \left[\frac{1}{\varepsilon_r} \operatorname{curl} v \cdot \operatorname{curl} \psi - k^2 v \cdot \psi \right] dx = \int_{\mathbb{R}^3} f \cdot \operatorname{curl} \psi dx \quad (76)$$

for all $\psi \in H(\operatorname{curl}, \mathbb{R}^3)$ with compact support. For any domain Ω , the Sobolev space $H(\operatorname{curl}, \Omega)$ is the space of all vector fields $v \in L^2(\Omega)^3$ such that also $\operatorname{curl} v \in L^2(\Omega)^3$. Furthermore, $H_{loc}(\operatorname{curl}, \mathbb{R}^3) = \{v : v|_B \in H(\operatorname{curl}, B) \text{ for all balls } B \subset \mathbb{R}^3\}$.

Outside of the supports of $\varepsilon_r - 1$ and f , the solution satisfies $\operatorname{curl}^2 v - k^2 v = 0$. Taking the divergence of this equation and using the identities $\operatorname{div} \operatorname{curl} = 0$ and $\operatorname{curl}^2 = -\Delta + \operatorname{grad} \operatorname{div}$, this system is equivalent to the pair of equations

$$\Delta v + k^2 v = 0 \text{ and } \operatorname{div} v = 0.$$

Classical interior regularity results (cf. [80] combined with [36]) yield that v is analytic outside of the supports of $\varepsilon_r - 1$ and f . In particular, the radiation condition (74) is well defined.

There are several ways to show the Fredholm property of Eq. (75). We refer to [81] for the treatment by a variational equation with nonlocal boundary conditions or to [73] for a treatment by an integrodifferential equation of Lippmann-Schwinger type.

The question of uniqueness of radiating solutions to (75) is closely related to the validity of the unique continuation principle. It is known to hold for piecewise Hölder-continuously differentiable functions ε_r (see [81]).

As in the case of the Helmholtz equation, every radiating vector field v satisfying $\operatorname{curl}^2 v - k^2 v = 0$ outside of some ball has the asymptotic behavior

$$v(x) = \frac{\exp(ik|x|)}{4\pi|x|} v^\infty(\hat{x}) + \mathcal{O}(|x|^{-2}), \quad |x| \rightarrow \infty,$$

uniformly with respect to $\hat{x} = x/|x| \in S^2$ (see again [36]). The vector field v^∞ is uniquely determined and again called the *far field pattern* of v . It is a tangential vector field, i.e., $v^\infty \in L_t^2(S^2)$ where

$$L_t^2(S^2) = \{w \in L^2(S^2)^3 : w(\hat{x}) \cdot \hat{x} = 0, \hat{x} \in S^2\}.$$

The **inverse problem** is to determine the shape D of the support of the contrast q from the far field pattern $H^\infty(\hat{x}; \hat{\theta}, p)$ for all $\hat{x}, \hat{\theta} \in S^2$ and $p \in \mathbb{C}^3$ with $p \cdot \hat{\theta} = 0$. Because of the linear dependence of H^∞ on p , it is sufficient to know H^∞ only for a basis of two vectors for p . As in impedance tomography, the task of determining only D is rather modest since it is well known that one can even reconstruct q uniquely from this set of data (see [38]). However, the proof of uniqueness is nonconstructive, while the factorization method will provide an explicit characterization of the characteristic function of D which can, e.g., be used for numerical purposes. Also, the factorization method can – with only minor

modifications – be carried over for anisotropic media (as in section “Conducting Obstacles”) where it is well known that ε_r can only be determined up to a smooth change of coordinates.

For the remaining part of this section, we make the following assumption:

Assumption 12. Let $D \subset \mathbb{R}^3$ be a finite union $D = \cup_{i=1}^m D_i$ of bounded domains D_i such that $\overline{D}_i \cap \overline{D}_j = \emptyset$ for $i \neq j$. Furthermore, we assume that the boundaries ∂D_i are Lipschitz continuous and the exterior $\mathbb{R}^3 \setminus \overline{D}$ of \overline{D} is connected. Let $\varepsilon_r \in L^\infty(D)$ be such that the values $\varepsilon_r(x)$ vary in a compact subset of the half disk $\{z \in \mathbb{C} : (\operatorname{Re} z - 1/2)^2 + (\operatorname{Im} z)^2 < 1/4, \operatorname{Im} z \geq 0\}$, and that for every $f \in L^2(\mathbb{R}^3)^3$ with compact support there exists a unique radiating solution of (75).

We extend ε_r by one outside of D and define the contrast by $q = 1 - 1/\varepsilon_r$; thus, $\operatorname{Im} q \geq 0$ and $\operatorname{Re} q \leq -\gamma|q|$ on D for some $\gamma > 0$.

Condition (3) is, e.g., satisfied for Hölder-continuously differentiable parameters ε and σ (see [81]).

The far field operator $F : L_t^2(S^2) \rightarrow L_t^2(S^2)$ is defined as

$$(Fp)(\hat{x}) := \int_{S^2} H^\infty(\hat{x}; \theta, p(\theta)) ds(\theta), \quad \hat{x} \in S^2. \quad (77)$$

F is a linear operator since H^∞ depends linearly on the polarization p .

The first step in the factorization method is to derive a factorization of F in the form $F = AT^*A^*$ where the operators $A : L^2(D)^3 \rightarrow L_t^2(S^2)$ and $T : L^2(D)^3 \rightarrow L^2(D)^3$ are defined as follows.

The data-to-pattern operator $A : L^2(D)^3 \rightarrow L_t^2(S^2)$ is defined by $Af := v^\infty$, where v^∞ denotes the far field pattern corresponding to the radiating (variational) solution $v \in H_{loc}(\operatorname{curl}, \mathbb{R}^3)$ of

$$\operatorname{curl} \left[\frac{1}{\varepsilon_r} \operatorname{curl} v \right] - k^2 v = \operatorname{curl} \left[\frac{q}{\sqrt{|q|}} f \right] \quad \text{in } \mathbb{R}^3. \quad (78)$$

Again, the contrast is given by $q = 1 - 1/\varepsilon_r$. We note that the solution exists by part (3) of Assumption 12.

The operator $T : L^2(D)^3 \rightarrow L^2(D)^3$ is defined by $Tf = (\operatorname{sign} \bar{q})f - \sqrt{|q|} \operatorname{curl} w|_D$, where $w \in H_{loc}(\operatorname{curl}, \mathbb{R}^3)$ is the radiating solution of

$$\operatorname{curl}^2 w - k^2 w = \operatorname{curl} \left[\sqrt{|q|} f \right] \quad \text{in } \mathbb{R}^3. \quad (79)$$

The solution exists and is unique (see, e.g., [73]).

Theorem 15. Let Assumption 12 hold. Then F from (77) can be factorized as

$$F = AT^*A^*, \quad (80)$$

where $A^* : L_t^2(S^2) \rightarrow L^2(D)^3$ and $T^* : L^2(D)^3 \rightarrow L^2(D)^3$ denote the adjoints of A and T , respectively. Furthermore, A^* is injective.

For a proof of this and the following result, we refer to [73].

Remark 3. The solution w of (79) can be expressed in the form (see [73])

$$w(x) = \operatorname{curl} \int_D \sqrt{|q(y)|} f(y) \Phi(x, y) dy, \quad x \in \mathbb{R}^3,$$

which yields an explicit expression of T .

The following theorem corresponds to Theorem 11 and collects properties of the operator T needed for the analysis of the factorization method.

Theorem 16. *Let the conditions of Assumption 12 hold, and let $T : L^2(D)^3 \rightarrow L^2(D)^3$ be defined above. Then the following holds:*

(a) *The imaginary part $\operatorname{Im} T = \frac{1}{2i}(T - T^*)$ is non-positive, i.e.,*

$$\operatorname{Im}(Tf, f)_{L^2(D)^3} \leq 0 \quad \text{for all } f \in L^2(D)^3.$$

- (b) *Define the operator T_0 in the same way as T but for $k = i$. Then $-\operatorname{Re} T_0$ is coercive, and $T - T_0$ is compact in $L^2(D)^3$.*
(c) *T is an isomorphism from $L^2(D)^3$ onto itself.*

As in section ‘‘Inverse Acoustic Scattering by a Sound-Soft Obstacle’’ we first characterize the domain D by the range $\mathcal{R}(A)$ of A . The proof of the following result can again be found in [73].

Theorem 17. *Let the conditions of Assumption 12 hold. For any $z \in \mathbb{R}^3$ and fixed $p \in \mathbb{C}^3$, we define $\phi_z \in L_t^2(S^2)$ as the far field pattern of the electric dipole at z with moment p , i.e.,*

$$\phi_z(\hat{x}) = -ik(\hat{x} \times p) \exp(-ik\hat{x} \cdot z), \quad \hat{x} \in S^2. \quad (81)$$

Then z belongs to D , if and only if $\phi_z \in \mathcal{R}(A)$.

In contrast to the data operators $\Lambda_0 - \Lambda_1$ or $\Lambda - \Lambda_1$ of Sect. 2 or the far field operator F of section ‘‘Inverse Acoustic Scattering by a Sound-Soft Obstacle’’, the far field operator for absorbing media – as in the present case – fails to be normal or even self-adjoint. Therefore, the approaches of the previous sections – i.e., the application of the range identities of Corollaries 4 and 5 – are not applicable. However, application of Theorem 27 to the far field operator F from $L_t^2(S^2)$ into itself and the operator $G = T^* : L^2(D)^3 \rightarrow L^2(D)^3$ yields the characterization of D via an auxiliary operator

$$F_{\#} = |\operatorname{Re} F| + \operatorname{Im} F, \quad (82)$$

cf. (109), which is easily obtained from the given far field data.

Theorem 18. *Let the conditions of Assumption 12 hold. For any $z \in \mathbb{R}^3$, define again $\phi_z \in L_t^2(S^2)$ by (81). Then, with $F_{\#}$ of (82), there holds*

$$z \in D \iff \phi_z \in \mathcal{R}(F_{\#}^{1/2}) \iff \sum_j \frac{|(\phi_z, \psi_j)_{L^2(S^2)}|^2}{|\lambda_j|} < \infty. \quad (83)$$

Here, $\lambda_j \in \mathbb{C}$ are the eigenvalues of the self-adjoint and positive compact operator $F_{\#}$ with corresponding normalized eigenfunctions $\psi_j \in L_t^2(S^2)$.

Historical Remarks and Open Questions

Historically, the factorization method originated from the linear sampling method which will be explained in section “The Linear Sampling Method” (see also section “The Linear Sampling Method” in chapter ▶ [Inverse Scattering](#)). The linear sampling method studies the *far field equation* $Fg = \phi_z$ in contrast to the factorization method which characterizes the domain D by *exactly* those points z for which the modified far field equation $F_{\#}^{1/2}g = \phi_z$ is solvable where $F_{\#} = (F^*F)^{1/2}$ in the case of section “Inverse Acoustic Scattering by a Sound-Soft Obstacle” and $F_{\#} = |\operatorname{Re} F| + \operatorname{Im} F$ in the case of section “Inverse Electromagnetic Scattering by an Inhomogeneous Medium.” It is easily seen that the points for which the far field equation $Fg = \phi_z$ is solvable determines only a subset of D – which can consist of a single point only, as the example of a ball shows.

The implementation of the factorization method is as simple and universal as of the linear sampling method. Only the far field operator F – i.e., in practice a finite-dimensional approximation – has to be known. No other a priori information on the unknown domain D such as the number of components or the kind of boundary condition has to be known in advance. The mathematical justification, however, has to be proven for every single situation. Since their first presentations, the factorization method has been justified for several problems in inverse acoustic and electromagnetic scattering theory such as the scattering by inhomogeneous media [67, 69, 72, 73], scattering by periodic structures [11, 12], and scattering by obstacles under different kinds of boundary conditions [49, 73]. The factorization method can also be adapted for scattering problems for a crack [74] with certain modifications; we refer to the remarks concerning the crack problem in section “Other Generalizations.” The factorization method for elastic scattering problems and wave guides is studied in [9] and [30], respectively.

In many situations near field measurements on some surface Γ for point sources on the same surface Γ as incident fields rather than far field measurements for plane waves as incident fields are available. The corresponding “near field operator” M :

$L^2(\Gamma) \rightarrow L^2(\Gamma)$ allows a factorization in the form $M = BGB'$ where B' is the adjoint with respect to the bilinear form $\int_{\Gamma} uvds$ rather than the (sesquilinear) inner product $\int_{\Gamma} u\bar{v}ds$. The validity of the range identity for these kinds of factorizations is not known so far and is one of the open problems in this field. For certain situations (see [73]), the corresponding far field operator F can be computed from M , and the factorization method can then be applied to F .

Also the cases where the background medium is more complicated than the free space can be treated (see [48, 73] for scattering problems in a half space and [71] for scattering problems in layered media).

The justification of the factorization method for arbitrary elliptic boundary value problems or even more general problems is treated in [44, 70, 82].

4 Related Sampling Methods

This section is devoted to some alternate examples of sampling methods which were developed during the last decade: the *linear sampling method*, first introduced by Colton and Kirsch in [35], the closely related *MUSIC*, the *singular sources method* by Potthast (see [85]), and Ikehata's *probe method* (see [62]). However, it is not the aim of this section to report on all sampling methods. In particular, we do not discuss the *enclosure method* or the *no-response test* but refer to the monograph [86] and the survey article [87].

The Linear Sampling Method

Here we reconsider the inverse scattering problem for time-harmonic plane acoustic waves of section “Inverse Acoustic Scattering by a Sound-Soft Obstacle,” i.e., the problem to determine the shape of an acoustically soft obstacle D from the knowledge of the far field pattern $u^\infty(\hat{x}; \hat{\theta})$ for all $\hat{x}, \hat{\theta} \in S^2$. We refer to (42)–(47) for the mathematical model and the definition of the far field operator F from $L^2(S^2)$ into itself.

The factorization method for inverse scattering problems studies solvability of the equation $F_\#^{1/2}g = \phi_z$ in $L^2(S^2)$ where $F_\# = (F^*F)^{1/2}$ in the case where F is normal (as, e.g., in section “Inverse Acoustic Scattering by a Sound-Soft Obstacle”) and $F_\# = |\operatorname{Re} F| + \operatorname{Im} F$ in the general case with absorption (see Theorems 14 and 18, respectively). In contrast to this equation, the *linear sampling method* considers the *far field equation*

$$Fg = \phi_z \quad \text{in } L^2(S^2). \tag{84}$$

We mention again that in general no solution of this equation exists. However, one can compute “approximate solutions” $g = g_{z,\epsilon}$ of (84) such that $\|g\|_{L^2(S^2)}$ behaves differently for z being inside or outside of D . We refer to chapter ▶ [Inverse Scattering](#), Theorem 5.3, for a more precise formulation of this behavior.

The drawback of this result – and all the other attempts to justify the linear sampling method rigorously – is that there is no guarantee that the solution of a regularized version of (84), e.g., by Tikhonov regularization, will actually pick the density $g = g_{z,\varepsilon}$ with the properties of the aforementioned “approximate solution.” We refer to [53] for a discussion of this fact. However, numerically the method has proven to be very effective for a large class of inverse scattering problems (see, e.g., [26] for the scattering by cracks, [27] for inverse scattering problems for anisotropic media, [19] for wave guide scattering problems, [33, 34, 51] for electromagnetic scattering problems, and [29, 31, 40] for elastic scattering problems). Modifications of the linear sampling method and combinations with other methods can be found in [8, 20, 79].

For the cases in which the factorization method in the form $(F^*F)^{1/4}g = \phi_z$ is applicable, a complete characterization of the unknown obstacle D by a modification of the linear sampling method can be derived by replacing the indicator value $\|g\|_{L^2(S^2)}$ by $(g, \phi_z)_{L^2(S^2)}$. This is summarized in the following theorem (see [10, 13] and, for the following presentation, [73]).

Theorem 19. *Let $u^\infty = u^\infty(\hat{x}; \hat{\theta})$ be the far field pattern corresponding to the scattering problem (42)–(45) with associated far field operator F , and assume that k^2 is not a Dirichlet eigenvalue of $-\Delta$ in D . Furthermore, for every $z \in D$, let $g_z \in L^2(S^2)$ denote the solution of $(F^*F)^{1/4}g_z = \phi_z$, i.e., the solution obtained by the factorization method, and for every $z \in \mathbb{R}^3$ and $\varepsilon > 0$, let $g = g_{z,\varepsilon} \in L^2(S^2)$ be the Tikhonov approximation of (84), i.e., the unique solution of*

$$(\varepsilon I + F^*F)g = F^*\phi_z \quad (85)$$

which is computed by the linear sampling method (if Tikhonov’s regularization technique is chosen). Here, $\phi_z \in L^2(S^2)$ is defined in (55). Furthermore, let $v_{g_{z,\varepsilon}}(z) = (g_{z,\varepsilon}, \phi_z)_{L^2(S^2)} = \int_{S^2} g_{z,\varepsilon}(\hat{\theta}) \exp(i k \hat{\theta} \cdot z) d\hat{\theta}$ denote the corresponding Herglotz wave function evaluated at z .

- (a) For every $z \in D$, the limit $\lim_{\varepsilon \rightarrow 0} v_{g_{z,\varepsilon}}(z)$ exists. Furthermore, there exists $c > 0$, depending on F only, such that for all $z \in D$ the following estimates hold:

$$c \|g_z\|_{L^2(S^2)}^2 \leq \lim_{\varepsilon \rightarrow 0} |v_{g_{z,\varepsilon}}(z)| \leq \|g_z\|_{L^2(S^2)}^2. \quad (86)$$

- (b) For $z \notin D$, the absolute values $|v_{g_{z,\varepsilon}}(z)|$ tend to infinity as ε tends to zero.

Proof. Using an orthonormal system $\{\psi_j : j \in \mathbb{N}\}$ of eigenfunctions ψ_j corresponding to eigenvalues $\lambda_j \in \mathbb{C}$ of F , one computes the Tikhonov approximation $g_{z,\varepsilon}$ from (85) as

$$g_{z,\varepsilon} = \sum_{j=1}^{\infty} \frac{\overline{\lambda_j}}{|\lambda_j|^2 + \varepsilon} (\phi_z, \psi_j)_{L^2(S^2)} \psi_j.$$

From $v_g(z) = (g, \phi_z)_{L^2(S^2)}$ for any $g \in L^2(S^2)$, we conclude that

$$v_{g_{z,\varepsilon}}(z) = \sum_{j=1}^{\infty} \frac{\overline{\lambda_j}}{|\lambda_j|^2 + \varepsilon} |(\phi_z, \psi_j)_{L^2(S^2)}|^2. \quad (87)$$

- (a) Let now $z \in D$. Then $(F^* F)^{1/4} g_z = \phi_z$ is solvable in $L^2(S^2)$ by Theorem 14, and thus $(\phi_z, \psi_j)_{L^2(S^2)} = ((F^* F)^{1/4} g_z, \psi_j)_{L^2(S^2)} = (g_z, (F^* F)^{1/4} \psi_j)_{L^2(S^2)} = \sqrt{|\lambda_j|} (g_z, \psi_j)_{L^2(S^2)}$.

Therefore, we can express $v_{g_{z,\varepsilon}}(z)$ as

$$v_{g_{z,\varepsilon}}(z) = \sum_{j=1}^{\infty} \frac{\overline{\lambda_j} |\lambda_j|}{|\lambda_j|^2 + \varepsilon} |(g_z, \psi_j)_{L^2(S^2)}|^2 = \|g_z\|_{L^2(S^2)}^2 \sum_{j=1}^{\infty} \rho_j \frac{\overline{\lambda_j} |\lambda_j|}{|\lambda_j|^2 + \varepsilon}, \quad (88)$$

where $\rho_j = |(g_z, \psi_j)_{L^2(S^2)}|^2 / \|g_z\|_{L^2(S^2)}^2$ is nonnegative with $\sum_j \rho_j = 1$. An elementary argument (theorem of dominated convergence) yields convergence

$$\sum_{j=1}^{\infty} \rho_j \frac{\overline{\lambda_j} |\lambda_j|}{|\lambda_j|^2 + \varepsilon} \rightarrow \sum_{j=1}^{\infty} \rho_j \frac{\overline{\lambda_j}}{|\lambda_j|} = \sum_{j=1}^{\infty} \rho_j \overline{s_j}$$

as ε tends to zero where again $s_j = \lambda_j / |\lambda_j|$. The properties of ρ_j imply that the limit belongs to the closure \mathcal{C} of the convex hull of the complex numbers $\{s_j : j \in \mathbb{N}\}$. The same argument as in the proof of Theorem 13 yields that \mathcal{C} has a positive distance c from the origin, i.e., $\left| \sum_{j=1}^{\infty} \rho_j \overline{s_j} \right| \geq c$ which proves the lower bound. The upper estimate is seen directly from (88).

- (b) Let now $z \notin D$, and assume on the contrary that there exists a sequence $\{\varepsilon_n\}$ which tends to zero and such that $|v_{\varepsilon_n}(z)|$ is bounded. Here we have set $v_n = v_{g_{z,\varepsilon_n}}$ for abbreviation. Since s_j converges to 1, there exists $j_0 \in \mathbb{N}$ with $\operatorname{Re} \lambda_j > 0$ for $j \geq j_0$. From (87) for $\varepsilon = \varepsilon_n$, we get

$$v_n(z) = \sum_{j=1}^{j_0-1} \frac{\overline{\lambda_j}}{|\lambda_j|^2 + \varepsilon_n} |(\phi_z, \psi_j)_{L^2(S^2)}|^2 + \sum_{j=j_0}^{\infty} \frac{\overline{\lambda_j}}{|\lambda_j|^2 + \varepsilon_n} |(\phi_z, \psi_j)_{L^2(S^2)}|^2.$$

Since the finite sum is certainly bounded for $n \in \mathbb{N}$, there exists $c_1 > 0$ such that

$$\left| \sum_{j=j_0}^{\infty} \frac{\lambda_j}{|\lambda_j|^2 + \varepsilon_n} |(\phi_z, \psi_j)_{L^2(S^2)}|^2 \right| \leq c_1 \quad \text{for all } n \in \mathbb{N}.$$

Observing that for any complex number $w \in \mathbb{C}$ with $\operatorname{Re} w \geq 0$ and $\operatorname{Im} w \geq 0$ we have that $\operatorname{Re} w + \operatorname{Im} w \geq |w|$, we conclude (note that also $\operatorname{Im} \lambda_j > 0$)

$$\begin{aligned} 2c_1 &\leq 2 \left| \sum_{j=j_0}^{\infty} \frac{\lambda_j}{|\lambda_j|^2 + \varepsilon_n} |(\phi_z, \psi_j)_{L^2(S^2)}|^2 \right| \geq \sum_{j=j_0}^{\infty} \frac{\operatorname{Re} \lambda_j + \operatorname{Im} \lambda_j}{|\lambda_j|^2 + \varepsilon_n} |(\phi_z, \psi_j)_{L^2(S^2)}|^2 \\ &\geq \sum_{j=j_0}^{\infty} \frac{|\lambda_j|}{|\lambda_j|^2 + \varepsilon_n} |(\phi_z, \psi_j)_{L^2(S^2)}|^2 \geq \sum_{j=j_0}^J \frac{|\lambda_j|}{|\lambda_j|^2 + \varepsilon_n} |(\phi_z, \psi_j)_{L^2(S^2)}|^2 \end{aligned}$$

for all $n \in \mathbb{N}$ and all $J \geq j_0$. Letting n tend to infinity yields boundedness of the finite sum uniformly w.r.t. J and thus convergence of the series $\sum_{j=j_0}^{\infty} \frac{1}{|\lambda_j|} |(\phi_z, \psi_j)_{L^2(S^2)}|^2$. From (62) therefore follows that $z \in D$, which is the desired contradiction. ■

Obviously, this kind of modification of the original linear sampling method can be done for all inverse scattering problems for which Theorem 14 holds. This includes scattering by acoustically hard obstacles or inhomogeneous nonabsorbing media or, with appropriate modifications, scattering by open arcs.

MUSIC

The linear sampling method investigates “to what extent” the far field equation

$$Fg = \phi_z$$

is solvable for a number of sampling points z within some region of interest. As we have mentioned before, this equation has a solution in very rare cases only and usually not for every $z \in D$.

However, if the obstacle is very small, then it turns out that the far field operator almost degenerates to a finite rank operator, in which case the “numerical range” of F and $(F^* F)^{1/4}$ would be the same finite-dimensional subspace, where the latter is known to contain ϕ_z for every $z \in D$ – under appropriate assumptions on the particular problem setting (see Sects. 2 and 3).

To investigate this observation in more detail, we embed the real scene in a parameterized family of problems, where the parameter $\delta > 0$ reflects the scale of the problem. Assume that the scatterer $D = \cup_{i=1}^m D_i$ consists of m obstacles given as

$$D_i = z_i + \delta U_i \quad i = 1, \dots, m, \tag{89}$$

where each domain U_i contains the origin and has Lipschitz continuous boundary and the closure of U_i has a connected complement. We shall call z_i the *location*

of D_i and U_i its *shape*. We focus our presentation on an inhomogeneous medium setting for acoustic scattering, i.e., the Helmholtz equation, to provide analogies to both settings from Sect. 3. Let ρ_0 and c_0 be the density and the speed of sound in vacuum, $k = \omega/c_0$ be the associated wave number with frequency ω , and $u^i(x) = \exp(ikx \cdot \hat{\theta})$ be an incoming plane wave. Then, if we assume that the density ρ_i and the sound of speed c_i in each object D_i are real and constant, then the total field $u_\delta = u^i + u_\delta^s$ solves the Helmholtz equation (see, e.g., [36])

$$\operatorname{div} \left(\frac{1}{\rho} \operatorname{grad} u_\delta \right) + \omega^2 \eta u_\delta = 0 \quad \text{in } \mathbb{R}^3, \quad (90)$$

with the radiation condition

$$\frac{\partial u_\delta^s}{\partial r} - ik u_\delta^s = \mathcal{O}(r^{-2}) \quad \text{for } r = |x| \rightarrow \infty, \quad (91)$$

uniformly with respect to $\hat{x} = x/|x|$, and the parameter η equals $\eta_0 = 1/\rho_0$ in $\mathbb{R}^3 \setminus \overline{D}$, and $\eta_i = c_0^2/(c_i^2 \rho_i)$ in D_i , $i = 1, \dots, m$, respectively. We mention that for constant $\eta = 1/\rho_0$, it has been shown in [72] that the standard factorization method (with $F_\# = (F^* F)^{1/2}$) applies for this setting with fixed scaling parameter δ . We know of no result, however, where the factorization method is used to reconstruct the supports of $\rho - \rho_0$ and $\eta - \eta_0$ in this setting simultaneously, although there are partial results for a similar problem (in a bounded domain and with a different sign of η) arising in optical tomography, cf. [43, 59].

The idea to approach this problem is based on an asymptotic expansion of the far field u_δ^∞ of the scattered wave with respect to the parameter δ in (89). We quote the following result from [4].

Theorem 20. *The far field of the scattering problem (90) and (91) for the scatterers given in (89) satisfies*

$$\begin{aligned} & u_\delta^\infty(\hat{x}; \hat{\theta}) \\ &= \delta^3 k^2 \sum_{i=1}^m \left(\left(\frac{\rho_i}{\rho_0} - 1 \right) \hat{x} \cdot M_i \hat{\theta} - \left(\frac{\eta_i}{\eta_0} - 1 \right) |U_i| \right) \exp(ik(\hat{\theta} - \hat{x}) \cdot z_i) + o(\delta^3), \end{aligned} \quad (92)$$

and the associated far field operator can be rewritten as

$$F = \delta^3 \hat{F} + o(\delta^3) \quad (93)$$

in the norm of $\mathcal{L}(L^2(S^2))$, where the rank of the operator \hat{F} is at most $4m$. Here, $|U_i|$ is the Lebesgue measure of U_i , and $M_i \in \mathbb{R}^{3 \times 3}$ are symmetric positive definite matrices that depend on the shape U_i , the so-called polarization tensors.

As is obvious, the scattered field and its far field vanish as $\delta \rightarrow 0$. The corresponding rate δ^3 reflects the space dimension; in \mathbb{R}^2 , the corresponding field decays like δ^2 as $\delta \rightarrow 0$.

The importance of Theorem 20 stems from the fact that the leading order approximation \hat{F} of the far field operator F has finite rank, whereas F has infinite dimensional range. The rank of \hat{F} is $4m$, unless some of the scatterers have the same material parameters as the background vacuum. Note that the dominating term of u_δ^∞ consists of two parts: the first contribution stems from the change in the density ρ and corresponds to the far field of a dipole (point source) in z_i ; likewise, the second term corresponds to the far field of a monopole in z_i , and this is the result of a change in the parameter η .

It is easy to deduce from Theorem 20 that we can factorize \hat{F} quite naturally in three factors.

Theorem 21. *The operator $\hat{F} : L^2(S^2) \rightarrow L^2(S^2)$ admits a factorization of the form*

$$\hat{F} = -BMB', \quad (94)$$

where $B : \mathbb{C}^{4m} \rightarrow L^2(S^2)$ maps a vector $[p_1, \dots, p_m, a_1, \dots, a_m]^T \in \mathbb{C}^{4m}$ with $p_i \in \mathbb{C}^3$ and $a_i \in \mathbb{C}$, $i = 1, \dots, m$, to the far field of

$$u(x) = \sum_{i=1}^m (p_i \cdot \text{grad}_z \Phi(x, z_i) + a_i \Phi(x, z_i)),$$

where Φ is as in (51), $M \in \mathbb{R}^{4m \times 4m}$ is a real block diagonal matrix with m blocks of size 3×3 and m single elements on its diagonal, and M is nonsingular, if and only if $\rho_i \neq \rho_0$ and $\eta_i \neq \eta_0$ for all $i = 1, \dots, m$. The operator B' is the dual operator of B with respect to the bilinear forms of \mathbb{C}^{4m} and $L^2(S^2)$, i.e., $B'g$ consists of the gradients and point values of the Herglotz wave function

$$v_g(x) = \int_{S^2} g(\hat{\theta}) \exp(i k x \cdot \hat{\theta}) d\hat{\theta}, \quad x \in \mathbb{R}^3,$$

evaluated at the points z_i , $i = 1, \dots, m$.

As M in (94) is invertible, the range of \hat{F} and the range of B coincide, and it consists of the far fields of the monopoles and all possible dipoles emanating from the locations z_i of D_i , $i = 1, \dots, m$. Using the unique continuation principle, we can thus conclude the following result.

Corollary 2. *If each scatterer has a different parameter η than the background medium, then a point $z \in \mathbb{R}^3$ is the location z_i of one of the scatterers, if and only if ϕ_z of (55) belongs to the range of \hat{F} .*

When δ is small, it follows from (93) that numerically the range of F and the range of \hat{F} are the same, essentially. By this we mean that the dominating $4m$ singular values of F are small perturbations of the nonzero singular values of \hat{F} , and the corresponding singular subspaces are also close to each other. Moreover, we expect to see a sharp gap between the $4m$ th and the $4m + 1$ st singular value of F . We can search for this gap to determine the number m of the scatterers and then determine the angle between the test function ϕ_z and the $4m$ -dimensional dominating singular subspace of F . When z is close to the location of one of the scatterers, then this angle will be small, otherwise this angle will be larger. This way images can be produced that enable one to visualize the approximate locations of the scatterers, but not their shape.

This approach applies for all problem settings that have been discussed in Sects. 2 and 3 and many more. In impedance tomography, for example, the corresponding asymptotic expansion of the boundary potential has the form

$$u_\delta(x) - u_1(x) = \delta^n \sum_{i=1}^m \frac{1 - \kappa_i}{\kappa_i} \operatorname{grad}_z N(x, z_i) \cdot M_i \operatorname{grad} u_1(z_i) + o(\delta^n), \quad x \in \partial\Omega \quad (95)$$

where n is again the space dimension, N the Neumann function (7), and M_i the associated polarization tensor, cf. [28] or section “Asymptotic Analysis of the Voltage Perturbations” in chapter ▶ Expansion Methods. The leading order approximation of the difference between the associated Neumann-Dirichlet operators, $\Lambda_\delta - \Lambda_1$, can be factorized in a similar way as in Theorem 21 and has an nm -dimensional range that is spanned by dipole potentials sitting in the locations z_i of the obstacles D_i , $i = 1, \dots, m$; recall that n is the space dimension.

For the full Maxwell’s equations considered in section “Inverse Electromagnetic Scattering by an Inhomogeneous Medium,” the range space of the corresponding far field operator F of (77) consists of the magnetic far fields corresponding to electric dipoles at the infinitesimal scatterers; if the scatterers also differ in their magnetic permeability, then the range space also contains the far fields of the magnetic dipoles in z_i , $i = 1, \dots, m$.

The method described above for reconstructing the locations of small scatterers is often called *MUSIC* in the inverse problems community. Originally, the MUSIC algorithm is a signal processing tool for frequency estimation from the noisy spectrum of some signal (MUSIC stands for MULTiple SIgnal Classification.), cf., e.g., [90]. In a seminal report (Devaney, Super-resolution processing of multi-static data using time reversal and MUSIC. Unpublished manuscript, 2000), this algorithm was suggested to detect “point scatterers” on the basis of the Born approximation, which led to an algorithm that is not exactly the same, but related to the one we have sketched above. The relation between this algorithm and the factorization method has subsequently been recognized in [32, 69]. However, although the form of the factorization (94) is similar to the ones for the factorization method derived in Sects. 2 and 3, it is slightly different in its precise interpretation; this has been

exemplified in [2] by taking the limit of each of the factors from Theorem 4 as $\delta \rightarrow 0$.

The derivation of asymptotic formulas as in Theorem 20 goes back to the landmark paper [41]. In [24], formula (95) from [28] was used to provide the rigorous foundation of the MUSIC-type algorithm from above. Important extensions and generalizations to other problem settings include [1, 4, 7, 46, 91]; for a more detailed survey and further references, we refer to chapter ▶ Expansion Methods and the monographs [5, 6].

Numerical illustrations of this approach can be found in various papers (see, e.g., [3, 24, 46]).

The Singular Sources Method

As in section “Inverse Acoustic Scattering by a Sound-Soft Obstacle,” we reconsider the simple inverse scattering problem for the Helmholtz equation in \mathbb{R}^3 to determine the shape of an acoustically soft obstacle D from the knowledge of the far field pattern $u^\infty(\hat{x}; \hat{\theta})$ for all $\hat{x}, \hat{\theta} \in S^2$. We refer again to (42)–(47) for the mathematical model and the definition of the far field operator F from $L^2(S^2)$ into itself. Note that again $u^s = u^s(x; \hat{\theta})$ and $u^\infty = u^\infty(\hat{x}; \hat{\theta})$ denote the scattered field and far field pattern, respectively, corresponding to the incident plane wave of direction $\hat{\theta} \in S^2$.

The basic tool in the *singular sources method* is to consider also the scattered field $v^s = v^s(x; z)$ which corresponds to the incident field $v^i(x) = \Phi(x, z)$ of (51) of a point source, where $z \notin \overline{D}$ is a given point. The scattered field $v^s(z; z)$ evaluated at the source point blows up when z tends to a boundary point. One can prove (see [73, 86]) that there exists a constant $c > 0$ (depending on D and k only) such that

$$|v^s(z; z)| \geq \frac{c}{d(z, \partial D)} \quad \text{for all } z \notin \overline{D}. \quad (96)$$

Here, $d(z, \partial D) = \inf \{|z - y| : y \in \partial D\}$ denotes the distance of z to the boundary of D .

The idea of the singular sources method is to fix $z \notin \overline{D}$ and $\varepsilon > 0$ and a bounded domain $G_z \subset \mathbb{R}^3$ such that its exterior is connected and $z \notin \overline{G_z}$ and $\overline{D} \subset G_z$. Runge’s approximation theorem (see, e.g., [73]) yields the existence of $g \in L^2(S^2)$ depending on z , G_z and ε such that

$$\|v_g - \Phi(\cdot, z)\|_{C(\overline{G_z})} \leq \varepsilon, \quad (97)$$

where v_g denotes the Herglotz wave function, defined by

$$v_g(x) = \int_{S^2} g(\hat{\theta}) \exp(i k x \cdot \hat{\theta}) d\sigma(\hat{\theta}), \quad x \in \mathbb{R}^3.$$

In the following, only the dependence on ε is indicated by writing g_ε . The following convergence result for the Singular Sources Method is known (see [73, 86]).

Theorem 22. *Let $u^\infty = u^\infty(\hat{x}; \hat{\theta})$, $\hat{x}, \hat{\theta} \in S^2$ be the far field pattern of the scattering problem (43–45). Fix $z \notin \overline{D}$ and a bounded domain $G_z \subset \mathbb{R}^3$ such that its exterior is connected and $z \notin \overline{G_z}$ and $\overline{D} \subset G_z$. For any $\varepsilon > 0$, choose $g = g_\varepsilon \in L^2(S^2)$ with (97). Then*

$$\lim_{\delta \rightarrow 0} \lim_{\varepsilon \rightarrow 0} \int_{S^2} (Fg_\varepsilon)(-\hat{\theta}) g_\delta(\hat{\theta}) d\sigma(\hat{\theta}) = v^s(z; z),$$

i.e., by substituting the form of F ,

$$\lim_{\delta \rightarrow 0} \lim_{\varepsilon \rightarrow 0} \int_{S^2} \int_{S^2} u^\infty(-\hat{\theta}; \hat{\eta}) g_\varepsilon(\hat{\eta}) g_\delta(\hat{\theta}) d\sigma(\hat{\eta}) d\sigma(\hat{\theta}) = v^s(z; z).$$

Note that the limits are iterated, i.e., first the limit w.r.t. ε has to be taken and then the limit w.r.t. δ .

Combining this result with (96) yields

$$\lim_{\delta \rightarrow 0} \lim_{\varepsilon \rightarrow 0} \left| \int_{S^2} \int_{S^2} u^\infty(-\hat{\theta}; \hat{\eta}) g_\varepsilon(\hat{\eta}) g_\delta(\hat{\theta}) d\sigma(\hat{\eta}) d\sigma(\hat{\theta}) \right| \geq \frac{c}{d(z, \partial D)}. \quad (98)$$

This result assures that for z sufficiently close to the boundary ∂D (and regions G_z chosen appropriately) the quantity

$$\lim_{\delta \rightarrow 0} \lim_{\varepsilon \rightarrow 0} \left| \int_{S^2} \int_{S^2} u^\infty(-\hat{\theta}; \hat{\eta}) g_\varepsilon(\hat{\eta}) g_\delta(\hat{\theta}) d\sigma(\hat{\eta}) d\sigma(\hat{\theta}) \right|$$

becomes large.

It is convenient to use domains G_z of the special form

$$G_{z,p} = (z + \rho p) + \left\{ x \in \mathbb{R}^3 : |x| < R, \frac{x}{|x|} \cdot p > -\cos \beta \right\}$$

for some (large) radius $R > 0$, opening angle $\beta \in [0, \pi/2]$, direction of opening $p \in S^2$, and $\rho > 0$. The dependence on β , ρ , and R is not indicated since they are kept fixed. This domain $G_{z,p}$ is a ball centered at $z + \rho p$ with radius R from which the cone of direction $-p$ and opening angle β have been removed. Obviously, it is chosen such that $z \notin \overline{G_{z,p}}$. These sets $G_{z,p}$ are translations and rotations of the reference set

$$\hat{G} = \left\{ x \in \mathbb{R}^3 : |x| < R, \frac{x}{|x|} \cdot \hat{p} > -\cos \beta \right\}$$

for $\hat{p} = (0, 0, 1)^T$, i.e., $G_{z,p} = z + M\hat{G}$ for some orthogonal $M \in \mathbb{R}^{3 \times 3}$.

With these transformations, we can consider the singular sources method as a sampling method with sampling objects z and M .

From the arguments used in the proof of Theorem 22, it is not clear whether or not the common limit $\lim_{\varepsilon, \delta \rightarrow 0}$ exists. However, if k^2 is not a Dirichlet eigenvalue of $-\Delta$ in D , then the following stronger result than (49) can be obtained by using the factorization (49).

Theorem 23. *Let $z \notin \overline{D}$ and $G_z \subset \mathbb{R}^3$ be a bounded domain such that its exterior is connected and $z \notin \overline{G_z}$ and $\overline{D} \subset G_z$. For any $\varepsilon > 0$, choose $g_\varepsilon \in L^2(S^2)$ with (97) with respect to the H^1 -norm, i.e.,*

$$\|v_{g_\varepsilon} - \Phi(\cdot, z)\|_{H^1(G_z)} \leq \varepsilon.$$

Assume furthermore that k^2 is not a Dirichlet eigenvalue of $-\Delta$ in D . Then there exists a constant $c > 0$ depending only on D and k such that

$$\left| \lim_{\varepsilon \rightarrow 0} \int_{S^2} \int_{S^2} u^\infty(\hat{\theta}; \hat{\eta}) g_\varepsilon(\hat{\eta}) \overline{g_\varepsilon(\hat{\theta})} d\hat{s}(\hat{\eta}) d\hat{s}(\hat{\theta}) \right| = \lim_{\varepsilon \rightarrow 0} |(Fg_\varepsilon, g_\varepsilon)_{L^2(S^2)}| \geq \frac{c}{d(z, \partial D)}.$$

For a proof we refer to [73]. Numerical reconstructions with the Singular Sources Methods are shown in [86].

The Probe Method

The *probe method* has originally been proposed in [62] for the inverse problem of impedance tomography of section ‘‘Conducting Obstacles,’’ and here we also restrict our attention to this setting. To be precise, let $\sigma \in L^\infty(\Omega)$ be a (complex valued) admittance function, and define $u \in H_\diamond^1(\Omega)$ as the unique (weak) solution of the boundary value problem

$$\operatorname{div}(\sigma \operatorname{grad} u) = 0 \quad \text{in } \Omega \quad \sigma \frac{\partial}{\partial \nu} u = f \quad \text{on } \partial \Omega \quad \int_{\partial \Omega} u ds = 0, \quad (99)$$

where $f \in L_\diamond^2(\partial \Omega)$. For the spaces $H_\diamond^1(\Omega)$ and $L_\diamond^2(\partial \Omega)$, we refer to section ‘‘Impedance Tomography in the Presence of Insulating Inclusions.’’

As in section ‘‘Conducting Obstacles,’’ we assume that $\sigma \in L^\infty(\Omega)$ is a perturbation of the constant background admittance function $\sigma_1 = 1$. More precisely, let $D \subset \Omega$ be again the finite union of domains such that $\Omega \setminus \overline{D}$ is connected and $\sigma = 1$ in $\Omega \setminus D$, and let there be a constant $c_0 > 0$ such that

$$\operatorname{Im} \sigma(x) \leq 0 \quad \text{and} \quad \operatorname{Re} \sigma(x) \geq 1 + c_0 \quad \text{on } D. \quad (100)$$

The case $0 < c_0 \leq \operatorname{Re} \sigma(x) \leq 1 - c_0$ can be treated in a similar way (see [73]). The unique solvability of the **direct problem**, i.e., the boundary value problem (99), guarantees existence of the *Neumann-to-Dirichlet* operators $\Lambda, \Lambda_{\mathbb{1}} : L^2_{\diamond}(\partial\Omega) \rightarrow L^2_{\diamond}(\partial\Omega)$ corresponding to σ and $\sigma_{\mathbb{1}} = 1$, respectively.

As in section ‘‘Conducting Obstacles,’’ the goal of the **inverse problem** is to determine the support D of $\sigma - 1$ from the knowledge of the absolute data Λ or the relative data $\Lambda - \Lambda_{\mathbb{1}}$. The difference to the setting in section ‘‘Conducting Obstacles’’ is that σ is now a scalar and complex-valued function.

In the probe method, the sampling objects are curves in Ω starting at the boundary $\partial\Omega$ of Ω . In the original paper [62], these curves are called needles. We keep this notation but mention that – perhaps in contrast to the colloquial meaning – these needles do not need to be straight segments but can be curved in general. By choosing a family of needles, the probe method determines the first point on the needle which intersects the boundary ∂D (see Theorem 24 below). Therefore, in contrast to the factorization method and the linear sampling method, the probe method tests on curves instead of points.

Definition 1. A needle \mathcal{C} is the image of a continuously differentiable function $\eta : [0, 1] \rightarrow \overline{\Omega}$ such that $\eta(0) \in \partial\Omega$ and $\eta(t) \in \Omega$ for all $t \in (0, 1]$ and $\eta'(t) \neq 0$ for all $t \in [0, 1]$ and $\eta(t) \neq \eta(s)$ for $t \neq s$. We call η a parameterization of the needle.

The following monotonicity property is the basic ingredient for the Probe Method.

Under the above assumptions on $\sigma \in L^\infty(\Omega)$, there exists $c > 1$ such that

$$\frac{1}{c} \int_D |\operatorname{grad} u_{\mathbb{1}}|^2 dx \leq \operatorname{Re} \langle f, (\Lambda_{\mathbb{1}} - \Lambda) f \rangle \leq c \int_D |\operatorname{grad} u_{\mathbb{1}}|^2 dx \quad (101)$$

for every $f \in L^2_{\diamond}(\partial\Omega)$. Here, $u_{\mathbb{1}} \in H^1_{\diamond}(\Omega)$ denotes the unique solution of (99) for the constant background case $\sigma_{\mathbb{1}} = 1$.

Let $\eta : [0, 1] \rightarrow \overline{\Omega}$ be the parameterization of a given needle, $t \in (0, 1]$ a fixed parameter, and $\mathcal{C}_t = \{\eta(s) : 0 \leq s \leq t\}$ the part of the needle from $s = 0$ to $s = t$. Let $\Phi(x, y)$ denote the fundamental solution of the Laplace equation, e.g.,

$$\Phi(x, y) = \frac{1}{4\pi|x - y|}, x \neq y,$$

in \mathbb{R}^3 . Runge’s approximation theorem (see, e.g., [73]) yields the existence of a sequence $w_n \in H^1(\Omega)$ of harmonic functions in Ω such that

$$\|w_n - \Phi(\cdot, \eta(t))\|_{H^1(U)} \rightarrow 0, \quad n \rightarrow \infty \quad (102)$$

for every open subset U with $\overline{U} \subset \Omega \setminus \mathcal{C}_t$. We set $f_n = \partial w_n / \partial v$ on $\partial\Omega$ and note that f_n depends on \mathcal{C}_t but not on the unknown domain D . The dependence on \mathcal{C}_t is denoted by writing $f_n(\mathcal{C}_t)$. It can – at least in principle – be computed beforehand.

Theorem 24. Let the above assumptions on σ hold and fix a needle with parameterization $\eta : [0, 1] \rightarrow \overline{\Omega}$. Define the set $\mathcal{T} \subset [0, 1]$ by

$$\mathcal{T} = \left\{ t \in [0, 1] : \sup_{n \in \mathbb{N}} \{ |\operatorname{Re} \langle f_n(\mathcal{C}_t), (\Lambda - \Lambda_1) f_n(\mathcal{C}_t) \rangle| < \infty \} \right\}. \quad (103)$$

Here, $f_n(\mathcal{C}_t) = \partial w_n / \partial v \in H^{-1/2}(\partial\Omega)$ is determined from (102) (so far, we have chosen the boundary current f in (99) from $L^2(\partial\Omega)$ for convenience; however, the quadratic form in (103) extends as dual pairing $(H^{-1/2}(\partial\Omega), H^{1/2}(\partial\Omega))$ to $f \in H^{-1/2}(\partial\Omega)$ with vanishing mean). Then $\mathcal{T} \neq \emptyset$, and one can define $t^* = \sup \{t \in [0, 1] : [0, t] \in \mathcal{T}\}$, which satisfies

$$t^* = \begin{cases} \min \{t \in [0, 1] : \eta(t) \in \partial D\}, & \text{if } \mathcal{C}_1 \cap \overline{D} \neq \emptyset \\ 1, & \text{if } \mathcal{C}_1 \cap \overline{D} = \emptyset. \end{cases} \quad (104)$$

We recall that $\mathcal{C}_1 = \mathcal{C} = \{\eta(t) : t \in [0, 1]\}$.

For a proof we refer to [62, 73].

Note that for every needle the set \mathcal{T} of the form (103) is determined by the given data: it depends on η and the approximating functions w_n . Formula (104) provides a constructive way to determine ∂D from $\Lambda - \Lambda_1$: one has to choose a family of needles which cover the domain Ω , and for each needle one computes t^* as the largest point of \mathcal{T} ; if $t^* < 1$, then $\eta(t^*) \in \partial D$. Obviously, this procedure is very expensive from a computational point of view. However, if one samples with “linear” needles only, i.e., rays of the form $\mathcal{C} = \{z + tp : t \geq 0\} \cap \Omega$ for $z \in \Omega$ and unit vectors $p \in S^2$, then the computational effort can be reduced considerably since the approximating sequence (102) has to be computed only once for a reference needle. However, by using only rays as needles, one can not expect to detect the boundary of D completely. Only the “visible points” of ∂D can be detected, i.e., those which can be connected completely in $\Omega \setminus \overline{D}$ by straight lines to $\partial\Omega$.

In an implementation of the definition of \mathcal{T} of (103), one has to decide whether a supremum is finite or infinite. Numerically, this is certainly not an easy task. In [62], it has been suggested to replace \mathcal{T} of (103) by

$$\mathcal{T}_M = \{t \in [0, 1] : \sup_{n \in \mathbb{N}} \{ |\operatorname{Re} \langle f_n(\mathcal{C}_t), (\Lambda - \Lambda_1) f_n(\mathcal{C}_t) \rangle| \leq M \} \}$$

for some $M > 0$, for which a result analogously to the one in Theorem 24 can be established. We refer to [62] for more details.

Again, the probe method is general enough to have extensions to a number of related inverse problems in elasticity (see [63]) and scattering theory (see [61]). For numerical reconstructions, we refer to [87].

5 Conclusion

This chapter has considered a very general approach to identify obstacles within a homogeneous background. The method requires the underlying physics to be described by an elliptic differential equation and utilizes the fact that signals become smoother the longer they travel through the homogeneous material.

This technique has been exemplified for two model problems from impedance tomography and inverse scattering. Relations of this method to other techniques such as the probe method and MUSIC have also been explored.

6 Appendix

In this appendix, we collect some functional analytic results on range identities. The factorization method makes use of the fact that the unknown domain D can be characterized by the range of some compact operator $A : X \rightarrow Y$ where A is related to the known operator $M : Y \rightarrow Y$ through the factorization

$$M = AGA^*. \quad (105)$$

Throughout this whole chapter, we assume that Y is a Hilbert space and X a reflexive Banach space with dual X^* . We denote by $A^* : Y \rightarrow X^*$ the adjoint of A , where Y is identified with its dual.

For a computable characterization of D , the range of the operator A has to be expressed by the operator M which is the goal of the *range identity*.

In the simplest case where also X is a Hilbert space and G is the identity I , the range identity is easily obtained via the singular system of A and the Theorem of Picard. We recall that $\{\sigma_j, x_j, y_j : j \in J\}$ is a singular system of a linear and compact operator $T : X \rightarrow Y$ between Hilbert spaces X and Y if $\{x_j : j \in J\}$ and $\{y_j : j \in J\}$ are complete countable orthonormal systems in the subspaces $\mathcal{N}(T)^\perp \subset X$ and $\mathcal{N}(T^*)^\perp \subset Y$, respectively, and $\sigma_j \in \mathbb{R}_{>0}$ such that $Tx_j = \sigma_j y_j$ and $T^* y_j = \sigma_j x_j$ for all $j \in J$.

We note that $\{\sigma_j^2, x_j : j \in J\}$, together with a basis of the null-space $\mathcal{N}(T)$ of T and associated eigenvalue 0, is an eigensystem of the self-adjoint and nonnegative operator T^*T . Furthermore,

$$\begin{aligned} Tx &= \sum_{j \in J} \sigma_j (x, x_j)_X y_j, \quad x \in X, \\ T^*y &= \sum_{j \in J} \sigma_j (y, y_j)_Y x_j, \quad y \in Y \end{aligned}$$

Theorem 25 (Picard). *Let X, Y be Hilbert spaces and $T : X \rightarrow Y$ be a compact operator with singular system $\{\sigma_j, x_j, y_j : j \in J\}$. Then there holds: An element $y \in Y$ belongs to the range $\mathcal{R}(T)$ of T , if and only if,*

$$y \in \mathcal{N}(T^*)^\perp \quad \text{and} \quad \sum_{j \in J} \frac{|(y, y_j)_Y|^2}{\sigma_j^2} < \infty.$$

For a proof we refer to, e.g., [39]. Applying this theorem to the factorization (105) with $G = I$, and when X^* is identified with X , one obtains.

Corollary 3. Let $A : X \rightarrow Y$ be a compact operator between Hilbert spaces X and Y with dense range and $M = AA^* : Y \rightarrow Y$. Then the ranges of A and $M^{1/2}$ coincide. Here, the self-adjoint and nonnegative operator $M^{1/2} : Y \rightarrow Y$ is given by

$$M^{1/2}y = \sum_{j \in J} \sqrt{\lambda_j} (y, y_j)_Y y_j, \quad y \in Y,$$

where $\{y_j : j \in J\}$ are the orthonormal eigenelements of the self-adjoint, compact, and nonnegative operator M corresponding to the positive eigenvalues λ_j . It follows that

$$y \in \mathcal{R}(A) \iff \sum_{j \in J} \frac{|(y, y_j)_Y|^2}{\lambda_j} < \infty.$$

For more general factorizations of the form $M = AGA^*$, the following (preliminary) characterization is useful (see [68]; for an equivalent formulation, see Theorem 3 of [82]).

Theorem 26. Let X be a reflexive Banach space with dual X^* and dual form $\langle \cdot, \cdot \rangle$ in $\langle X^*, X \rangle$. Furthermore, let Y be a Hilbert space and $M : Y \rightarrow Y$ and $A : X \rightarrow Y$ be linear-bounded operators such that the factorization (105) holds for some linear and bounded operator $G : X^* \rightarrow X$, which satisfies a coercivity condition of the form: There exists $c > 0$ with

$$|\langle \varphi, G\varphi \rangle| \geq c \|\varphi\|_{X^*}^2 \quad \text{for all } \varphi \in \mathcal{R}(A^*) \subset X^*. \quad (106)$$

Then, for any $\phi \in Y\phi \neq 0$,

$$\phi \in \mathcal{R}(A) \iff \inf \{ |(\psi, M\psi)_Y| : \psi \in Y, (\psi, \phi)_Y = 1 \} > 0. \quad (107)$$

Proof. The form $|(\psi, M\psi)_Y|$ can be estimated by

$$|(\psi, M\psi)_Y| = |\langle A^*\psi, GA^*\psi \rangle| \geq c \|A^*\psi\|_{X^*}^2 \quad \text{for all } \psi \in Y. \quad (108)$$

Let first $\phi = A\varphi_0$ for some $\varphi_0 \in X$. For $\psi \in Y$ with $(\psi, \phi)_Y = 1$, there holds that

$$\begin{aligned} |(\psi, M\psi)_Y| &\geq c \|A^*\psi\|_{X^*}^2 = \frac{c}{\|\varphi_0\|_X^2} \|A^*\psi\|_{X^*}^2 \|\varphi_0\|_X^2 \\ &\geq \frac{c}{\|\varphi_0\|_X^2} |\langle A^*\psi, \varphi_0 \rangle|^2 = \frac{c}{\|\varphi_0\|_X^2} |(\psi, \underbrace{A\varphi_0}_{=\phi})_Y|^2 = \frac{c}{\|\varphi_0\|_X^2}. \end{aligned}$$

This provides the lower bound of the infimum.

Second, assume that $\phi \notin \mathcal{R}(A)$. Define the closed subspace $V := \{\psi \in Y : (\psi, \phi)_Y = 0\}$. Then $A^*(V)$ is dense in $\mathcal{R}(A^*) \subset X^*$. Indeed, this is equivalent to the statement that the annihilators $[A^*(V)]^\perp$ and $[\mathcal{R}(A^*)]^\perp = \mathcal{N}(A)$ coincide. Therefore, let $\varphi \in [A^*(V)]^\perp$, i.e., $\langle A^*\psi, \varphi \rangle = 0$ for all $\psi \in V$, i.e., $(\psi, A\varphi)_Y = 0$ for all $\psi \in V$, i.e., $A\varphi \in V^\perp = \text{span}\{\phi\}$. Since $\phi \notin \mathcal{R}(A)$, this implies $A\varphi = 0$, i.e., $\varphi \in \mathcal{N}(A)$. Therefore, $A^*(V)$ is dense in $\mathcal{R}(A^*)$.

Choose a sequence $\{\hat{\psi}_n\}$ in V such that $A^*\hat{\psi}_n \rightarrow -\frac{1}{\|\phi\|_Y^2} A^*\phi$ as n tends to infinity and set $\psi_n = \hat{\psi}_n + \phi / \|\phi\|_Y^2$. Then $(\psi_n, \phi)_Y = 1$ and $A^*\psi_n \rightarrow 0$. The first equation of (108) yields

$$|(\psi_n, M\psi_n)_Y| \leq \|G\| \|A^*\psi_n\|_{X^*}^2$$

and thus $(\psi_n, M\psi_n)_Y \rightarrow 0, n \rightarrow \infty$, which proves that $\inf \{|(\psi, M\psi)_Y| : \psi \in Y, (\psi, \phi)_Y = 1\} = 0$.

We note that the inf-condition only depends on M and not on the factorization. Therefore, we have as a corollary.

Corollary 4. *Let Y be a Hilbert space and X_1 and X_2 be reflexive Banach spaces with duals X_1^* and X_2^* , respectively. Furthermore, let $M : Y \rightarrow Y$ have two factorizations of the form $M = A_1 G_1 A_1^* = A_2 G_2 A_2^*$ as in (105) with compact operators $A_j : X_j \rightarrow Y$ and bounded operators $G_j : X_j^* \rightarrow X_j$, which both satisfy the coercivity condition (106). Then the ranges of A_1 and A_2 coincide.*

Corollary 4 is useful for the analysis of the factorization method as long as M is normal. However, there are many scattering problems for which the corresponding far field operator fails to be normal, e.g., in the case of absorbing media. For these problems, one can utilize the self-adjoint operator

$$M_\# = |\text{Re } M| + \text{Im } M, \quad (109)$$

which can be computed from M . Note that $\text{Re } M = \frac{1}{2}(M + M^*)$ and $\text{Im } M = \frac{1}{2i}(M - M^*)$ are again self-adjoint and compact, and the absolute value $|\text{Re } M|$ of $\text{Re } M$ is defined to be

$$|\text{Re } M|\psi = \sum_{j \in J} |\lambda_j|(\psi, \psi_j)_Y \psi_j, \quad \psi \in Y,$$

where $\{\lambda_j, \psi_j : j \in J\}$ denotes the spectral system of $\text{Re } M$.

Now we can apply Corollary 4 to obtain the following result (see [73] for the lengthy proof and [76] for a weaker form of assumption (d)).

Theorem 27. *Let X be a reflexive Banach space with dual X^* and dual form $\langle \cdot, \cdot \rangle$ in $\langle X^*, X \rangle$. Furthermore, let Y be a Hilbert space and $M : Y \rightarrow Y$ and $A : X \rightarrow Y$ be linear-bounded operators such that the factorization (105) holds true for some linear and bounded operator $G : X^* \rightarrow X$. Furthermore, let the following conditions be satisfied:*

- (a) *The range of A is dense in Y .*
- (b) *There holds $\operatorname{Re} G = G_0 + G_1$, where G_0 satisfies (106) and $G_1 : X^* \rightarrow X$ is compact.*
- (c) *The imaginary part $\operatorname{Im} G$ of G is non-negative, i.e., $\operatorname{Im}\langle \varphi, G\varphi \rangle \geq 0$ for all $\varphi \in X^*$.*
- (d) *G is injective or $\operatorname{Im} G$ is positive on the null-space of $\operatorname{Re} G$.*

Then the self-adjoint operator $M_\#$ of (109) is positive, and the ranges of A and $M_\#^{1/2}$ coincide.

As an immediate corollary, we have:

Corollary 5. *Let $M : Y \rightarrow Y$ and $A : X \rightarrow Y$ and $G : X^* \rightarrow X$ be as in Theorem 27, and let G be self-adjoint, i.e., $G^* = G$, and satisfy (106). Then the ranges of A and $M^{1/2}$ coincide, and*

$$y \in \mathcal{R}(A) \iff \sum_{j \in J} \frac{|(y, y_j)_Y|^2}{\lambda_j} < \infty,$$

where $\{\lambda_j, y_j : j \in J\}$ denotes a spectral system of the self-adjoint and compact operator $M = AGA^*$.

Abstract

We give a survey of the mathematical basis of inverse scattering theory, concentrating on the case of time-harmonic acoustic waves. After an introduction and historical remarks, we give an outline of the direct scattering problem. This is then followed by sections on uniqueness results in inverse scattering theory and iterative and decomposition methods to reconstruct the shape and material properties of the scattering object. We conclude by discussing qualitative methods in inverse scattering theory, in particular the linear sampling method and its use in obtaining lower bounds on the constitutive parameters of the scattering object.

1 Introduction

Scattering theory is concerned with the effects that obstacles and inhomogeneities have on the propagation of waves and in particular time-harmonic waves. In the context of this book, scattering theory provides the mathematical tools for imaging via acoustic and electromagnetic waves with applications to such fields as radar, sonar, geophysics, medical imaging, and nondestructive testing.

For reasons of brevity, in this survey, we focus our attention on the case of acoustic waves and only give passing references to the case of electromagnetic waves. We will furthermore give few proofs, referring the reader interested in further details to [22]. Since the literature in the area is enormous, we have only referenced a limited number of papers and hope that the reader can use these as starting point for further investigations.

Mathematical acoustics begins with the modeling of acoustic waves, i.e., sound waves. The two main media for the propagation and scattering of sound waves are air and water (underwater acoustics). A third important medium with properties close to those of water is the human body, i.e., biological tissue (ultrasound). Since sound waves are considered as small perturbations in a gas or a fluid, the equation of acoustics, i.e., the wave equation

$$\frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} = \Delta p \quad (1)$$

for the pressure $p = p(x, t)$, is obtained by linearization of the equations for the motion of fluids. Here, $c = c(x)$ denotes the local speed of sound, and the fluid velocity is proportional to $\text{grad } p$. For time-harmonic acoustic waves of the form

$$p(x, t) = \text{Re} \{u(x) e^{-i\omega t}\} \quad (2)$$

with frequency $\omega > 0$, it follows that the complex-valued space-dependent part u satisfies the reduced wave equation

$$\Delta u + \frac{\omega^2}{c^2} u = 0. \quad (3)$$

Here we emphasize that the physical quantity describing the sound wave is the real-valued sound pressure $p(x, t)$ and not the complex-valued amplitude $u(x)$ in the representation $u(x) e^{-i\omega t}$. For a homogeneous medium, the speed of sound c is constant and (3) becomes the *Helmholtz equation*

$$\Delta u + k^2 u = 0, \quad (4)$$

where the wave number k is given by the positive constant $k = \omega/c$.

A solution to the Helmholtz equation whose domain of definition contains the exterior of some sphere is called radiating if it satisfies the *Sommerfeld radiation condition*

$$\lim_{r \rightarrow \infty} r \left(\frac{\partial u^s}{\partial r} - iku^s \right) = 0, \quad (5)$$

where $r = |x|$ and the limit holds uniformly in all directions $x/|x|$. Here, and in the sequel, $|x| := \sqrt{x_1^2 + x_2^2 + x_3^2}$ denotes the Euclidean norm of $x = (x_1, x_2, x_3) \in \mathbb{R}^3$. For more details on the physical background of linear acoustic waves, the reader is referred to [66].

We will confine our presentation of scattering theory for time-harmonic acoustic waves to two basic problems, namely, scattering by a bounded impenetrable obstacle and scattering by a penetrable inhomogeneous medium of compact support. For a vector $d \in \mathbb{R}^3$ with $|d| = 1$, the function $e^{ikx \cdot d}$ satisfies the Helmholtz equation for all $x \in \mathbb{R}^3$. It is called a *plane wave*, since $e^{i(kx \cdot d - \omega t)}$ is constant on the planes $kx \cdot d - \omega t = \text{const}$. Note that these wave fronts travel with velocity c in the direction d . Assume that an incident field is given by the plane wave $u^i(x) = e^{ikx \cdot d}$. Then the simplest obstacle scattering problem is to find the scattered field u^s as a radiating solution to the Helmholtz equation in the exterior of a bounded scatterer D such that the total field $u = u^i + u^s$ satisfies the Dirichlet boundary condition

$$u = 0 \quad \text{on } \partial D \quad (6)$$

corresponding to a sound-soft obstacle with the total pressure, i.e., the excess pressure over the static pressure p_0 , vanishing on the boundary. Concerning the geometry of scattering obstacles, for simplicity, we always will assume that D is a bounded domain with a connected boundary ∂D of class C^2 . In particular, this implies that the complement $\mathbb{R}^3 \setminus \overline{D}$ is connected. However, our results remain valid for a finite number of scattering obstacles.

Boundary conditions other than the Dirichlet condition also need to be considered such as the Neumann or sound-hard boundary condition

$$\frac{\partial u}{\partial \nu} = 0 \quad \text{on } \partial D \quad (7)$$

or, more generally, the impedance boundary condition

$$\frac{\partial u}{\partial \nu} + i \lambda u = 0 \quad \text{on } \partial D, \quad (8)$$

where ν is the outward unit normal to ∂D and λ is a positive constant called the surface impedance. More generally the impedance λ can also vary on ∂D . Since $\operatorname{grad} u$ is proportional to the fluid velocity, the impedance boundary condition describes obstacles for which the normal velocity of the fluid on the boundary is proportional to the excess pressure on the boundary. The Neumann condition corresponds to a vanishing normal velocity on the boundary. In order to avoid repetitions by considering all possible types of boundary conditions, we will in general confine ourselves to presenting the basic ideas in acoustic obstacle scattering for the case of a sound-soft obstacle.

The simplest scattering problem for an inhomogeneous medium assumes that the speed of sound is constant outside a bounded domain D . Then the total field $u = u^i + u^s$ satisfies

$$\Delta u + k^2 n u = 0 \quad \text{in } \mathbb{R}^3, \quad (9)$$

and the scattered wave u^s fulfills the Sommerfeld radiation condition (5), where the wave number is given by $k = \omega/c_0$ and $n = c_0^2/c^2$ is the *refractive index* given by the ratio of the square of the sound speeds $c = c_0$ in the homogeneous host medium and $c = c(x)$ in the inhomogeneous medium. The refractive index is positive and satisfies $n(x) = 1$ for $x \notin D$, and we assume n to be continuously differentiable in \mathbb{R}^3 (our results are also in general valid for n being merely piecewise continuous in \mathbb{R}^3). An absorbing medium is modeled by adding an absorption term which leads to a refractive index with a positive imaginary part of the form

$$n = \frac{c_0^2}{c^2} + i \frac{\gamma}{k}$$

in terms of a possibly space-dependent absorption coefficient γ .

Summarizing, given the incident wave and the physical properties of the scatterer, the *direct scattering problem* is to find the scattered wave and in particular its behavior at large distances from the scattering object, i.e., its far-field behavior. The *inverse scattering problem* takes this answer to the direct scattering problem as its starting point and asks what the nature of the scatterer that gave rise to such far-field behavior is.

To be more specific, it can be shown that radiating solutions u^s to the Helmholtz equation have the asymptotic behavior

$$u^s(x) = \frac{e^{ik|x|}}{|x|} \left\{ u_\infty(\hat{x}) + O\left(\frac{1}{|x|}\right) \right\}, \quad |x| \rightarrow \infty, \quad (10)$$

uniformly for all directions $\hat{x} = x/|x|$, where the function u_∞ defined on the unit sphere S^2 is known as the *far-field pattern* of the scattered wave. For plane wave incidence, we indicate the dependence of the far-field pattern on the incident direction d and the observation direction \hat{x} by writing $u_\infty = u_\infty(\hat{x}, d)$. The inverse scattering problem can now be formulated as the problem of determining either the sound-soft obstacle D or the index of refraction n (and hence also D) from a knowledge of the far-field pattern $u_\infty(\hat{x}, d)$ for \hat{x} and d on the unit sphere S^2 (or a subset of S^2).

One of the earliest mathematical results in inverse scattering theory was Schiffer's proof in 1967 that the far-field pattern $u_\infty(\hat{x}, d)$ for $\hat{x}, d \in S^2$ uniquely determines the shape of a sound-soft obstacle D . Unfortunately, Schiffer's proof does not immediately generalize to other boundary conditions. This problem was remedied by Kirsch and Kress in 1993 who, using an idea originally proposed by Isakov, showed that $u_\infty(\hat{x}, d)$ for $\hat{x}, d \in S^2$ uniquely determines the shape of D as long as the solution of the direct scattering problem depends continuously on the boundary data [54]. In particular, it is not necessary to know the boundary condition a priori in order to guarantee uniqueness! The uniqueness problem for inverse scattering by an inhomogeneous medium was solved by Nachman [68], Novikov [70], and Ramm [79] in 1988 who based their analysis on the fundamental work of Sylvester and Uhlmann [88]. Their uniqueness proof was subsequently considerably simplified by Hähner [35].

The first attempt to reconstruct the shape of a sound-soft scattering obstacle from a knowledge of the far-field pattern in a manner acknowledging the nonlinear and ill-posed nature of the problem was made by Roger in 1981 using Newton's iteration method [81]. A characterization and rigorous proof of the existence of the Fréchet derivative of the solution operator in Newton's method were then established by Kirsch [47] and Potthast [75] in 1993 and 1994, respectively. An alternative approach to solving the inverse scattering problem was proposed by Colton and Monk in 1986 and by Kirsch and Kress in 1987 who broke up the inverse scattering problem into a linear, ill-posed problem and a nonlinear, well-posed problem [24, 53]. The optimization method of Kirsch and Kress has the attractive feature of needing only a single incident field for its implementation. On the other hand, to use such methods, it is necessary to know the number of components of the scatterer as well as the boundary condition satisfied by the field on the surface of the scatterer. These problems were overcome by Colton and Kirsch in 1996 through the derivation of a *linear* integral equation with the far-field data as its kernel (i.e., multistatic data is needed for its implementation) [19]. This method, subsequently called the *linear sampling method*, was further developed by Colton et al. [29]

and numerous other researchers. A significant development in this approach to the inverse scattering problem was the introduction of the *factorization method* by Kirsch in 1998 [48]. For further historical information on these “sampling” methods in inverse scattering theory, we refer the reader to the chapter in this handbook on sampling methods as well as the monographs [7, 52].

Optimization methods and sampling methods for the inverse scattering problem for inhomogeneous media have been extensively investigated by numerous authors. In general, the optimization methods are based on rewriting the scattering problem corresponding to (9) as the *Lippmann–Schwinger integral equation*

$$u(x) = e^{ikx \cdot d} - \frac{k^2}{4\pi} \int_{\mathbb{R}^3} \frac{e^{ik|x-y|}}{|x-y|} m(y) u(y) dy, \quad x \in \mathbb{R}^3, \quad (11)$$

where $m := 1 - n$ and the object is to determine m from a knowledge of

$$u_\infty(\hat{x}, d) = -\frac{k^2}{4\pi} \int_{\mathbb{R}^3} e^{-ik\hat{x} \cdot y} m(y) u(y) dy, \quad \hat{x}, d \in S^2. \quad (12)$$

On the other hand, sampling methods have also been used to study the inverse scattering problem associated with (9) where now the object is to only determine the support of m . For details and further references, see [7, 22, 52].

Finally, as pointed out in [21], an alternative direction in inverse scattering theory than that discussed above is to only try to obtain lower and upper bounds on a few relevant features of the scattering object rather than attempting a complete reconstruction. This relatively new direction in inverse scattering theory will be discussed in Sect. 5.

2 Direct Scattering Problems

The Helmholtz Equation

Most of the basic properties of solutions to the Helmholtz equation (3) can be deduced from the *fundamental solution*

$$\Phi(x, y) := \frac{1}{4\pi} \frac{e^{ik|x-y|}}{|x-y|}, \quad x \neq y. \quad (13)$$

For fixed $y \in \mathbb{R}^3$, it satisfies the Helmholtz equation in $\mathbb{R}^3 \setminus \{y\}$. In addition, it satisfies the radiation condition (5) uniformly with respect to y on compact subsets of \mathbb{R}^3 . Physically speaking, the fundamental solution represents an acoustic point source located at the point y . In addition to plane waves, point sources will also occur as incident fields in scattering problems.

Green’s integral theorems provide basic tools for investigating the Helmholtz equation. As an immediate consequence, they imply the *Helmholtz representation*

$$u(x) = \int_{\partial D} \left\{ \frac{\partial u}{\partial \nu}(y) \Phi(x, y) - u(y) \frac{\partial \Phi(x, y)}{\partial \nu(y)} \right\} ds(y), \quad x \in D, \quad (14)$$

for solutions $u \in C^2(D) \cap C^1(\overline{D})$ to the Helmholtz equation. The representation (2) implies that solutions to the Helmholtz equation inherit analyticity from the fundamental solution. Any solution u to the Helmholtz equation in D satisfying

$$u = \frac{\partial u}{\partial \nu} = 0 \quad \text{on } \Gamma \quad (15)$$

for some open subset $\Gamma \subset \partial D$ must vanish identically in D . This can be seen via extending the definition of u by (2) for $x \in (\mathbb{R}^3 \setminus \overline{D}) \cup \Gamma$. Then, by Green's integral theorem, applied to u and $\Phi(x, \cdot)$, we have $u = 0$ in $\mathbb{R}^3 \setminus \overline{D}$. Clearly u solves the Helmholtz equation in $(\mathbb{R}^3 \setminus \partial D) \cup \Gamma$ and therefore by analyticity $u = 0$ in D since D and $\mathbb{R}^3 \setminus \overline{D}$ are connected through the gap Γ in ∂D .

As a consequence of the radiation condition (5), the Helmholtz representation is also valid in the exterior domain $\mathbb{R}^3 \setminus \overline{D}$, i.e., we have

$$u(x) = \int_{\partial D} \left\{ u(y) \frac{\partial \Phi(x, y)}{\partial \nu(y)} - \frac{\partial u}{\partial \nu}(y) \Phi(x, y) \right\} ds(y), \quad x \in \mathbb{R}^3 \setminus \overline{D}, \quad (16)$$

for radiating solutions $u \in C^2(\mathbb{R}^3 \setminus \overline{D}) \cap C^1(\mathbb{R}^3 \setminus D)$ to the Helmholtz equation. From Eq. (4) we observe that radiating solutions u to the Helmholtz equation satisfy *Sommerfeld's finiteness condition*

$$u(x) = O\left(\frac{1}{|x|}\right), \quad |x| \rightarrow \infty, \quad (17)$$

uniformly for all directions and that the validity of the Sommerfeld radiation condition (5) is invariant under translations of the origin.

We are now in a position to introduce the fundamental notion of the *far-field pattern* of radiating solutions to the Helmholtz equation.

Theorem 1. *Every radiating solution u to the Helmholtz equation has an asymptotic behavior of the form*

$$u(x) = \frac{e^{ik|x|}}{|x|} \left\{ u_\infty(\hat{x}) + O\left(\frac{1}{|x|}\right) \right\}, \quad |x| \rightarrow \infty, \quad (18)$$

uniformly in all directions $\hat{x} = x/|x|$, where the function u_∞ defined on the unit sphere S^2 is called the far-field pattern of u . Under the assumptions of (16), we have

$$u_\infty(\hat{x}) = \frac{1}{4\pi} \int_{\partial D} \left\{ u(y) \frac{\partial e^{-ik\hat{x} \cdot y}}{\partial \nu(y)} - \frac{\partial u}{\partial \nu}(y) e^{-ik\hat{x} \cdot y} \right\} ds(y), \quad \hat{x} \in S^2. \quad (19)$$

Proof. This follows from (16) by using the estimates

$$\begin{aligned} \frac{e^{ik|x-y|}}{|x-y|} &= \frac{e^{ik|x|}}{|x|} \left\{ e^{-ik\hat{x}\cdot y} + O\left(\frac{1}{|x|}\right) \right\}, \quad \frac{\partial}{\partial\nu(y)} \frac{e^{ik|x-y|}}{|x-y|} \\ &= \frac{e^{ik|x|}}{|x|} \left\{ \frac{\partial e^{-ik\hat{x}\cdot y}}{\partial\nu(y)} + O\left(\frac{1}{|x|}\right) \right\} \end{aligned}$$

which hold uniformly for all $y \in \partial D$ and all directions $x/|x|$ as $|x| \rightarrow \infty$. \blacksquare

From the representation (19), it follows that the far-field pattern is an analytic function on S^2 . As an extension of (18), each radiating solution u to the Helmholtz equation has an Atkinson–Wilcox expansion of the form

$$u(x) = \frac{e^{ik|x|}}{|x|} \sum_{\ell=0}^{\infty} \frac{1}{|x|^{\ell}} F_{\ell} \left(\frac{x}{|x|} \right) \quad (20)$$

that converges absolutely and uniformly on compact subsets of $\mathbb{R}^3 \setminus B$, where $B \supset \overline{D}$ is a ball centered at the origin. The coefficients in the expansion (20) are determined in terms of the far-field pattern $F_0 = u_{\infty}$ by the recursion

$$2ik\ell F_{\ell} = \ell(\ell - 1)F_{\ell-1} + BF_{\ell-1}, \quad \ell = 1, 2, \dots, \quad (21)$$

where B denotes the Laplace–Beltrami operator for the unit sphere. The following consequence of the expansion (20) is known as *Rellich's lemma*.

Lemma 1. *Let u be a radiating solution to the Helmholtz equation for which the far-field pattern u_{∞} vanishes identically. Then u vanishes identically.*

Proof. This follows from (20) and (21) together with the analyticity of solutions to the Helmholtz equation. \blacksquare

Corollary 1. *Let $u \in C^2(\mathbb{R}^3 \setminus \overline{D}) \cap C^1(\mathbb{R}^3 \setminus D)$ be a radiating solution to the Helmholtz equation in $\mathbb{R}^3 \setminus \overline{D}$ for which*

$$\operatorname{Im} \int_{\partial D} u \frac{\partial \bar{u}}{\partial \nu} ds \geq 0. \quad (22)$$

Then $u = 0$ in $\mathbb{R}^3 \setminus \overline{D}$.

Proof. Using Green's integral theorem, the radiation condition can be utilized to establish that

$$\lim_{r \rightarrow \infty} \int_{|x|=r} \left\{ \left| \frac{\partial u}{\partial v} \right|^2 + k^2 |u|^2 \right\} ds = -2k \operatorname{Im} \int_{\partial D} u \frac{\partial \bar{u}}{\partial v} ds.$$

Now the assumption (22) implies $\lim_{r \rightarrow \infty} \int_{|x|=r} |u|^2 ds = 0$, and the statement follows from Lemma 1. ■

Scattering from infinitely long cylindrical obstacles or inhomogeneities leads to the Helmholtz equation in \mathbb{R}^2 . The two-dimensional case can be used as an approximation for scattering from finitely long cylinders, and more importantly, it can serve as a model case for testing numerical approximation schemes in direct and inverse scattering. Without giving details, we can summarize that our analysis remains valid in two dimensions after appropriate modifications of the fundamental solution and the radiation condition. The fundamental solution to the Helmholtz equation in two dimensions is given by

$$\Phi(x, y) := \frac{i}{4} H_0^{(1)}(k|x - y|), \quad x \neq y, \quad (23)$$

in terms of the Hankel function $H_0^{(1)}$ of the first kind of order zero. In \mathbb{R}^2 the Sommerfeld radiation condition has to be replaced by

$$\lim_{r \rightarrow \infty} \sqrt{r} \left(\frac{\partial u}{\partial r} - iku \right) = 0, \quad r = |x|, \quad (24)$$

uniformly for all directions $x/|x|$. According to the form (24) of the radiation condition, the definition of the far-field pattern (18) has to be replaced by

$$u(x) = \frac{e^{ik|x|}}{\sqrt{|x|}} \left\{ u_\infty(\hat{x}) + O\left(\frac{1}{|x|}\right) \right\}, \quad |x| \rightarrow \infty, \quad (25)$$

and the representation (19) assumes the form

$$u_\infty(\hat{x}) = \frac{e^{i\frac{\pi}{4}}}{\sqrt{8\pi k}} \int_{\partial D} \left\{ u(y) \frac{\partial e^{-ik\hat{x} \cdot y}}{\partial v(y)} - \frac{\partial u}{\partial v}(y) e^{-ik\hat{x} \cdot y} \right\} ds(y) \quad (26)$$

for $\hat{x} = x/|x|$.

Obstacle Scattering

After renaming the unknown functions, the direct scattering problem for sound-soft obstacles is a special case of the following exterior Dirichlet problem: Given a function $f \in C(\partial D)$, find a radiating solution $u \in C^2(\mathbb{R}^3 \setminus \overline{D}) \cap C(\mathbb{R}^3 \setminus D)$ to the Helmholtz equation that satisfies the boundary condition

$$u = f \quad \text{on } \partial D. \quad (27)$$

Theorem 2. *The exterior Dirichlet problem for the Helmholtz equation has at most one solution.*

Proof. Let u satisfy the homogeneous boundary condition $u = 0$ on ∂D . If u were continuously differentiable up to the boundary, we could immediately apply Corollary 1 to obtain $u = 0$ in $\mathbb{R}^3 \setminus \overline{D}$. However, in the formulation of the exterior Dirichlet problem, u is only assumed to be in $C(\mathbb{R}^3 \setminus D)$. We refrain from discussing possibilities to overcome this regularity gap and refer to the literature [22]. ■

Theorem 3. *The exterior Dirichlet problem has a unique solution.*

Proof. The existence of a solution can be elegantly based on boundary integral equations. In the layer approach, one tries to find the solution in the form of a combined acoustic double- and single-layer potential

$$u(x) = \int_{\partial D} \left\{ \frac{\partial \Phi(x, y)}{\partial \nu(y)} - i \Phi(x, y) \right\} \varphi(y) ds(y) \quad (28)$$

for $x \in \mathbb{R}^3 \setminus \overline{D}$ with a density $\varphi \in C(\partial D)$. Then, after introducing the single- and double-layer integral operators $S, K : C(\partial D) \rightarrow C(\partial D)$ by

$$(S\varphi)(x) := 2 \int_{\partial D} \Phi(x, y) \varphi(y) ds(y), \quad x \in \partial D, \quad (29)$$

$$(K\varphi)(x) := 2 \int_{\partial D} \frac{\partial \Phi(x, y)}{\partial \nu(y)} \varphi(y) ds(y), \quad x \in \partial D, \quad (30)$$

and using their regularity and jump relations, it can be seen that (28) solves the exterior Dirichlet problem provided the density φ is a solution of the integral equation

$$\varphi + K\varphi - iS\varphi = 2f. \quad (31)$$

Due to their weakly singular kernels, the operators S and K turn out to be compact. Hence, the existence of a solution to (31) can be established with the aid of the Riesz–Fredholm theory for compact operators by showing that the homogeneous form of (31) only allows the trivial solution $\varphi = 0$.

Let φ be a solution of the homogeneous equation, and let the subscripts \pm denote the limits obtained by approaching ∂D from $\mathbb{R}^3 \setminus \overline{D}$ and D , respectively. Then the potential u defined by (28) in all of $\mathbb{R}^3 \setminus \partial D$ satisfies the homogeneous boundary condition $u_+ = 0$ on ∂D whence $u = 0$ in $\mathbb{R}^3 \setminus \overline{D}$ followed by Theorem 2. The jump relations for single- and double-layer potentials now yield

$$-u_- = \varphi, \quad -\frac{\partial u_-}{\partial v} = i\varphi \quad \text{on } \partial D.$$

Hence, using Green's first integral theorem, we obtain

$$i \int_{\partial D} |\varphi|^2 ds = \int_{\partial D} \bar{u}_- \frac{\partial u_-}{\partial v} ds = \int_D \{|\operatorname{grad} u|^2 - k^2 |u|^2\} dx,$$

and taking the imaginary part yields $\varphi = 0$. ■

We note that, in addition to existence of a solution, the Riesz–Fredholm theory also establishes well-posedness, i.e., the continuous dependence of the solution on the data. Instead of the classical setting of continuous function spaces, the existence analysis can also be considered in the Sobolev space $H^{1/2}(\partial D)$ for the boundary integral operators leading to solutions in the energy space $H_{\text{loc}}^1(\mathbb{R}^3 \setminus \overline{D})$ (see [64, 69]).

We further note that without the single-layer potential included in (28), the corresponding double-layer integral equation suffers from nonuniqueness if k is a so-called irregular wave number or internal resonance, i.e., if there exist nontrivial solutions u to the Helmholtz equation in the interior domain D satisfying homogeneous Neumann boundary conditions $\partial u / \partial v = 0$ on ∂D .

For the numerical solution of the boundary integral equations in scattering theory via spectral methods in two and three dimensions, we refer to [22]. For boundary element methods, we refer to [80].

In general, for the scattering problem, the boundary values are as smooth as the boundary, since they are given by the restriction of the analytic function u^i to ∂D . Therefore, we may use the Helmholtz representation (16) and Green's second integral theorem applied to u^i and $\Phi(x, \cdot)$ to obtain the following theorem.

Theorem 4. *For scattering from a sound-soft obstacle D , we have*

$$u(x) = u^i(x) - \int_{\partial D} \frac{\partial u}{\partial v}(y) \Phi(x, y) ds(y), \quad x \in \mathbb{R}^3 \setminus \overline{D}, \quad (32)$$

and the far-field pattern of the scattered field u^s is given by

$$u_\infty(\hat{x}) = -\frac{1}{4\pi} \int_{\partial D} \frac{\partial u}{\partial v}(y) e^{-ik\hat{x} \cdot y} ds(y), \quad \hat{x} \in S^2. \quad (33)$$

The representation (32) for the scattered field through the so-called secondary sources on the boundary is known as *Huygens' principle*. Here we will use it for the motivation of the *Kirchhoff* or *physical optics approximation* as an intuitive procedure to simplify the direct scattering problem. For large wave numbers k , i.e., for small wave lengths, in a first approximation, a convex object D locally may be considered at each point x of ∂D as a plane with normal $v(x)$. This suggests

$$\frac{\partial u}{\partial \nu} = 2 \frac{\partial u^i}{\partial \nu}$$

on the part $\partial D_- := \{x \in \partial D : \nu(x) \cdot d < 0\}$ that is illuminated and

$$\frac{\partial u}{\partial \nu} = 0$$

in the shadow region $\partial D_+ := \{x \in \partial D : \nu(x) \cdot d \geq 0\}$. Thus, the Kirchhoff approximation for the scattering of a plane wave with incident direction d at a convex sound-soft obstacle is given by

$$u(x) \approx e^{ikx \cdot d} - 2 \int_{\partial D_-} \frac{\partial e^{iky \cdot d}}{\partial \nu(y)} \Phi(x, y) ds(y) \quad (34)$$

for $x \in \mathbb{R}^3 \setminus \overline{D}$.

Scattering by an Inhomogeneous Medium

Recall the scattering problem for an inhomogeneous medium with refractive index n as described by (9) for the total wave $u = u^i + u^s$ with incident field u^i and the scattered wave u^s satisfying the Sommerfeld radiation condition. The function $m := 1 - n$ has support \overline{D} .

The counterpart of the Helmholtz representation is given by the *Lippmann–Schwinger equation*

$$u(x) = u^i(x) - k^2 \int_D \Phi(x, y) m(y) u(y) dy, \quad x \in \mathbb{R}^3, \quad (35)$$

which can be shown to be equivalent to the scattering problem.

In order to establish existence of a solution to (35) via the Riesz–Fredholm theory, it must be shown that the homogeneous equation has only the trivial solution or, equivalently, that the only solution to (9) satisfying the radiation condition is identically zero. For this, in addition to Rellich’s lemma, the following *unique continuation principle* is required: Any solution $u \in C^2(G)$ of Eq. (9) in a domain $G \subset \mathbb{R}^3$ such that $n \in C(G)$ and u vanishes in an open subset of G vanishes identically. Hence, we have the following result on existence and uniqueness for the inhomogeneous medium scattering problem.

Theorem 5. *For a refractive index $n \in C^1(\mathbb{R}^3)$ with $\operatorname{Re} n \geq 0$ and $\operatorname{Im} n \geq 0$, the Lippmann–Schwinger equation or, equivalently, the inhomogeneous medium scattering problem has a unique solution.*

Proof. From Green’s first integral theorem, it follows that

$$\int_{\partial D} u \frac{\partial \bar{u}}{\partial \nu} ds = \int_D \{ |\operatorname{grad} u|^2 - k^2 \bar{n}|u|^2 \} dx.$$

Taking the imaginary part and applying Corollary 1 yields $u = 0$ in $\mathbb{R}^3 \setminus D$ in view of the assumptions on n , and the proof is finished by the unique continuation principle. ■

From (35) we see that

$$u^s(x) = -k^2 \int_{\mathbb{R}^3} \Phi(x, y) m(y) u(y) dy, \quad x \in \mathbb{R}^3.$$

Hence, the far-field pattern u_∞ is given by

$$u_\infty(\hat{x}) = -\frac{k^2}{4\pi} \int_{\mathbb{R}^3} e^{-ik\hat{x} \cdot y} m(y) u(y) dy, \quad \hat{x} \in S^2. \quad (36)$$

We note that for $k^2 \|m\|_\infty$ sufficiently small, u can be obtained by the method of successive approximations. If in (36) we replace u by the first term in this iterative process, we obtain the *Born approximation*

$$u_\infty(\hat{x}) \approx -\frac{k^2}{4\pi} \int_{\mathbb{R}^3} e^{-ik\hat{x} \cdot y} m(y) u^i(y) dy, \quad \hat{x} \in S^2. \quad (37)$$

For numerical solutions of the inverse medium scattering problem by finite element methods coupled with boundary element methods via nonlocal boundary conditions, we refer to [65].

The Maxwell Equations

We now consider the *Maxwell equations* as the foundation of electromagnetic scattering theory. Our presentation is organized parallel to that on the Helmholtz equation, i.e., on acoustic scattering, and will be confined to homogeneous isotropic media. Consider electromagnetic wave propagation in an isotropic dielectric medium in \mathbb{R}^3 with constant electric permittivity ε and magnetic permeability μ . The electromagnetic wave is described by the electric field \mathcal{E} and the magnetic field \mathcal{H} satisfying the time-dependent Maxwell equations

$$\operatorname{curl} \mathcal{E} + \mu \frac{\partial \mathcal{H}}{\partial t} = 0, \quad \operatorname{curl} \mathcal{H} - \varepsilon \frac{\partial \mathcal{E}}{\partial t} = 0. \quad (38)$$

For time-harmonic electromagnetic waves of the form

$$\mathcal{E}(x, t) = \operatorname{Re} \{ \varepsilon^{-1/2} E(x) e^{-i\omega t} \}, \quad \mathcal{H}(x, t) = \operatorname{Re} \{ \mu^{-1/2} H(x) e^{-i\omega t} \} \quad (39)$$

with frequency $\omega > 0$, the complex-valued space-dependent parts E and H satisfy the reduced Maxwell equations

$$\operatorname{curl} E - ikH = 0, \quad \operatorname{curl} H + ikE = 0, \quad (40)$$

where the wave number k is given by the positive constant $k = \sqrt{\varepsilon\mu}\omega$. We will only be concerned with the reduced Maxwell equations and will henceforth refer to them as the Maxwell equations.

A solution E, H to the Maxwell equations whose domain of definition contains the exterior of some sphere is called radiating if it satisfies one of the *Silver–Müller radiation conditions*

$$\lim_{r \rightarrow \infty} (H \times x - rE) = 0 \quad (41)$$

or

$$\lim_{r \rightarrow \infty} (E \times x + rH) = 0, \quad (42)$$

where $r = |x|$ and the limits hold uniformly in all directions $x/|x|$. For more details on the physical background of electromagnetic waves, we refer to [46, 67].

For the Maxwell equations, the counterpart of the Helmholtz representation (2) is given by the *Stratton–Chu formula*

$$\begin{aligned} E(x) = & -\operatorname{curl} \int_{\partial D} v(y) \times E(y) \Phi(x, y) ds(y) \\ & + \frac{1}{ik} \operatorname{curl} \operatorname{curl} \int_{\partial D} v(y) \times H(y) \Phi(x, y) ds(y), \quad x \in D, \end{aligned} \quad (43)$$

for solutions $E, H \in C^1(D) \cap C(\overline{D})$ to the Maxwell equations. A corresponding representation for H can be obtained from (43) with the aid of $H = \operatorname{curl} E / ik$.

The representation (43) implies that each continuously differentiable solution to the Maxwell equations automatically has analytic Cartesian components. Therefore, one can employ the vector identity $\operatorname{curl} \operatorname{curl} E = -\Delta E + \operatorname{grad} \operatorname{div} E$ to prove that for a solution E, H to the Maxwell equations, both E and H are divergence-free and satisfy the vector Helmholtz equation. Conversely, if E is a solution to the vector Helmholtz equation $\Delta E + k^2 E = 0$ satisfying $\operatorname{div} E = 0$, then E and $H := \operatorname{curl} E / ik$ satisfy the Maxwell equations.

It can be shown that solutions E, H to the Maxwell equations in D satisfying

$$v \times E = v \times H = 0 \quad \text{on } \Gamma \quad (44)$$

for some open subset $\Gamma \subset \partial D$ must vanish identically in D .

As a consequence of the Silver–Müller radiation condition, the Stratton–Chu formula is also valid in the exterior domain $\mathbb{R}^3 \setminus \overline{D}$, i.e., we have

$$\begin{aligned} E(x) &= \operatorname{curl} \int_{\partial D} v(y) \times E(y) \Phi(x, y) ds(y) \\ &\quad - \frac{1}{ik} \operatorname{curl} \operatorname{curl} \int_{\partial D} v(y) \times H(y) \Phi(x, y) ds(y), \quad x \in \mathbb{R}^3 \setminus \overline{D}, \end{aligned} \quad (45)$$

for radiating solutions $E, H \in C^1(\mathbb{R}^3 \setminus \overline{D}) \cap C(\mathbb{R}^3 \setminus D)$ to the Maxwell equations. Again, a corresponding representation for H can be obtained from (45) with the aid of $H = \operatorname{curl} E / ik$.

From (45) it can be seen that the radiation condition (41) implies (42) and vice versa. Furthermore, one can deduce that radiating solutions E, H to the Maxwell equations automatically satisfy the *Silver–Müller finiteness conditions*

$$E(x) = O\left(\frac{1}{|x|}\right), \quad H(x) = O\left(\frac{1}{|x|}\right), \quad |x| \rightarrow \infty, \quad (46)$$

uniformly for all directions and that the validity of the Silver–Müller radiation conditions (41) and (42) is invariant under translations of the origin. From the Helmholtz representation (16) for radiating solutions to the Helmholtz equation and the Stratton–Chu formulas for radiating solutions to the Maxwell equations, it can be deduced that for solutions to the Maxwell equations, the Silver–Müller radiation condition is equivalent to the Sommerfeld radiation condition for the Cartesian components of E and H .

The Stratton–Chu formula (45) can be used to introduce the notion of the *electric and magnetic far-field patterns*.

Theorem 6. *Every radiating solution E, H to the Maxwell equations has the asymptotic form*

$$E(x) = \frac{e^{ik|x|}}{|x|} \left\{ E_\infty(\hat{x}) + O\left(\frac{1}{|x|}\right) \right\}, \quad H(x) = \frac{e^{ik|x|}}{|x|} \left\{ H_\infty(\hat{x}) + O\left(\frac{1}{|x|}\right) \right\} \quad (47)$$

for $|x| \rightarrow \infty$ uniformly in all directions $\hat{x} = x/|x|$, where the vector fields E_∞ and H_∞ defined on the unit sphere S^2 are called the *electric far-field pattern* and *magnetic far-field pattern*, respectively. They satisfy

$$H_\infty = v \times E_\infty \quad \text{and} \quad v \cdot E_\infty = v \cdot H_\infty = 0 \quad (48)$$

with the unit outward normal v on S^2 . Under the assumptions of (45), we have

$$E_\infty(\hat{x}) = \frac{ik}{4\pi} \hat{x} \times \int_{\partial D} \{v(y) \times E(y) + [v(y) \times H(y)] \times \hat{x}\} e^{-ik\hat{x} \cdot y} ds(y) \quad (49)$$

for $\hat{x} \in S^2$ and a corresponding expression for H_∞ .

Rellich's lemma carries over immediately from the Helmholtz to the Maxwell equations.

Lemma 2. *Let E, H be a radiating solution to the Maxwell equations for which the electric far-field pattern E_∞ vanishes identically. Then E and H vanish identically.*

The electromagnetic counterpart of Corollary 1 is given by the following result.

Corollary 2. *Let $E, H \in C^1(\mathbb{R}^3 \setminus \bar{D}) \cap C(\mathbb{R}^3 \setminus D)$ be a radiating solution to the Maxwell equations in $\mathbb{R}^3 \setminus \bar{D}$ for which*

$$\operatorname{Re} \int_{\partial D} v \cdot E \times \bar{H} \, ds \leq 0.$$

Then $E = H = 0$ in $\mathbb{R}^3 \setminus \bar{D}$.

For two vectors $d, p \in \mathbb{R}^3$ with $|d| = 1$ and $p \cdot d = 0$, the *plane waves*

$$E^i(x) = p e^{ikx \cdot d}, \quad H^i(x) = d \times p e^{ikx \cdot d} \quad (50)$$

satisfy the Maxwell equations for all $x \in \mathbb{R}^3$. The orthogonal vectors p and $d \times p$ describe the polarization direction of the electric and the magnetic field, respectively. Given the incident field E^i, H^i and a bounded domain $D \subset \mathbb{R}^3$, the simplest obstacle scattering problem is to find the scattered field E^s, H^s as a radiating solution to the Maxwell equations in the exterior of the scatterer D such that the total field $E = E^i + E^s$, $H = H^i + H^s$ satisfies the perfect conductor boundary condition

$$v \times E = 0 \quad \text{on } \partial D, \quad (51)$$

where v is the outward unit normal to ∂D . A more general boundary condition is the impedance or Leontovich boundary condition

$$v \times H - \lambda (v \times E) \times v = 0 \quad \text{on } \partial D, \quad (52)$$

where λ is a positive constant or function called the surface impedance.

Theorem 7. *The scattering problem for a perfect conductor has a unique solution.*

Proof. Uniqueness follows from Corollary 2. The existence of a solution again can be based on boundary integral equations. In the layer approach, one tries to find the solution in the form of a combined magnetic and electric dipole distribution

$$\begin{aligned} E^s(x) &= \operatorname{curl} \int_{\partial D} a(y) \Phi(x, y) \, ds(y) \\ &\quad + i \operatorname{curl} \operatorname{curl} \int_{\partial D} v(y) \times (S_0^2 a)(y) \Phi(x, y) \, ds(y), \quad x \in \mathbb{R}^3 \setminus \partial D. \end{aligned} \quad (53)$$

Here S_0 denotes the single-layer operator (29) in the potential theoretic limit case $k = 0$, and the density a is assumed to belong to the space $C_{\text{div}}^{0,\alpha}(\partial D)$ of Hölder continuous tangential fields with Hölder continuous surface divergence. After defining the electromagnetic boundary integral operators M and N by

$$(Ma)(x) := 2 \int_{\partial D} v(x) \times \operatorname{curl}_x \{a(y)\Phi(x,y)\} ds(y), \quad x \in \partial D, \quad (54)$$

and

$$(Na)(x) := 2 v(x) \times \operatorname{curl} \operatorname{curl} \int_{\partial D} v(y) \times a(y) \Phi(x,y) ds(y), \quad x \in \partial D, \quad (55)$$

it can be shown that E^s given by (53) together with $H^s = \operatorname{curl} E^s / ik$ solves the perfect conductor scattering problem provided the density a satisfies the integral equation

$$a + Ma + iNPS_0^2a = -2 v \times E^i. \quad (56)$$

Here the operator P is defined by $Pb := (\nu \times b) \times \nu$ for (not necessarily tangential) vector fields b . Exploiting the smoothing properties of the operator S_0 , it can be shown that $M + iNPS_0^2$ is a compact operator from $C_{\text{div}}^{0,\alpha}(\partial D)$ into itself. The existence of a solution to (56) can now be based on the Riesz–Fredholm theory by establishing that the homogeneous form of (56) only has the trivial solution [22].

■

Note that, analogous to the acoustic case, without the electric dipole distribution included in (53), the corresponding magnetic dipole integral equation is not uniquely solvable if k is a irregular wave number, i.e., if there exists a nontrivial solution E, H to the Maxwell equations in D satisfying the homogeneous boundary condition $\nu \times E = 0$ on ∂D .

Instead of the classical setting of Hölder continuous functions, the integral equation can also be considered in the Sobolev space $H_{\text{div}}^{1/2}(\partial D)$ of tangential fields in $H^{1/2}(\partial D)$ that have a weak surface divergence in $H^{1/2}(\partial D)$ (see [69]).

In addition to electromagnetic obstacle scattering, one can also consider scattering from an inhomogeneous medium where outside a bounded domain D the electric permittivity ε and magnetic permeability μ are constant and the conductivity σ vanishes, i.e., $\varepsilon = \varepsilon_0$, $\mu = \mu_0$ and $\sigma = 0$ in $\mathbb{R}^3 \setminus \overline{D}$. For simplicity we will assume that the magnetic permeability is constant throughout \mathbb{R}^3 . Then, again assuming the time-harmonic form (39) with ε and μ replaced by ε_0 and μ_0 , respectively, the total fields $E = E^i + E^s$, $H = H^i + H^s$ satisfy

$$\operatorname{curl} E - ikH = 0, \quad \operatorname{curl} H + iknE = 0 \quad \text{in } \mathbb{R}^3 \quad (57)$$

and the scattered wave E^s, H^s satisfies the Silver–Müller radiation condition, where the wave number is given by $k = \sqrt{\varepsilon_0 \mu_0} \omega$ and $n = (\varepsilon + i \sigma/\omega)/\varepsilon_0$ is the refractive index. Establishing uniqueness requires an electromagnetic analogue of the unique continuation principle, and existence can be based on an electromagnetic variant of the Lippmann–Schwinger equation [22].

The scattering of time-harmonic electromagnetic waves by an infinitely long cylinder with a simply connected cross section D leads to boundary value problems for the two-dimensional Helmholtz equation in the exterior $\mathbb{R}^2 \setminus \overline{D}$ of D . If the electric field is polarized parallel to the axis of the cylinder and if the axis of the cylinder is parallel to the x_3 axis, then

$$E = (0, 0, u), \quad H = \frac{1}{ik} \left(\frac{\partial u}{\partial x_2}, -\frac{\partial u}{\partial x_1}, 0 \right)$$

satisfies the Maxwell equations if and only if $u = u(x_1, x_2)$ satisfies the Helmholtz equation. The homogeneous perfect conductor boundary condition is satisfied on the boundary of the cylinder if the homogeneous Dirichlet boundary condition $u = 0$ on ∂D is satisfied. If the magnetic field is polarized parallel to the axis of the cylinder, then the roles of E and H have to be reversed, i.e.,

$$H = (0, 0, u), \quad E = \frac{i}{k} \left(\frac{\partial u}{\partial x_2}, -\frac{\partial u}{\partial x_1}, 0 \right),$$

and the perfect conductor boundary condition corresponds to the Neumann boundary condition $\partial u / \partial \nu = 0$ on ∂D with the unit normal ν to the boundary ∂D of the cross section D . Hence, the analysis of two-dimensional electromagnetic scattering problems coincides with that of two-dimensional acoustic scattering problems.

Historical Remarks

Equation (4) carries the name of Helmholtz (1821–1894) for his contributions to mathematical acoustics. The radiation condition (5) was introduced by Sommerfeld in 1912 to characterize an outward energy flux. The expansion (20) was first established by Atkinson in 1949 and generalized by Wilcox in 1956. The fundamental Lemma 1 is due to Rellich (1943) and Vekua (1943). The combined single- and double-layer approach (28) for the existence analysis was introduced independently by Leis, Brakhage and Werner, and Panich in the 1960s in order to remedy the nonuniqueness deficiency of the classical double-layer approach due to Vekua, Weyl, and Müller from the 1950s. Huygens' principle is also referred to as the Huygens–Fresnel principle and named for Huygens (1629–1695) and Fresnel (1788–1827) in recognition of their contributions to wave optics. The physical optics approximation (34) is named for Kirchhoff (1824–1887) for his contributions to optics. The terms Lippmann–Schwinger equation and Born approximation are adopted from quantum physics. Equation (38) is named for Maxwell (1831–

1879) for his fundamental contributions to electromagnetic theory. The radiation conditions (41) and (42) were independently introduced in the 1940s by Silver and Müller. The integral representations (43) and (45) were first presented by Stratton and Chu in 1939. Extending the ideas of Leis, Brakhage and Werner, and Panich from acoustics to electromagnetics, the approach (53) was introduced independently by Knauff and Kress, Jones, and Mautz and Harrington in the 1970s in order to remedy the nonuniqueness deficiency of the classical approach due to Weyl and Müller from the 1950s.

3 Uniqueness in Inverse Scattering

Scattering by an Obstacle

The first step in studying any inverse scattering problem is to establish a uniqueness result, i.e., if a given set of data is known exactly, does this data uniquely determine the support and/or the material properties of the scatterer? We will begin with the case of scattering by an impenetrable obstacle and then proceed to the case of a penetrable obstacle.

From section “Obstacle Scattering,” we recall that the direct obstacle scattering problem is to find $u \in C^2(\mathbb{R}^3 \setminus \overline{D}) \cap C(\mathbb{R}^3 \setminus D)$ such that the total field $u = u^i + u^s$ satisfies the Helmholtz equation

$$\Delta u + k^2 u = 0 \quad \text{in } \mathbb{R}^3 \setminus \overline{D} \quad (58)$$

and the sound-soft boundary condition

$$u = 0 \quad \text{on } \partial D, \quad (59)$$

where $u^i(x) = e^{ikx \cdot d}$, $|d| = 1$, and u^s is a radiating solution. We also recall from Theorem 1 that u^s has the asymptotic behavior

$$u^s(x, d) = \frac{e^{ik|x|}}{|x|} \left\{ u_\infty(\hat{x}, d) + O\left(\frac{1}{|x|}\right) \right\}, \quad |x| \rightarrow \infty, \quad (60)$$

uniformly for all directions $\hat{x} = x/|x|$, where u_∞ is the far-field pattern of the scattered field E^s . By Green’s integral theorem and the far-field representation (33), it can be shown that the far-field pattern satisfies the *reciprocity relation* [22]

$$u_\infty(\hat{x}, d) = u_\infty(-d, -\hat{x}), \quad \hat{x}, d \in S^2. \quad (61)$$

The *inverse scattering problem* we are concerned with is to determine D from a knowledge of $u_\infty(\hat{x}, d)$ for \hat{x} and d on the unit sphere S^2 and fixed wave number k . In particular, for the acoustic scattering problem (58) and (59), we want to show that D is uniquely determined by $u_\infty(\hat{x}, d)$ for $\hat{x}, d \in S^2$. We note that by the

reciprocity relation (61), the far-field pattern u_∞ is an analytic function of both \hat{x} and d , and hence it would suffice to consider u_∞ for \hat{x} and d restricted to a surface patch of the unit sphere S^2 .

Theorem 8. *Assume that D_1 and D_2 are two obstacles such that the far-field patterns corresponding to the exterior Dirichlet problem (58) and (59) for D_1 and D_2 coincide for all incident directions d . Then $D_1 = D_2$.*

Proof. Let u_1^s and u_2^s be the scattered fields corresponding to D_1 and D_2 , respectively. By the analyticity of the scattered field as a function of x and Rellich's Lemma 1, the scattered fields satisfy $u_1^s(\cdot, d) = u_2^s(\cdot, d)$ in the unbounded component G of the complement of $\overline{D_1} \cup \overline{D_2}$ for all $d \in S^2$. This in turn implies that the scattered fields corresponding to $\Phi(\cdot, z)$ as incident field and D_1 or D_2 as the scattering obstacle satisfy $u_1^s(x, z) = u_2^s(x, z)$ for all $x, z \in G$. Now assume that $D_1 \neq D_2$. Then, without loss of generality, there exists $x^* \in \partial G$ such that $x^* \in \partial D_1$ and $x^* \notin \overline{D_2}$. Then setting $z_n := x^* + \frac{1}{n}v(x^*)$, we have that $\lim_{n \rightarrow \infty} u_2^s(x^*, z_n)$ exists but $\lim_{n \rightarrow \infty} u_1^s(x^*, z_n) = \infty$ which is a contradiction and hence $D_1 = D_2$. ■

An open problem is to determine if one incident plane wave at a fixed wave number k is sufficient to uniquely determine the scatterer D . If it is known a priori that in addition to the sound-soft boundary condition (59) D is contained in a ball of radius R such that $kR < 4.49$, then D is uniquely determined by its far-field pattern for a single incident direction d and fixed wave number k [32] (see also [22]). D is also uniquely determined if instead of assuming that D is contained in a ball of sufficiently small radius, it is assumed that D is close to a given obstacle [87]. It is also known that for a wide class of sound-soft scatterers, a finite number of incident fields are sufficient to uniquely determine D [82]. Finally, if it is assumed that D is polyhedral, then a single incident plane wave is sufficient to uniquely determine D [1, 63].

We conclude this section on uniqueness results for the inverse scattering problem for an obstacle by considering the scattering of electromagnetic waves by a perfectly conducting obstacle D . From section "The Maxwell Equations" we recall that the direct obstacle scattering problem is to find $E, H \in C^2(\mathbb{R}^3 \setminus \overline{D}) \cap C(\mathbb{R}^3 \setminus D)$ such that the total field $E = E^i + E^s$, $H = H^i + H^s$ satisfies the Maxwell equations

$$\operatorname{curl} E - ikH = 0, \quad \operatorname{curl} H + ikE = 0 \quad \text{in } \mathbb{R}^3 \setminus \overline{D} \quad (62)$$

and the perfect conductor boundary condition

$$v \times E = 0 \quad \text{on } \partial D, \quad (63)$$

where E^i, H^i is the plane wave given by (50) and E^s, H^s is a radiating solution. We also recall from Theorem 1 that u^s has the asymptotic behavior

$$E^s(x, d, p) = \frac{e^{ik|x|}}{|x|} \left\{ E_\infty(\hat{x}, d, p) + O\left(\frac{1}{|x|}\right) \right\}, \quad |x| \rightarrow \infty, \quad (64)$$

where E_∞ is the electric far-field pattern of the scattered field E^s .

The inverse scattering problem is to determine D from a knowledge of $E_\infty(\hat{x}, d, p)$ for \hat{x} and d on the unit sphere S^2 , three linearly independent polarizations p , and fixed wave number k . We note that E_∞ is an analytic function of \hat{x} and d and is linear with respect to p . The following theorem can be proved using the same ideas as in the proof of Theorem 8.

Theorem 9. *Assume that D_1 and D_2 are two perfect conductors such that for a fixed wave number k , the electric far-field patterns for both scatterers coincide for all incident directions d and three linearly independent polarizations p . Then $D_1 = D_2$.*

In the case when D consists of finitely many polyhedra, a single incident wave is sufficient to uniquely determine D [62].

Scattering by an Inhomogeneous Medium

We now return to scattering of acoustic waves, but instead of scattering by a sound-soft obstacle, we consider scattering by an inhomogeneous medium where the governing equation (see section “Scattering by an Inhomogeneous Medium”) is

$$\Delta u + k^2 n u = 0 \quad \text{in } \mathbb{R}^3 \quad (65)$$

for $u = u^i + u^s \in C^2(\mathbb{R}^2)$, where $n \in C^1(\mathbb{R}^3)$ is the refractive index satisfying $\operatorname{Re} n > 0$ and $\operatorname{Im} n \geq 0$, $u^i(x) = e^{ikx \cdot d}$ and u^s is radiating. We let \overline{D} denote the support of $m := 1 - n$. By Theorem 1 the scattered wave u^s again has the asymptotic behavior (60). The inverse scattering problem we are now concerned with is to determine the index of refraction n (and hence D) from a knowledge of $u_\infty(\hat{x}, d)$ for \hat{x} and d on the unit sphere S^2 and fixed wave number k . In particular, we want to show that n is uniquely determined from $u_\infty(\hat{x}, d)$ for $\hat{x}, d \in S^2$ and fixed wave number k .

Theorem 10. *The refractive index n in (65) is uniquely determined by $u_\infty(\hat{x}, d)$ for $\hat{x}, d \in S^2$ and a fixed value of the wave number k .*

Proof. Let B be an open ball centered at the origin and containing the support of $m = 1 - n$. The first step in the proof is to construct a solution of (65) in B of the form

$$w(x) = e^{iz \cdot x} (1 + r(x)), \quad (66)$$

where $z \cdot z = 0$, $z \in \mathbb{C}^3$, and

$$\|r\|_{L^2(B)} \leq \frac{C}{|\operatorname{Re} z|}$$

for some positive constant C and $|\operatorname{Re} z|$ sufficiently large. This is done in [35] by using Fourier series. The second step is to show that, given two open balls B_1 and B_2 centered at the origin and containing the support of m such that $\overline{B_1} \subset B_2$, the set of solutions $\{u(\cdot, d) : d \in S^2\}$ satisfying (65) is complete in

$$H := \{w \in C^2(B_2) : \Delta w + k^2 n w = 0 \text{ in } B_2\}$$

with respect to the norm in $L^2(B_1)$ [35]. Now assume that n_1 and n_2 are refractive indices such that the corresponding far-field patterns satisfy $u_{1,\infty}(\cdot, d) = u_{2,\infty}(\cdot, d)$, $d \in S^2$, and assume that the supports of $1 - n_1$ and $1 - n_2$ are contained in $\overline{B_1}$. Then using Rellich's Lemma 1 and Green's integral theorem, it can be shown that

$$\int_{B_1} u_1(\cdot, \tilde{d}) u_2(\cdot, d) (n_1 - n_2) dx = 0$$

for all $d, \tilde{d} \in S^2$ and hence

$$\int_{B_1} w_1 w_2 (n_1 - n_2) dx = 0 \tag{67}$$

for all solutions $w_1, w_2 \in C^2(B_2)$ of $\Delta w_1 + k^2 n_1 w_1 = 0$ and $\Delta w_2 + k^2 n_2 w_2 = 0$ in B_2 . Now choose $z_1 := y + \rho a + i b$ and $z_2 := y - \rho a - i b$ such that $\{y, a, b\}$ is an orthogonal basis in \mathbb{R}^3 with the properties that $|a| = 1$ and $|b|^2 = |y|^2 + \rho^2$, and substitute these values of z into (66) arriving at functions w_1 and w_2 . Substitute these functions into (67), and let $\rho \rightarrow \infty$ to arrive at

$$\int_{B_1} e^{2i y \cdot x} (n_1(x) - n_2(x)) dx = 0$$

for arbitrary $y \in \mathbb{R}^3$, i.e., $n_1(x) = n_2(x)$ for $x \in B_1$ by the Fourier integral theorem.

■

In the case of scattering by a sound-soft obstacle, the proof of uniqueness given in Theorem 8 remains valid in \mathbb{R}^2 . However, this is not the case for scattering by an inhomogeneous medium. Indeed, until recently, the question of whether or not Theorem 10 remains valid in \mathbb{R}^2 was one of the outstanding open problems in inverse scattering theory. The problem was finally resolved in 2008 by Bukhgeim [4] who showed that in \mathbb{R}^2 the index of refraction n is uniquely determined by $u_\infty(\hat{x}, d)$ for $\hat{x}, d \in S^1$ and a fixed value of the wave number k .

We conclude this section with a few remarks on scattering by an anisotropic medium. Let n be as above and recall that \overline{D} is the support of $m := 1 - n$. Let A be a 3×3 matrix-valued function whose entries a_{jk} are continuously differentiable functions in \overline{D} such that A is symmetric and satisfies

$$\bar{\xi} \cdot (\operatorname{Im} A)\xi \leq 0, \quad \bar{\xi} \cdot (\operatorname{Re} A)\xi > \gamma |\xi|^2$$

for all $\xi \in \mathbb{C}^3$ and $x \in D$, where γ is a positive constant. We assume that $A(x) = I$ for $x \in \mathbb{R}^3 \setminus \overline{D}$. The anisotropic scattering problem is to find $u = u^i + u^s \in H_{\text{loc}}^1(\mathbb{R}^3)$ such that

$$\nabla \cdot A \nabla u + k^2 n u = 0 \quad \text{in } \mathbb{R}^3 \tag{68}$$

in the weak sense where again $u^i(x) = e^{ikx \cdot d}$ and u^s is radiating. The existence of a unique solution to this scattering problem has been established by Hähner [36].

The scattered field again has the asymptotics (60). The inverse scattering problem is now to determine D from a knowledge of the far-field pattern $u_\infty(\hat{x}, d)$ for $\hat{x}, d \in S^2$. We note that the matrix A is not uniquely determined by u_∞ , and hence without further a priori assumptions, the determination of D is the most that can be hoped for [33, 74]. To this end we have the following theorem due to Hähner [36].

Theorem 11. *Assume $\gamma > 1$. Then D is uniquely determined by $u_\infty(\hat{x}, d)$ for $\hat{x}, d \in S^2$.*

We note that Theorem 11 remains valid if the condition on $\operatorname{Re} A$ is replaced by the condition

$$\bar{\xi} \cdot (\operatorname{Re} A^{-1})\xi \geq \mu |\xi|^2$$

for all $\xi \in \mathbb{C}^3$ and $x \in \overline{D}$ where μ is a positive constant such that $\mu > 1$ [7]. Note that the isotropic case when $A = I$ is handled by Theorem 10.

Uniqueness theorems for the Maxwell equations in an isotropic inhomogeneous medium have been established by Colton and Päivärinta [27] and Hähner [37]. The proof is similar to that of Theorem 10 for the scalar problem except that technical problems arise due to the fact that we must now construct a solution E, H to the Maxwell equations in an inhomogeneous isotropic medium such that E has the form

$$E(x) = e^{iz \cdot x} (\eta + r(x)),$$

where $z, \eta \in \mathbb{C}^3$, $\eta \cdot z = 0$, and $z \cdot z = k^2$. In contrast to the case of acoustic waves, it is no longer true that $r(x)$ decays to zero as $|\operatorname{Re} z|$ tends to infinity. Finally, the generalization of Theorem 11 to the case of the Maxwell equations in an anisotropic media has been done by Cakoni and Colton [5].

Historical Remarks

As previously mentioned, the first uniqueness theorem for the acoustic inverse obstacle problem was given by Schiffer in 1967 for the case of a sound-soft obstacle [61], whereas in 1988 Nachman [68], Novikov [70], and Ramm [79] established a uniqueness result for the inverse scattering problem for an inhomogeneous medium. In 1990 Isakov [40, 41] proved a series of uniqueness theorems for the transmission problem with discontinuities of u across ∂D . His ideas were subsequently utilized by Kirsch, Kress, and their coworkers to establish uniqueness theorems for a variety of inverse scattering problems for both acoustic and electromagnetic waves (for references, see [22]). In particular, the proofs of Theorems 8 and 9 are based on the ideas of Kirsch and Kress [22, 54].

A global uniqueness theorem for the Maxwell equations in an isotropic inhomogeneous medium was first established in 1992 by Colton and Päivärinta [27] (see also [37]). The results of [27, 37] are for the case when the magnetic permeability μ is constant. For uniqueness results in the case when μ is no longer constant, we refer to [71, 72].

4 Iterative and Decomposition Methods in Inverse Scattering

Newton Iterations in Inverse Obstacle Scattering

We now turn to reconstruction methods for the inverse scattering problem for sound-soft scatterers, and as a first group we describe iterative methods. Here the inverse problem is interpreted as a nonlinear ill-posed operator equation which is solved by iteration methods such as regularized Newton methods, Landweber iterations, or conjugate gradient methods. For a fixed incident field u^i , the solution to the direct scattering problem defines the *boundary to far field operator* $\mathcal{F} : \partial D \mapsto u_\infty$ which maps the boundary ∂D of the scatterer D onto the far-field pattern u_∞ of the scattered wave u^s . In particular, \mathcal{F} is the imaging operator that takes the scattering object D into its image u_∞ via the scattering process. In terms of this imaging operator, i.e., the boundary to far field operator, given a far-field pattern u_∞ , the inverse problem consists in solving the operator equation

$$\mathcal{F}(\partial D) = u_\infty \tag{69}$$

for the unknown boundary ∂D . As opposed to the direct obstacle scattering problem which is linear and well-posed, the operator equation (69), i.e., the inverse obstacle scattering problem, is nonlinear and ill-posed. It is nonlinear since the solution to the direct scattering problem depends nonlinearly on the boundary, and it is ill-posed because the far-field mapping is extremely smoothing due to the analyticity of the far-field pattern.

In order to define the operator \mathcal{F} properly, the most appropriate approach is to choose a fixed reference domain D and consider a family of scatterers D_h with boundaries represented in the form $\partial D_h = \{x + h(x) : x \in \partial D\}$, where $h : \partial D \rightarrow \mathbb{R}^3$ is of class C^2 and is sufficiently small in the C^2 norm on ∂D . Then we may consider the operator \mathcal{F} as a mapping from a ball

$$V := \{h \in C^2(\partial D) : \|h\|_{C^2} < a\} \subset C^2(\partial D)$$

with sufficiently small radius $a > 0$ into $L^2(S^2)$. However, for ease of presentation, we proceed differently and restrict ourselves to boundaries ∂D that can be parameterized by mapping them globally onto the unit sphere S^2 , i.e.,

$$\partial D = \{p(\hat{x}) : \hat{x} \in S^2\} \quad (70)$$

for some injective C^2 function $p : S^2 \rightarrow \mathbb{R}^3$. As a simple example, the reader should consider the case of starlike domains where

$$p(\hat{x}) = r(\hat{x})\hat{x}, \quad \hat{x} \in S^2, \quad (71)$$

with a radial distance function $r : S^2 \rightarrow (0, \infty)$. Then, with some appropriate subspace $W \subset C^2(S^2)$, we may interpret the operator \mathcal{F} as a mapping

$$\mathcal{F} : W \rightarrow L^2(S^2), \quad \mathcal{F} : p \mapsto u_\infty,$$

and consequently the inverse obstacle scattering problem consists in solving

$$\mathcal{F}(p) = u_\infty \quad (72)$$

for the unknown function p .

Since \mathcal{F} is nonlinear we may linearize

$$\mathcal{F}(p + q) = \mathcal{F}(p) + \mathcal{F}'(p)q + O(q^2)$$

in terms of a Fréchet derivative \mathcal{F}' . Then, given an approximation p for the solution of (72), in order to obtain an update $p + q$, we solve the approximate linear equation

$$\mathcal{F}(p) + \mathcal{F}'(p)q = u_\infty \quad (73)$$

for q . We note that the linearized equation inherits the ill-posedness of the nonlinear equation and therefore regularization is required. As in the classical Newton iterations, this linearization procedure is iterated until some stopping criteria is satisfied.

In principle the parameterization of the update $\partial D_{p+q} = \{p(\hat{x}) + q(\hat{x}) : \hat{x} \in S^2\}$ is not unique. To cope with this ambiguity, the simplest possibility is to allow only perturbations of the form

$$q(\hat{x}) = z(\hat{x}) v(p(\hat{x})), \quad x \in S^2, \quad (74)$$

with a scalar function z . We denote the corresponding linear space of normal L^2 vector fields by $L^2_{\text{normal}}(S^2)$.

The Fréchet differentiability of the operator \mathcal{F} is addressed in the following theorem.

Theorem 12. *The boundary to far-field mapping $\mathcal{F}: p \mapsto u_\infty$ is Fréchet differentiable. The derivative is given by*

$$\mathcal{F}'(p)q = v_{q,\infty},$$

where $v_{q,\infty}$ is the far-field pattern of the radiating solution v_q to Helmholtz equation in $\mathbb{R}^3 \setminus \overline{D}$ satisfying the Dirichlet boundary condition

$$v_q = -\nu \cdot q \frac{\partial u}{\partial \nu} \quad \text{on } \partial D \quad (75)$$

in terms of the total field $u = u^i + u^s$.

The boundary condition (75) for the derivative can be obtained formally by using the chain rule to differentiate the boundary condition $u = 0$ on ∂D with respect to the boundary. Extensions of Theorem 12 to the Neumann boundary condition, the perfect conductor boundary condition, and to the impedance boundary condition in acoustics and electromagnetics are also available.

To justify the application of regularization methods for stabilizing (73), injectivity and dense range of the operator $\mathcal{F}'(p) : L^2_{\text{normal}}(S^2) \rightarrow L^2(S^2)$ need to be established. This is settled for the Dirichlet condition and, for λ sufficiently large, for the impedance boundary condition and remains an open problem for the Neumann boundary condition. In the classical Tikhonov regularization, (73) is replaced by

$$\alpha q + [\mathcal{F}'(p)]^* \mathcal{F}'(p)q = [\mathcal{F}'(p)]^* \{u_\infty - \mathcal{F}(p)\} \quad (76)$$

with some positive regularization parameter α and the L^2 adjoint $[\mathcal{F}'(p)]^*$ of $\mathcal{F}'(p)$. For details on the numerical implementation, we refer to [22] and the references therein. The numerical examples strongly indicate that it is advantageous to use some Sobolev norm instead of the L^2 norm as the penalty term in the Tikhonov regularization. Numerical examples in three dimensions have been reported by Farhat et al. [31] and by Harbrecht and Hohage [38].

In closing this section on Newton iterations, we note as their main advantages that this approach is conceptually simple and, as the numerical examples in the literature indicate, leads to highly accurate reconstructions with reasonable stability against errors in the far-field pattern. On the other hand, it should be noted that for the numerical implementation, an efficient forward solver is needed and good a

priori information is required in order to ensure convergence. On the theoretical side, the convergence of regularized Newton iterations for inverse obstacle scattering problems has not been completely settled, although some progress has been made through the work of Hohage [39] and Potthast [77].

Newton-type iterations can also be employed for the simultaneous determination of the boundary shape and the impedance function λ in the impedance boundary condition (8) [58].

Decomposition Methods

The main idea of decomposition methods is to break up the inverse obstacle scattering problem into two parts: The first part deals with the ill-posedness by constructing the scattered wave u^s from its far-field pattern u_∞ and the second part deals with the nonlinearity by determining the unknown boundary ∂D of the scatterer as the location where the boundary condition for the total field $u^i + u^s$ is satisfied in a least-squares sense. In the *potential method*, for the first part, enough a priori information on the unknown scatterer D is assumed so one can place a closed surface Γ inside D . Then the scattered field u^s is sought as a single-layer potential

$$u^s(x) = \int_{\Gamma} \varphi(y) \Phi(x, y) ds(y), \quad x \in \mathbb{R}^3 \setminus \overline{D}, \quad (77)$$

with an unknown density $\varphi \in L^2(\Gamma)$. In this case the far-field pattern u_∞ has the representation

$$u_\infty(\hat{x}) = \frac{1}{4\pi} \int_{\Gamma} e^{-ik\hat{x} \cdot y} \varphi(y) ds(y), \quad \hat{x} \in S^2.$$

Given the far-field pattern u_∞ , the density φ is now found by solving the integral equation of the first kind

$$S_\infty \varphi = u_\infty \quad (78)$$

with the compact integral operator $S_\infty : L^2(\Gamma) \rightarrow L^2(S^2)$ given by

$$(S_\infty \varphi)(\hat{x}) := \frac{1}{4\pi} \int_{\Gamma} e^{-ik\hat{x} \cdot y} \varphi(y) ds(y), \quad \hat{x} \in S^2.$$

Due to the analytic kernel of S_∞ , the integral equation (78) is severely ill-posed. For a stable numerical solution of (78), Tikhonov regularization can be applied, i.e., the ill-posed equation (78) is replaced by

$$\alpha \varphi_\alpha + S_\infty^* S_\infty \varphi_\alpha = S_\infty^* u_\infty \quad (79)$$

with some positive regularization parameter α and the adjoint S_∞^* of S_∞ .

Given an approximation of the scattered wave u_α^s obtained by inserting a solution φ_α of (79) into the potential (77), the unknown boundary ∂D is then determined by requiring the sound-soft boundary condition

$$u^i + u^s = 0 \quad \text{on } \partial D \quad (80)$$

to be satisfied in a least-squares sense, i.e., by minimizing the L^2 norm of the defect

$$\|u^i + u_\alpha^s\|_{L^2(\Lambda)}^2 \quad (81)$$

over a suitable set of admissible surfaces Λ . Instead of solving this minimization problem, one can also visualize ∂D by color coding the values of the modulus $|u|$ of the total field $u \approx u^i + u_\alpha^s$ on a sufficiently fine grid over some domain containing the scatterer.

Clearly we can expect (78) to have a solution $\varphi \in L^2(\Gamma)$ if and only if u_∞ is the far field of a radiating solution to the Helmholtz equation in the exterior of Γ with sufficiently smooth boundary values on Γ . Hence, the solvability of (78) is related to the regularity properties of the scattered wave which in general cannot be known in advance for the unknown scatterer D . Nevertheless, it is possible to provide a solid theoretical foundation to the above procedure [22, 53]. This is achieved by combining the minimization of the Tikhonov functional for (78) and the defect minimization for (81) into one cost functional

$$\|S_\infty \varphi - u_\infty\|_{L^2(S^2)}^2 + \alpha \|\varphi\|_{L^2(\Gamma)}^2 + \gamma \|u^i + u_\alpha^s\|_{L^2(\Lambda)}^2. \quad (82)$$

Here $\gamma > 0$ denotes a coupling parameter which has to be chosen appropriately for the numerical implementation in order to make the two terms in (82) be of the same magnitude, for example, $\gamma = \|u_\infty\|_{L^2(S^2)} / \|u^i\|_\infty$.

Note that the potential approach can also be employed for the inverse problem to recover the impedance given the shape of the scatterer. In this case the far-field equation (78) is solved with Γ replaced by the known boundary ∂D . After the density φ is obtained, λ can be determined in a least-squares sense from the impedance boundary condition (8) after evaluating the trace and the normal derivative of the single-layer potential (77) on ∂D .

The *point source method* of Potthast [76] can also be interpreted as a decomposition method. Its motivation is based on Huygens' principle from Theorem 4, i.e., the scattered field representation

$$u^s(x) = - \int_{\partial D} \frac{\partial u}{\partial v}(y) \Phi(x, y) ds(y), \quad x \in \mathbb{R}^3 \setminus \overline{D}, \quad (83)$$

and the far-field representation

$$u_\infty(\hat{x}) = - \frac{1}{4\pi} \int_{\partial D} \frac{\partial u}{\partial v}(y) e^{-ik\hat{x} \cdot y} ds(y), \quad \hat{x} \in S^2. \quad (84)$$

For $z \in \mathbb{R}^3 \setminus \overline{D}$ we choose a domain B_z such that $z \notin B_z$ and $\overline{D} \subset B_z$ and approximate the point source $\Phi(\cdot, z)$ by a *Herglotz wave function*, i.e., a superposition of plane waves such that

$$\Phi(y, z) \approx \int_{S^2} e^{ik y \cdot d} g_z(d) ds(d), \quad y \in B_z, \quad (85)$$

for some $g_z \in L^2(S^2)$. Under the assumption that there does not exist a nontrivial solution to the Helmholtz equation in B_z with homogeneous Dirichlet boundary condition on ∂B_z , the Herglotz wave functions are dense in $H^{1/2}(\partial B_z)$ [23, 30], and consequently the approximation (85) can be achieved uniformly with respect to y on compact subsets of B_z . We can now insert (85) into (32) and use (33) to obtain

$$u^s(z) \approx 4\pi \int_{S^2} g_z(\hat{x}) u_\infty(-\hat{x}) ds(\hat{x}) \quad (86)$$

as an approximation for the scattered wave u^s . Knowing an approximation for the scattered wave, the boundary ∂D can be found as above from the boundary condition (80).

The approximation (85) can in practice be obtained by solving the ill-posed linear integral equation

$$\int_{S^2} e^{ik y \cdot d} g_z(d) ds(d) = \Phi(y, z), \quad y \in \partial B_z, \quad (87)$$

via Tikhonov regularization and the Morozov discrepancy principle. Note that although the integral equation (87) is in general not solvable, the approximation property (86) is ensured through the above denseness result on Herglotz wave functions.

An advantage of decomposition methods is that the separation of the ill-posedness and the nonlinearity is conceptually straightforward. A second and main advantage consists in the fact that their numerical implementation does not require a forward solver. As a disadvantage, as in the Newton method of the previous section, if we go beyond visualization of the level surfaces of $|u|$ and proceed with the minimization, good a priori information on the unknown scatterer is needed for the iterative solution of the optimization problem. The accuracy of the reconstructions using decomposition methods is slightly inferior to that using Newton iterations.

Iterative Methods Based on Huygens' Principle

We recall Huygens' principle (83) and (84). In view of the sound-soft boundary condition, from (83), we conclude that

$$u^i(x) = \int_{\partial D} \frac{\partial u}{\partial \nu}(y) \Phi(x, y) ds(y), \quad x \in \partial D. \quad (88)$$

Now we can interpret (84) and (88) as a system of two integral equations for the unknown boundary ∂D of the scatterer and the induced surface flux

$$\varphi := -\frac{\partial u}{\partial \nu} \quad \text{on } \partial D.$$

It is convenient to call (84) the *data equation* since it contains the given far field for the inverse problem and (88) the *field equation* since it represents the boundary condition. Both equations are linear with respect to the flux and nonlinear with respect to the boundary. Equation (84) is severely ill-posed whereas (88) is only mildly ill-posed.

Obviously there are three options for an iterative solution of (84) and (88). In a first method, given an approximation for the boundary ∂D , one can solve the mildly ill-posed integral equation of the first kind (88) for φ . Then, keeping φ fixed, Eq. (84) is linearized with respect to ∂D to update the boundary approximation. This approach has been proposed by Johansson and Sleeman [45]. In a second approach, following ideas first developed for the Laplace equation by Kress and Rundell [59], one also can solve the system (84) and (88) simultaneously for ∂D and φ by Newton iterations, i.e., by linearizing both equations with respect to both unknowns. This idea has been analyzed by Ivanyshyn and Kress [42,43]. Whereas in the first method the burden of the ill-posedness and nonlinearity is put on one equation, in a third method, a more even distribution of the difficulties is obtained by reversing the roles of (84) and (88), i.e., by solving the severely ill-posed equation (84) for φ and then linearizing (88) to obtain the boundary update. With a slight modification, this approach may also be interpreted as a decomposition method since to some extent it separates the ill-posedness and the nonlinearity. It combines the decomposition method from the previous section ‘‘Decomposition Methods’’ with elements of Newton iterations from section ‘‘Newton Iterations in Inverse Obstacle Scattering’’. Therefore, it has also been termed as a *hybrid method* and as such was analyzed by Kress and Serrano [57,85].

For a more detailed description of these three methods, using the parameterization (70), we introduce the parameterized single-layer operator and far-field operator $A, A_\infty : C^2(S^2) \times L^2(S^2) \rightarrow L^2(S^2)$ by

$$A(p, \psi)(\hat{x}) := \int_{S^2} \Phi(p(\hat{x}), p(\hat{y})) \psi(\hat{y}) ds(\hat{y}), \quad \hat{x} \in S^2,$$

and

$$A_\infty(p, \psi)(\hat{x}) := \frac{1}{4\pi} \int_{S^2} e^{-ik \hat{x} \cdot p(\hat{y})} \psi(\hat{y}) ds(\hat{y}), \quad \hat{x} \in S^2.$$

Then (84) and (88) can be written in the operator form

$$A_\infty(p, \psi) = u_\infty \tag{89}$$

and

$$A(p, \psi) = -u^i \circ p, \quad (90)$$

where we have incorporated the surface element into the density function via

$$\psi(\hat{x}) := J(\hat{x}) \varphi(p(\hat{x})) \quad (91)$$

with the Jacobian J of the mapping p . The linearization of these equations requires the Fréchet derivatives of the operators A and A_∞ with respect to p . These can be obtained by formally differentiating their kernels with respect to p , i.e.,

$$(A'(p, \psi)q)(\hat{x}) = \int_{S^2} \text{grad}_x \Phi(p(\hat{x}), p(\hat{y})) \cdot [q(\hat{x}) - q(\hat{y})] \psi(\hat{y}) ds(\hat{y}), \quad x \in S^2,$$

and

$$(A'_\infty(p, \psi)q)(\hat{x}) = -\frac{ik}{4\pi} \int_{S^2} e^{-ik\hat{x} \cdot p(\hat{y})} \hat{x} \cdot q(\hat{y}) \psi(\hat{y}) ds(\hat{y}), \quad x \in S^2.$$

For fixed p , provided k^2 is not a Dirichlet eigenvalue of the negative Laplacian in D , both in a Hölder space setting $A(p, \cdot) : C^{0,\alpha}(S^2) \rightarrow C^{1,\alpha}(S^2)$ or in a Sobolev space setting $A(p, \cdot) : H^{-1/2}(S^2) \rightarrow H^{1/2}(S^2)$, the operator $A(p, \cdot)$ is a homeomorphism [22]. In this case, given an approximation to the boundary parameterization p , the field equation (90) can be solved for the density ψ . Then, keeping ψ fixed, linearizing the data equation (89) with respect to p leads to the linear equation

$$A'_\infty \left(p, \underbrace{[A(p, \cdot)]^{-1}(u^i \circ p)}_{-\psi} \right) q = -u_\infty - A_\infty \left(p, \underbrace{[A(p, \cdot)]^{-1}(u^i \circ p)}_{-\psi} \right) \quad (92)$$

for q to update the parameterization p via $p + q$. This procedure can be iterated.

For fixed p the operator $A'_\infty(p, [A(p, \cdot)]^{-1}(u^i \circ p))$ has a smooth kernel and therefore is severely ill-posed. This requires stabilization, for example, via Tikhonov regularization. The following theorem ensures injectivity and dense range as prerequisites for Tikhonov regularization. We recall the form (74) introduced for uniqueness of the parameterization of the update and the corresponding linear space $L^2_{\text{normal}}(S^2)$ of normal L^2 vector fields.

Theorem 13. *Assume that k^2 is not a Neumann eigenvalue of the negative Laplacian in D . Then the operator*

$$A'_\infty(p, [A(p, \cdot)]^{-1}(u^i \circ p)) : L^2_{\text{normal}}(S^2) \rightarrow L^2(S^2)$$

is injective and has dense range.

One can relate this approach to the Newton iterations for the nonlinear equation (69) for the boundary to far-field operator of section ‘‘Newton Iterations in Inverse Obstacle Scattering’’. In the case when k^2 is not a Dirichlet eigenvalue of the negative Laplacian in D , one can write

$$\mathcal{F}(p) = -A_\infty(p, [A(p, \cdot)]^{-1}(u^i \circ p)).$$

By the product and chain rule, this implies

$$\begin{aligned} \mathcal{F}'(p)q &= -A'_\infty(p, [A(p, \cdot)]^{-1}(u^i \circ p))q \\ &\quad + A_\infty(p, [A(p, \cdot)]^{-1}A'(p, [A(p, \cdot)]^{-1}(u^i \circ p))q) \\ &\quad - A_\infty(p, [A(p, \cdot)]^{-1}((\text{grad } u^i) \circ p) \cdot q). \end{aligned} \quad (93)$$

Hence, we observe a relation between the above iterative scheme and the Newton iterations for the boundary to far-field map as expressed by the following theorem.

Theorem 14. *The iteration scheme given by (92) can be interpreted as Newton iterations for (69) with the derivative of \mathcal{F} approximated by the first term in the representation (93).*

As to be expected from this close relation to Newton iterations for (69), the quality of the reconstructions via (92) can compete with those of Newton iterations with the benefit of reduced computational costs.

The second approach for iteratively solving the system (89) and (90) consists in simultaneously linearizing both equations with respect to both unknowns. In this case, given approximations p and ψ both for the boundary parameterization and the density, the system of linear equations

$$A'_\infty(p, \psi)q + A_\infty(p, \chi) = -A_\infty(p, \psi) + u_\infty \quad (94)$$

and

$$A'(p, \psi)q + ((\text{grad } u^i) \circ p) \cdot q + A(p, \chi) = -A(p, \psi) - u^i \circ p \quad (95)$$

has to be solved for q and χ in order to obtain updates $p + q$ for the boundary parameterization and $\psi + \chi$ for the density. This procedure again is iterated and coincides with Newton’s method for the system (89) and (90).

For uniqueness reasons the updates must be restricted, for example, to normal fields of the form (74). Due to the smoothness of the kernels, both Eqs. (94) and (95) are severely ill-posed and require regularization with respect to both unknowns. In particular for the parameterization update, it is appropriate to incorporate penalties for Sobolev norms of q to guarantee smoothness of the boundary whereas for the density L^2 penalty terms on χ are sufficient.

The simultaneous iterations (94) and (95) again exhibit connections to the Newton iteration for (69).

Theorem 15. Assume that k^2 is not a Dirichlet eigenvalue of the negative Laplacian in D , and set $\psi := -[A(p, \cdot)]^{-1}(u^i \circ p)$. If q satisfies the linearized boundary to far-field equation (73), then q and

$$\chi := -[A(p, \cdot)]^{-1}(A'(p, \psi)q + ((\text{grad } u^i) \circ p) \cdot q)$$

satisfy the linearized data and field equations (94) and (95). Conversely, if q and χ satisfy (94) and (95), then q satisfies (73).

Theorem 15 illustrates the difference between the iteration method based on (94) and (95) and the Newton iterations for (69). In general when performing (94) and (95) in the sequence of updates, the relation $A(p, \psi) = -(u^i \circ p)$ between the approximations p and ψ for the parameterization and the density will not be satisfied. This observation also indicates a possibility to use (94) and (95) for implementing a Newton scheme for (69). It is only necessary to replace the update $\psi + \chi$ for the density by $-[A(p + q, \cdot)]^{-1}(u^i \circ (p + q))$, i.e., at the expense of throwing away χ and solving a boundary integral equation for a new density. For a numerical implementation and three-dimensional examples, we refer to [44].

In a third method, in order to evenly distribute the burden of the ill-posedness and the nonlinearity of the inverse obstacle scattering problem, instead of solving the field equation (90) for the density and then linearizing the data equation, one can also solve the severely ill-posed data equation (91) for the density and then linearize the mildly ill-posed field equation (92) to update the boundary. In this case, given an approximation for the boundary parameterization p , first the data equation (91) is solved for the density ψ . Then, keeping ψ fixed, the field equation (92) is linearized to obtain the linear equation

$$A'(p, \psi)q + ((\text{grad } u^i) \circ p) \cdot q = -A(p, \psi) - u^i \circ p \quad (96)$$

for q to update the parameterization p via $p + q$. This procedure of alternatingly solving (91) and (96) can be iterated. To some extent this procedure mimics a decomposition method in the sense that it decomposes the inverse problem into a severely ill-posed linear problem and a nonlinear problem.

The hybrid method suggested by Kress and Serranho [57, 85] can be considered as a slight modification of the above procedure. In this method, given an approximation p for the parameterization of the boundary, the data equation (91) is solved for the density ψ via regularization. Injectivity and dense range of the operator $A_\infty(p, \cdot) : L^2(S^2) \rightarrow L^2(S^2)$ are guaranteed provided k^2 is not a Dirichlet eigenvalue for the negative Laplacian in D [22]. Then one can define the single-layer potential

$$u^s(x) = \int_{S^2} \Phi(x, p(\hat{y}))\psi(\hat{y}) ds(\hat{y})$$

and evaluate the boundary values of $u := u^i + u^s$ and its derivatives on the surface represented by p via the jump relations. Finally an update $p + q$ is found by linearizing the boundary condition $u \circ (p + q) = 0$, i.e., by solving the linear equation

$$u \circ p + ((\text{grad } u) \circ p) \cdot q = 0 \quad (97)$$

for q . For uniqueness of the update representation, the simplest possibility is to allow only perturbations of the form (74). Then injectivity for the linear equation (97) can be established for the exact boundary.

After introducing the operator

$$\begin{aligned} (\tilde{A}(p, \psi) q)(\hat{x}) &:= \int_{S^2} \text{grad}_x \Phi(p(\hat{x}), p(\hat{y})) \cdot q(\hat{x}) \psi(\hat{y}) ds(\hat{y}) \\ &\quad - \frac{1}{2} \frac{\psi(\hat{x}) [v(p(\hat{x})) \cdot q(\hat{x})]}{J(\hat{x})} \end{aligned}$$

and observing the jump relations for the single-layer potential and (91), Eq. (97) can be rewritten as

$$\tilde{A}(p, \psi) q + ((\text{grad } u^i) \circ p) \cdot q = -A(p, \psi) - u^i \circ p. \quad (98)$$

Comparing this with (96), we discover a relation between solving the data and field equation iteratively via (89) and (96) and the hybrid method of Kress and Serranho. In the hybrid method, the Fréchet derivative of A with respect to p is replaced by the operator \tilde{A} where one linearizes only with respect to the evaluation surface for the single-layer potential but not with respect to the integration surface. For the numerical implementation of the hybrid method and numerical examples in three dimensions, we refer to [86].

All three methods of this section can be applied to the Neumann boundary condition, the perfect conductor boundary condition, and to the impedance boundary condition in acoustics and electromagnetics. They also can be employed for the simultaneous reconstruction of the boundary shape and the impedance function λ in the impedance boundary condition (8) [84].

Newton Iterations for the Inverse Medium Problem

Analogously to the inverse obstacle scattering problem, we can reformulate the inverse medium problem as a nonlinear operator equation. To this end we define the *far-field operator* $\mathcal{F} : m \mapsto u_\infty$ that maps $m := 1 - n$ to the far-field pattern u_∞ for plane wave incidence $u^i(x) = e^{ikx \cdot d}$. Since by Theorem 10 we know that m is uniquely determined by a knowledge of $u_\infty(\hat{x}, d)$ for all incident and observation directions $\hat{x}, d \in S^2$, we interpret \mathcal{F} as an operator from $C(B)$ into $L^2(S^2 \times S^2)$ for a ball B that contains the unknown support of m .

In view of the Lippmann–Schwinger equation (35) and the far-field representation (36), we can write

$$(\mathcal{F}(m))(\hat{x}, d) = -\frac{k^2}{4\pi} \int_B e^{-ik\hat{x}\cdot y} m(y) u(y, d) dy, \quad \hat{x}, d \in S^2, \quad (99)$$

where $u(\cdot, d)$ is the unique solution of

$$u(x, d) + k^2 \int_B \Phi(x, y) m(y) u(y, d) dy = u^i(x, d), \quad x \in B. \quad (100)$$

From (100) it can be seen that the Fréchet derivative v_q of u with respect to m (in direction q) satisfies the Lippmann–Schwinger equation

$$v_q(x, d) + k^2 \int_B \Phi(x, y) [m(y) v_q(y, d) + q(y) u(y, d)] dy = 0, \quad x \in B. \quad (101)$$

From this and (99), it follows that the Fréchet derivative of \mathcal{F} is given by

$$(\mathcal{F}'(m) q)(\hat{x}, d) = -\frac{k^2}{4\pi} \int_B e^{-ik\hat{x}\cdot y} [m(y) v_q(y, d) + q(y) u(y, d)] dy, \quad \hat{x}, d \in S^2,$$

which coincides with the far-field pattern of the solution $v_q(\cdot, d)$ of (101). Hence, we have proven the following theorem.

Theorem 16. *The far-field mapping $\mathcal{F} : m \mapsto u_\infty$ is Fréchet differentiable. The derivative is given by*

$$\mathcal{F}'(m)q = v_{q,\infty},$$

where $v_{q,\infty}$ is the far-field pattern of the radiating solution v_q to

$$\Delta v + k^2 nv = -k^2 uq \quad \text{in } \mathbb{R}^3. \quad (102)$$

This characterization of the Fréchet derivative can be used to establish injectivity of $\mathcal{F}'(m)$. We now have all the prerequisites available for a regularized Newton iteration analogous to (76).

A similar approach as that given above is also possible for the electromagnetic inverse medium problem.

Least-Squares Methods for the Inverse Medium Problem

In view of the Lippmann–Schwinger equation (35) and the far-field representation (36), the inverse medium problem is equivalent to solving the system consisting of the *field equation*

$$u(x, d) + k^2 \int_B \Phi(x, y) m(y) u(y, d) dy = u^i(x, d), \quad x \in B, d \in S^2, \quad (103)$$

and the *data equation*

$$-\frac{k^2}{4\pi} \int_B e^{-ik\hat{x}\cdot y} m(y) u(y, d) dy = u_\infty(\hat{x}, d), \quad \hat{x}, d \in S^2, \quad (104)$$

where B is a ball containing the support of m . In principle one can first solve the ill-posed linear equation (104) to determine the source mu from the far-field pattern and then solve the nonlinear equation (103) to construct the contrast m . After defining the volume potential operator $T : L^2(B \times S^2) \rightarrow L^2(B \times S^2)$ and the far-field operator $F : L^2(B \times S^2) \rightarrow L^2(S^2 \times S^2)$ by

$$(Tv)(x, d) := -k^2 \int_B \Phi(x, y) v(y, d) dy, \quad x \in B, d \in S^2,$$

and

$$(Fv)(\hat{x}, d) := -\frac{k^2}{4\pi} \int_B e^{-ik\hat{x}\cdot d} v(y, d) dy, \quad \hat{x}, d \in S^2,$$

we rewrite the field equation (103) as

$$u^i + Tmu = u \quad (105)$$

and the data equation (104) as

$$Fmu = u_\infty. \quad (106)$$

We can now define the cost function

$$\mu(m, u) := \frac{\|u^i + Tmu - u\|_{L^2(B \times S^2)}^2}{\|u^i\|_{L^2(B \times S^2)}^2} + \frac{\|u_\infty - Fmu\|_{L^2(S^2 \times S^2)}^2}{\|u_\infty\|_{L^2(S^2 \times S^2)}^2} \quad (107)$$

and reformulate the inverse medium problem as the optimization problem to minimize μ over the contrast $m \in V$ and the fields $u \in W$ where V and W are appropriately chosen admissible sets. The weights in the cost function are chosen such that the two terms are of the same magnitude.

This optimization problem is similar in structure to that used in (82) in connection with the decomposition method for the inverse obstacle scattering problem. However, since by Theorem 10 all incident directions are required, the discrete versions of the optimization problem suffer from a large number of unknowns. Analogous to the two step approaches of sections “Decomposition Methods” and “Iterative Methods Based on Huygens’ Principle” for the inverse obstacle scattering problem,

one way to reduce the computational complexity is to treat the fields and the contrast separately, for example, by a modified conjugate gradient method as proposed by Kleinman and van den Berg [55]. In a modified version of this approach, van den Berg and Kleinman [89] transformed the Lippmann–Schwinger equation (105) into the equation

$$mu^i + mTw = w \quad (108)$$

for the contrast sources $w := mu$, and instead of simultaneously updating the contrast m and the fields u , the contrast is updated together with the contrast source w . The cost function (107) is now changed to

$$\mu(m, w) := \frac{\|mu^i + mTw - w\|_{L^2(B \times S^2)}^2}{\|u^i\|_{L^2(B \times S^2)}^2} + \frac{\|u_\infty - Fmu\|_{L^2(S^2 \times S^2)}^2}{\|u_\infty\|_{L^2(S^2 \times S^2)}^2}.$$

The above approach for the acoustic inverse medium problem can be adapted to the case of electromagnetic waves.

Born Approximation

The Born approximation turns the inverse medium scattering problem into a linear problem and therefore is often employed in practical applications. In view of (36), for plane wave incidence, we have the linear integral equation

$$-\frac{k^2}{4\pi} \int_{\mathbb{R}^3} e^{-ik(\hat{x}-d) \cdot y} m(y) dy = u_\infty(\hat{x}, d) \quad \hat{x}, d \in S^2. \quad (109)$$

Solving (109) for the unknown m corresponds to inverting the Fourier transform of m restricted to the ball of radius $2k$ centered at the origin, i.e., only incomplete data is available. This causes uniqueness ambiguities and leads to severe ill-posedness of the inversion. Thus, the ill-posedness which seemed to have disappeared through the inversion of the Fourier transform is back on stage. For details, we refer to [60].

A counterpart of the Born approximation in inverse obstacle scattering starts from the far field of the physical optics approximation (36) for a convex sound-soft scatterer D in the *back scattering* direction, i.e.,

$$u_\infty(-d; d) = -\frac{1}{4\pi} \int_{v(y) \cdot d < 0} \frac{\partial}{\partial v(y)} e^{2ik d \cdot y} ds(y).$$

Analogously, replacing d by $-d$, we have

$$u_\infty(d; -d) = -\frac{1}{4\pi} \int_{v(y) \cdot d > 0} \frac{\partial}{\partial v(y)} e^{-2ik d \cdot y} ds(y).$$

Combining the last two equations and using Green's integral theorem, we find

$$\int_{\mathbb{R}^3} \chi(y) e^{2ikd \cdot y} dy = \frac{\pi}{k^2} \left\{ u_\infty(-d; d) + \overline{u_\infty(d; -d)} \right\}, \quad d \in S^2, \quad (110)$$

with the characteristic function χ of the scatterer D . Equation (110) is known as the *Bojarski identity*. Hence, in the physical optics approximation, the Fourier transform has again to be inverted from incomplete data since the physical optics approximation is valid only for large wave numbers k . For details, we refer to [60].

Historical Remarks

The boundary condition (75) was obtained by Roger [81] who first employed Newton-type iterations for the approximate solution of inverse obstacle scattering problems. Rigorous foundations for the Fréchet differentiability were given by Kirsch [47] in the sense of a domain derivative via variational methods and by Potthast [75] via boundary integral equation techniques. The potential method as a prototype of decomposition methods has been proposed by Kirsch and Kress [53]. The point source method has been suggested by Potthast [76]. The iterative methods based on Huygens' principle were introduced by Johansson and Sleeman [45], by Ivanyshyn and Kress [43] (extending a method proposed by Kress and Rundel [59] from potential theory to acoustics), and by Kress [57] and Serranho [85]. The methods described in sections "Newton Iterations for the Inverse Medium Problem," "Least Squares Methods for the Inverse Medium Problem," and "Born Approximation" have been investigated by numerous researchers over the past 30 years.

5 Qualitative Methods in Inverse Scattering

The Far-Field Operator and Its Properties

A different approach to solving inverse scattering problems than the use of iterative methods is the use of qualitative methods [7]. These methods have the advantage of requiring less a priori information than iterative methods (e.g., it is not necessary to know the topology of the scatterer or the boundary conditions satisfied by the total field) and in addition reduce a nonlinear problem to a linear problem. On the other hand, the implementation of such methods often requires more data than iterative methods do and in the case of a penetrable inhomogeneous medium only recovers the support of the scatterer together with some estimates on its material properties.

We begin by considering the scattering problem for a sound-soft obstacle (58) and (59). The *far-field operator* $F : L^2(S^2) \rightarrow L^2(S^2)$ for this problem is defined by

$$(Fg)(\hat{x}) := \int_{S^2} u_\infty(\hat{x}, d) g(d) ds(d), \quad \hat{x} \in S^2, \quad (111)$$

where u_∞ is the far-field pattern associated with (58) and (59). By superposition, Fg is seen to be the far-field pattern corresponding to the Herglotz wave function

$$v_g(x) := \int_{S^2} e^{ikx \cdot d} g(d) ds(d), \quad x \in \mathbb{R}^3, \quad (112)$$

as incident field. The function $g \in L^2(S^2)$ is known as the kernel of the Herglotz wave function. The far-field operator F is compact. It can also be shown that for the case of scattering by a sound-soft obstacle, the far-field operator is normal [7]. Of basic importance to us is the following theorem [22].

Theorem 17. *The far-field operator F corresponding to (58) and (59) is injective with dense range if and only if there does not exist a Dirichlet eigenfunction for D which is a Herglotz wave function.*

Proof. The proof is based on the reciprocity relation (61). In particular, for the L^2 adjoint $F^* : L^2(S^2) \rightarrow L^2(S^2)$, the reciprocity relation implies that

$$F^* g = \overline{RFR\bar{g}}, \quad (113)$$

where $R : L^2(S^2) \rightarrow L^2(S^2)$ is defined by $(Rg)(d) := g(-d)$. Hence, the operator F is injective if and only if its adjoint F^* is injective. Recalling that the denseness of the range of F is equivalent to the injectivity of F^* , by (113), we need only to show the injectivity of F . To this end, we note that $Fg = 0$ is equivalent to the existence of a Herglotz wave function v_g with kernel g for which the far-field pattern of the corresponding scattered field v^s is $v_\infty = 0$. By Rellich's lemma this implies that $v^s = 0$ in $\mathbb{R}^3 \setminus \overline{D}$ and the boundary condition $v_g + v^s = 0$ on ∂D now shows that $v_g = 0$ on ∂D . Since by hypothesis v_g is not a Dirichlet eigenfunction, we can conclude that $v_g = 0$ in D and hence $g = 0$. ■

We will now turn our attention to the far-field operator associated with the inhomogeneous medium problems (65) and (68). In both cases we again define the far-field operator by (111) where u_∞ is now the far-field pattern corresponding to (65) or (68). We first consider Eq. (65) which corresponds to scattering by an inhomogeneous medium. The analogue of Theorem 17 is the following [22].

Theorem 18. *The far-field operator F corresponding to (65) is injective with dense range if and only if there does not exist a solution $v, w \in L^2(D)$, $v - w \in H^2(D)$ of the interior transmission problem*

$$\Delta v + k^2 v = 0 \quad \text{in } D \quad (114)$$

$$\Delta w + k^2 nw = 0 \quad \text{in } D \quad (115)$$

$$v = w \quad \text{on } \partial D \quad (116)$$

$$\frac{\partial v}{\partial \nu} = \frac{\partial w}{\partial \nu} \quad \text{on } \partial D \quad (117)$$

such that v is a Herglotz wave function. Values of $k > 0$ for which there exists a nontrivial solution of (114)–(117) are called transmission eigenvalues.

A similar theorem holds for Eq. (68) which corresponds to scattering by an anisotropic medium where now (115) is replaced by

$$\nabla \cdot A \nabla w + k^2 nw = 0 \quad \text{in } D \quad (118)$$

and in (117) the normal derivative $\frac{\partial w}{\partial \nu}$ is replaced by $v \cdot A \nabla w$. If the coefficients in (115) or (118) are real valued, then the far-field operator is normal.

In the case of electromagnetic waves, the far-field operator becomes

$$(Fg)(\hat{x}) := \int_{S^2} E_\infty(\hat{x}, d, g(d)) ds(d), \quad \hat{x} \in S^2, \quad (119)$$

where now $g \in L^2(S^2)$, the space of square integrable tangential vector fields defined on S^2 , and E_∞ is the electric far-field pattern defined by (64). Theorems analogous to Theorems 17 and 18 are also valid in this case [22].

The Linear Sampling Method

The linear sampling method is a non-iterative method for solving the inverse scattering problem that was first introduced by Colton and Kirsch [19] and Colton et al. [29]. To describe this method, we first consider the case of scattering by a sound-soft obstacle, i.e., (58) and (59), and assume that for every $z \in D$, there exists a solution $g = g(\cdot, z) \in L^2(S^2)$ to the *far-field equation*

$$Fg = \Phi_\infty(\cdot, z), \quad (120)$$

where

$$\Phi_\infty(\hat{x}, z) = \frac{1}{4\pi} e^{-ik\hat{x} \cdot z}, \quad \hat{x} \in S^2.$$

Since the right-hand side of (120) is the far-field pattern of the fundamental solution (13), it follows from Rellich's lemma that

$$\int_{S^2} u^s(x, d) g(d) ds(d) = \Phi(x, z)$$

for $x \in \mathbb{R}^3 \setminus D$. From the boundary condition $u = 0$ on ∂D , we see that

$$v_g(x) + \Phi(x, z) = 0 \quad \text{for } x \in \partial D, \quad (121)$$

where v_g is the Herglotz wave function with kernel g . We can now conclude from (121) that v_g becomes unbounded as $z \rightarrow x \in \partial D$ and hence

$$\lim_{\substack{z \rightarrow \partial D \\ z \in D}} \|g(\cdot, z)\|_{L^2(S^2)} = \infty,$$

i.e., ∂D is characterized by points z where the solution of (120) becomes unbounded.

Unfortunately, in general, the far-field equation (120) does not have a solution nor does the above analysis say anything about what happens when $z \in \mathbb{R}^3 \setminus D$. To address these issues, we first define the single-layer operator $S : H^{-1/2}(\partial D) \rightarrow H^{1/2}(\partial D)$ by

$$(S\varphi)(x) := \int_{\partial D} \varphi(y) \Phi(x, y) ds(y), \quad x \in \partial D,$$

define the Herglotz operator $H : L^2(\partial D) \rightarrow H^{-1/2}(\partial D)$ as the operator mapping g to the trace of the Herglotz wave function (112) on ∂D , and let $\mathcal{F} : H^{-1/2}(\partial D) \rightarrow L^2(S^2)$ be defined by

$$(\mathcal{F}\varphi)(\hat{x}) := \int_{\partial D} \varphi(y) e^{-ik\hat{x} \cdot y} ds(y), \quad \hat{x} \in S^2.$$

Then, using on the one hand the fact that Herglotz wave functions are dense in the space of solutions to the Helmholtz equation in D with respect to the norm in the Sobolev space $H^1(D)$ and on the other the factorization of the far-field operator F as

$$F = -\frac{1}{4\pi} \mathcal{F} S^{-1} H,$$

one can prove the following result [7, 52].

Theorem 19. *Assume that k^2 is not a Dirichlet eigenvalue of the negative Laplacian for D , and let F be the far-field operator corresponding to (58) and (59). Then:*

1. *For $z \in D$ and a given $\epsilon > 0$, there exists $g_{z,\epsilon} \in L^2(S^2)$ such that*

$$\|Fg_{z,\epsilon} - \Phi_\infty(\cdot, z)\|_{L^2(S^2)} < \epsilon$$

and the corresponding Herglotz wave function $v_{g_{z,\epsilon}}$ converges to a solution of

$$\Delta u + k^2 u = 0 \quad \text{in } D$$

$$u = -\Phi(\cdot, z) \quad \text{on } \partial D$$

in $H^1(D)$ as $\epsilon \rightarrow 0$.

2. For $z \in \mathbb{R}^3 \setminus D$ and a given $\epsilon > 0$, every $g_{z,\epsilon} \in L^2(S^2)$ that satisfies

$$\|Fg_{z,\epsilon} - \Phi_\infty(\cdot, z)\|_{L^2(S^2)} < \epsilon$$

is such that $\lim_{\epsilon \rightarrow 0} \|v_{g_{z,\epsilon}}\|_{H^1(D)} = \infty$.

We note that the difference between cases (1) and (2) of this theorem is that for $z \in D$, the far-field pattern $\Phi_\infty(\cdot, z)$ is in the range of \mathcal{F} , whereas for $z \in \mathbb{R}^3 \setminus D$ this is no longer true. The *linear sampling method* is based on attempting to compute the function $g_{z,\epsilon}$ in the above theorem by using Tikhonov regularization to solve $Fg = \Phi_\infty(\cdot, z)$. In particular, one expects that the regularized solution will be relatively smaller for z in D than z in $\mathbb{R}^3 \setminus \overline{D}$, and this behavior can be visualized by color coding the values of the regularized solution on a grid over some domain containing D . A more precise statement of this observation will be made in the next section after we have discussed the factorization method for solving the inverse scattering problem. Further discussion of why linear sampling works if regularization methods are used to solve (120) can be found in [2, 3]. In addition to the inverse scattering problems (58) and (59), it is also possible to treat mixed boundary value problems as well as scattering by both isotropic and anisotropic inhomogeneous media where in the latter case we must assume that k is not a transmission eigenvalue. For full details we refer the reader to [7]. Note that in each case, it is not necessary to know the material properties of the scatterer in order to determine the support of the scatterer from a knowledge of the far-field pattern via solving the far-field equation $Fg = \Phi_\infty(\cdot, z)$.

The linear sampling method can also be extended to the case of electromagnetic waves where the far-field equation (120) is now replaced by

$$\int_{S^2} E_\infty(\hat{x}, d, g(d)) \, ds(d) = E_{e,\infty}(\hat{x}, z, q),$$

where $E_\infty(\hat{x}, d, p)$ is the electric far-field pattern corresponding to the incident field (50), $g \in L_t^2(S^2)$, and $E_{e,\infty}$ is the electric far-field pattern of the electric dipole

$$E_e(x, z, q) := \frac{i}{k} \operatorname{curl}_x \operatorname{curl}_x q \Phi(x, z), \quad H_e(x, z, q) := \operatorname{curl}_x q \Phi(x, z). \quad (122)$$

Full details can be found in the lecture notes [12].

We close this section by briefly describing a version of the linear sampling method based on the reciprocity gap functional which is applicable to objects situated in a piecewise homogeneous background medium. Assume that an unknown

scattering object is embedded in a portion B of a piecewise inhomogeneous medium where the index of refraction is constant with wave number k . Let $B_0 \subset B$ be a domain in B having a smooth boundary ∂B_0 such that the scattering obstacle D satisfies $D \subset B_0$, and let v be the unit outward normal to ∂B_0 . We now define the *reciprocity gap functional* by

$$R(u, v) := \int_{\partial B_0} \left(u \frac{\partial v}{\partial \nu} - v \frac{\partial u}{\partial \nu} \right) ds,$$

where u and v are solutions of the Helmholtz equation in $B_0 \setminus \overline{D}$ and $u, v \in C^1(\overline{B_0 \setminus D})$. In particular, we want u to be the total field due to a point source situated at $x_0 \in B \setminus \overline{B_0}$ and $v = v_g$ to be a Herglotz wave function with kernel g . We then consider the integral equation

$$R(u, v_g) = R(u, \Phi_z),$$

where $\Phi_z := \Phi(\cdot, z)$ is the fundamental solution (13) and $u = u(\cdot, x_0)$ where x_0 is now assumed to be on a smooth surface C in $B \setminus \overline{B_0}$ that is homotopic to ∂B_0 . If D is a sound-soft obstacle, we assume that k^2 is not a Dirichlet eigenvalue of the negative Laplacian in D , and if D is an isotropic inhomogeneous medium, we assume that k is not a transmission eigenvalue. We then have the following theorem [17].

Theorem 20. *Assume that the above assumptions on D are satisfied. Then:*

1. *If $z \in D$, then there exists a sequence $\{g_n\}$ in $L^2(S^2)$ such that*

$$\lim_{n \rightarrow \infty} R(u, v_{g_n}) = R(u, \Phi_z), \quad x_0 \in C,$$

and v_{g_n} converges in $L^2(D)$.

2. *If $z \in B_0 \setminus D$, then for every sequence $\{g_n\}$ in $L^2(S^2)$ such that*

$$\lim_{n \rightarrow \infty} R(u, v_{g_n}) = R(u, \Phi_z), \quad x_0 \in C,$$

we have that $\lim_{n \rightarrow \infty} \|v_{g_n}\|_{L^2(D)} = \infty$.

In particular, Theorem 20 provides a method for determining D from a knowledge of the Cauchy data of u on ∂B_0 in a manner analogous to that of the linear sampling method. Numerical examples using this method can be found in [17]. The extension of Theorem 20 to the Maxwell equations, together with numerical examples, can be found in [13].

The Factorization Method

The linear sampling method is complicated by the fact that in general $\Phi_\infty(\cdot, z)$ is not in the range of the far-field operator F for either $z \in D$ or $z \in \mathbb{R}^3 \setminus \overline{D}$. For the case of acoustic waves when F is normal (e.g., the scattering problem corresponding to (58) and (59) or (65) for n real valued), the problem was resolved by Kirsch in [48, 49] who proposed replacing the far field equation $Fg = \Phi_\infty(\cdot, z)$ by

$$(F^* F)^{1/4} g = \Phi_\infty(\cdot, z), \quad (123)$$

where F^* is again the adjoint of F in $L^2(S^2)$. In particular, if $G : H^{1/2}(\partial D) \rightarrow L^2(S^2)$ is defined by $Gf = v_\infty$ where v_∞ is the far field pattern of the solution to the radiating exterior Dirichlet problem (see Theorem 3) with boundary data $f \in L^2(\partial D)$, then the following theorem is valid [48].

Theorem 21. *Assume that k^2 is not a Dirichlet eigenvalue of the negative Laplacian for D . Then the ranges of $G : H^{1/2}(\partial D) \rightarrow L^2(S^2)$ and $(F^* F)^{1/4} : L^2(S^2) \rightarrow L^2(S^2)$ coincide.*

A result analogous to Theorem 21 is also valid for the scattering problem corresponding to (65) for n real valued where we now must assume the k is not an interior transmission eigenvalue [49]. Note that Theorem 21 provides an alternate method to the linear sampling method for solving the inverse scattering problem corresponding to the scattering of acoustic waves by a sound-soft obstacle. This follows from the fact that $\Phi_\infty(\cdot, z)$ is in the range of G if and only if $z \in D$, i.e., Eq. (123) is solvable if and only if $z \in D$. This is an advantage over the linear sampling method since if (123) is solved by using Tikhonov regularization, then as the noise level on u_∞ tends to zero, the norm of the regularized solution remains bounded if and only if $z \in D$. A similar statement cannot be made if regularization methods are used to solve $Fg = \Phi_\infty(\cdot, z)$. However, using Theorem 21, the following theorem has been established by Arens and Lechleiter [3] (see also [52]).

Theorem 22. *Let F be the far-field operator associated with the scattering problems (58) and (59), and assume that k^2 is not a Dirichlet eigenvalue of the negative Laplacian for D . For $z \in D$, let $g_z \in L^2(S^2)$ be the solution of $(F^* F)^{1/4} g_z = \Phi_\infty(\cdot, z)$, and for every $z \in \mathbb{R}^3$ and $\epsilon > 0$, let $g_{z,\epsilon}$ be the solution of $Fg = \Phi_\infty(\cdot, z)$ obtained by Tikhonov regularization, i.e., the unique solution of $\epsilon g + F^* Fg = F^* \Phi_\infty$. Then the following statements are valid:*

1. *Let $v_{g_{z,\epsilon}}$ be the Herglotz wave function with kernel $g_{z,\epsilon}$. Then for every $z \in D$, the limit $\lim_{\epsilon \rightarrow 0} v_{g_{z,\epsilon}}(z)$ exists. Furthermore, there exists $c > 0$, depending only on F , such that for every $z \in D$ we have that*

$$c \|g_z\|_{L^2(S^2)}^2 \leq \lim_{\epsilon \rightarrow 0} |v_{g_{z,\epsilon}}(z)| \leq \|g_z\|_{L^2(S^2)}^2.$$

2. *For $z \notin D$ we have that $\lim_{\epsilon \rightarrow 0} v_{g_{z,\epsilon}}(z) = \infty$.*

Using Theorem 21 to solve the inverse scattering problem associated with the scattering problems (58) and (59) is called the *factorization method*. This method has been extended to a wide variety of scattering problems for both acoustic and electromagnetic waves, and for details we refer the reader to [52]. Since this method and its generalizations are fully discussed in the chapter in this handbook on sampling methods, we will not pursue the topic further here. A drawback of both the linear sampling method and the factorization method is the large amount of data needed for the inversion procedure. In particular, although the linear sampling method can be applied for limited aperture far-field data, one still needs multistatic data defined on an open subset of S^2 .

Lower Bounds for the Surface Impedance

One of the advantages that the linear sampling method has over other qualitative methods in inverse scattering theory is that the far-field equation can not only be used to determine the support of the scatterer but in some circumstances can also be used to obtain lower bounds on the constitutive parameters of the scattering object. In this section we will consider two such problems: the determination of the surface impedance of a partially coated object and the determination of the index of refraction of a non-absorbing scatterer. In the first case, we will need to consider a mixed boundary value problem for the Helmholtz equation, whereas in the second case, we will need to investigate the spectral properties of the interior transmission problem introduced in Theorem 18 of the previous section.

Mixed boundary value problems typically model the scattering by objects that are coated by a thin layer of material on part of the boundary. In the study of inverse problems for partially coated obstacles, it is important to mention that, in general, it is not known a priori whether or not the scattering object is coated and if so what the extent of the coating is. We will focus our attention in this section on the special case when on the coated part of the boundary, the total field satisfies an impedance boundary condition and on the remaining part of the boundary, the total field (or the tangential component in the case of electromagnetic waves) vanishes. This corresponds to the case when a perfect conductor is partially coated by a thin dielectric layer. For other mixed boundary value problems in scattering theory and their associated inverse problems, we refer the reader to [7] and the references contained therein.

Let $D \subset \mathbb{R}^3$ be as described in Sect. 1, and let ∂D be dissected as $\partial D = \Gamma_D \cup \Pi \cup \Gamma_I$ where Γ_D and Γ_I are disjoint, relatively open subsets of ∂D having Π as their common boundary. Let $\lambda \in L_\infty(\Gamma_I)$ be such that $\lambda(x) \geq \lambda_0 > 0$ for all $x \in \Gamma_I$. We consider the scattering problem for the Helmholtz equation (58) where $u = u^i + u^s$ satisfies the boundary condition

$$\begin{aligned} u &= 0 \quad \text{on } \Gamma_D, \\ \frac{\partial u}{\partial \nu} + i\lambda u &= 0 \quad \text{on } \Gamma_I, \end{aligned} \tag{124}$$

$u^i(x) = e^{ikx \cdot d}$, and u^s is a radiating solution. It can be shown that this direct scattering problem has a unique solution in $H_{\text{loc}}(\mathbb{R}^3 \setminus \overline{D})$ [7]. We again define the far-field operator by (111) where u_∞ is now the far-field pattern corresponding to the boundary condition (124).

In [7] it is shown that there exists a unique solution $u_z \in H^1(D)$ of the interior mixed boundary value problem

$$\Delta u_z + k^2 u_z = 0 \quad \text{in } D \quad (125)$$

$$u_z + \Phi(\cdot, z) = 0 \quad \text{on } \Gamma_D \quad (126)$$

$$\frac{\partial}{\partial v} (u_z + \Phi(\cdot, z)) + i\lambda (u_z + \Phi(\cdot, z)) = 0 \quad \text{on } \Gamma_I \quad (127)$$

for $z \in D$ where Φ is the fundamental solution to the Helmholtz equation. Then, if $\Phi_\infty(\cdot, z)$ is the far-field pattern of $\Phi(\cdot, z)$, we have the following theorem [7].

Theorem 23. *Let $\epsilon > 0$, $z \in D$, and u_z be the unique solution of (125–127). Then there exists a Herglotz wave function $v_{g_{z,\epsilon}}$ with kernel $g_{z,\epsilon} \in L^2(S^2)$ such that*

$$\|u_z - v_{g_{z,\epsilon}}\|_{H^1(D)} \leq \epsilon.$$

Moreover, there exists a positive constant c independent of ϵ such that

$$\|Fg_{z,\epsilon} - \Phi_\infty(\cdot, z)\|_{L^2(S^2)} \leq c\epsilon.$$

We can now use Green's formula to show that [6]

$$\int_{\partial D} \lambda |u_z + \Phi(\cdot, z)|^2 ds = -\frac{k}{4\pi} - \text{Im } u_z(z).$$

From this we immediately deduce the inequality

$$\|\lambda\|_{L^\infty(\Gamma_I)} \geq \frac{-k/4\pi - \text{Im } u_z(z)}{\|u_z + \Phi(\cdot, z)\|_{L^2(\partial D)}^2}. \quad (128)$$

How is the inequality (128) of practical use? To evaluate the right-hand side of (128), we need to know ∂D and u_z . Both are determined by solving the far field equation $Fg = \Phi_\infty(\cdot, z)$ using Tikhonov regularization and then using the linear sampling method to determine ∂D and the regularized solution $g \in L^2(S^2)$ to construct the Herglotz wave function v_g . By Theorem 23 we expect that v_g is an approximation to u_z . However, at this time, there is no analogue of Theorem 22 for the mixed boundary value problem, and hence this is not guaranteed. Nevertheless in all numerical experiments to date, this approximation appears to be remarkably accurate and thus allows us to obtain a lower bound for $\|\lambda\|_{L^\infty(\Gamma_I)}$ via (128).

The corresponding scattering problem for the Maxwell equations is to find a solution $E = E^i + E^s$ to (62) satisfying the mixed boundary condition

$$\begin{aligned} \nu \times E &= 0 \quad \text{on } \Gamma_D \\ \nu \times \operatorname{curl} E - i\lambda(\nu \times E) \times \nu &= 0 \quad \text{on } \Gamma_I, \end{aligned} \quad (129)$$

where E^i is the plane wave (50) and E^s is radiating. The existence of a unique solution E in an appropriate Sobolev space is shown in [11]. We again define the far-field operator by (119) where E_∞ is now the electric far-field pattern corresponding to (129). Analogous to (125–127) we now have the interior mixed boundary value problem

$$\operatorname{curl} \operatorname{curl} E_z - k^2 E_z = 0 \quad \text{in } D \quad (130)$$

$$\nu \times [E_z + E_e(\cdot, z, q)] = 0 \quad \text{on } \Gamma_D \quad (131)$$

$$\nu \times \operatorname{curl} [E_z + E_e(\cdot, z, q)] - i\lambda [\nu \times (E_z + E_e(\cdot, z, q))] = 0 \quad \text{on } \Gamma_I, \quad (132)$$

where $z \in D$ and E_e is the electric dipole defined by (122). The existence of a unique solution to (130–132) in an appropriate Sobolev space is established in [11]. From the analysis in [6], we have the inequality

$$\|\lambda\|_{L^\infty(\Gamma_I)} \geq \frac{-k^2|q|^2/6\pi + k \operatorname{Re}(q \cdot E_z)}{\|E_z + E_e(\cdot, z, q)\|_{L_t^2(\partial D)}^2} \quad (133)$$

analogous to (128) for the Helmholtz equation. For numerical examples using (133), we refer the reader to [26].

Similar inequalities as those derived above for the impedance boundary value problem can also be obtained for the *conductive boundary value problem*, i.e., the case when a dielectric is partially coated by a thin, highly conducting layer [7, 26].

Transmission Eigenvalues

We have previously encountered transmission eigenvalues in Theorem 18 where they were connected with the injectivity and dense range of the far-field operator. In this section we shall examine transmission eigenvalues and the interior transmission problem in more detail. This investigation is particularly relevant to the inverse scattering problem since transmission eigenvalues can be determined from the far field pattern [10] and, as will be seen, can be used to obtain lower bounds for the index of refraction.

We begin by considering the interior transmission problem (114–117) from Theorem 18 and will be concerned with the existence and countability of transmission eigenvalues. The existence of transmission eigenvalues was first established by Päivärinta and Sylvester [73], and their results were strengthened by Cakoni et al. [14].

Theorem 24. Assume that n is real valued such that $n(x) > 1$ for all $x \in \overline{D}$ or $0 < n(x) < 1$ for all $x \in \overline{D}$. Then there exist an infinite number of transmission eigenvalues.

We note that it can be shown that as $\sup_{x \in D} |n(x) - 1| \rightarrow 0$, then the first transmission eigenvalue tends to infinity, i.e., in the Born approximation transmission, eigenvalues do not exist [28].

Similar results as in Theorem 24 can be obtained for an anisotropic medium and for the Maxwell equations [14].

By Theorem 24 the existence of transmission eigenvalues is established. It can also be shown that the set of transmission eigenvalues is discrete [15, 20, 50, 83]. The following theorem [28] establishes a lower bound for the first transmission eigenvalue which is reminiscent of the famous *Faber–Krahn inequality* for the first Dirichlet eigenvalue for the negative Laplacian (which we denote by λ_1).

Theorem 25. Assume that $n(x) > 1$ for $x \in \overline{D}$, and let $k_1 > 0$ be the first transmission eigenvalue for the interior transmission problem (114–117). Then

$$k_1^2 \geq \frac{\lambda_1(D)}{\sup_{x \in D} n(x)}.$$

Theorem 25 has been generalized to the case of anisotropic media and the Maxwell equations [8].

Finally, in the case of the interior transmission problem (114–117) where there are cavities in D , i.e., regions $D_0 \subset D$ where $n(x) = 1$ for $x \in D_0$, it can be shown that transmission eigenvalues exist and form a discrete set and the first transmission eigenvalue k_1 satisfies [9]

$$k_1^2 \geq \frac{\lambda_1(D)}{\sup_{x \in D \setminus D_0} n(x)}.$$

Note that since in each of the above cases D can be determined by the linear sampling method, $\lambda_1(D)$ is known, and hence given k_1 , the above inequalities yield a lower bound for the supremum of the index of refraction.

Historical Remarks

The use of qualitative methods to solve inverse scattering problems began with the 1996 paper of Colton and Kirsch [19] and the 1997 paper of Colton et al. [29]. These papers were in turn motivated by the dual space method of Colton and Monk developed in [24, 25]. Both [19] and [29] were concerned with the case of scattering of acoustic waves. The extension of the linear sampling method to electromagnetic waves was first outlined by Kress [56] and then discussed in more detail by Colton

et al. [18] and Haddar and Monk [34]. The factorization method was introduced in 1998 and 1999 by Kirsch [48, 49] for acoustic scattering problems. Attempts to extend the factorization method to the case of electromagnetic waves have been only partly successful. In particular, the factorization method for the scattering of electromagnetic waves by a perfect conductor remains an open question.

In addition to the linear sampling and factorization methods, there have been a number of other qualitative methods developed primarily by Ikehata and Potthast and their coworkers. Although space is too short to discuss these alternate qualitative methods in this survey, we refer the reader to [52, 78] for details and references.

The countability of transmission eigenvalues for acoustic waves was established by Colton et al. [20] and Rynne and Sleeman [83] and for the Maxwell equations by Cakoni and Haddar [15] and Kirsch [50]. The existence of transmission eigenvalues for acoustic waves was first given by Päivärinta and Sylvester [73] for the isotropic case and for the anisotropic case by Cakoni and Haddar [16] and Kirsch [51] who also established the existence of transmission eigenvalues for Maxwell's equations. These results were subsequently improved by Cakoni et al. [14]. Inequalities for the first transmission eigenvalues were first obtained by Colton et al. [28] and Cakoni et al. [8, 9].

Abstract

This chapter reviews the state of the art and the current open problems in electrical impedance tomography (EIT), which seeks to recover the conductivity

(or conductivity and permittivity) of the interior of a body from knowledge of electrical stimulation and measurements on its surface. This problem is also known as the inverse conductivity problem and its mathematical formulation is due to A. P. Calderón, who wrote in 1980, the first mathematical formulation of the problem, “On an inverse boundary value problem.” EIT has interesting applications in fields such as medical imaging (to detect air and fluid flows in the heart and lungs and imaging of the breast and brain) and geophysics (detection of conductive mineral ores and the presence of ground water). It is well known that this problem is severely ill-posed, and thus this chapter is devoted to the study of the uniqueness, stability, and reconstruction of the conductivity from boundary measurements. A detailed distinction between the isotropic and anisotropic case is made, pointing out the major difficulties with the anisotropic case. The issues of global and local measurements are studied, noting that local measurements are more appropriate for practical applications such as screening for breast cancer.

1 Introduction

Electrical impedance tomography (EIT) is the recovery of the conductivity (or conductivity and permittivity) of the interior of a body from a knowledge of currents and voltages applied to its surface. In geophysics, where the method is used in prospecting and archaeology, it is known as electrical resistivity tomography. In industrial process tomography it is known as electrical resistance tomography or electrical capacitance tomography. In medical imaging, when at the time of writing it is still an experimental technique rather than routine clinical practice, it is called EIT. A very similar technique is used by weakly electric fish to navigate and locate prey and in this context it is called electrosensing. An example of a medical application of EIT is given in Fig. 1, which shows a 10-day-old healthy neonate breathing spontaneously and lying in the prone position with the head turned to the left. Sixteen EIT electrodes are placed in a transverse plane around the chest, and EIT data acquired with the Goe MF-II system. This child was a subject in a study which used EIT to examine patterns of breathing in neonates and the relationship to body posture [57]. In this study, EIT was able to show, for the first time, that, in a prone position, the lung on the opposite side (contralateral) to the face receives significantly larger air flows.

The simplest mathematical formulation of inverse problem of EIT can be stated as follows. Let Ω be a conducting body described by a bounded domain in \mathbb{R}^n , $n \geq 2$, with electrical conductivity a bounded and positive function $\gamma(x)$ (later complex γ will be considered). In the absence of internal sources, the electrostatic potential u in Ω is governed by the elliptic partial differential equation

$$L_\gamma u := \nabla \cdot \gamma \nabla u = 0 \quad \text{in } \Omega. \quad (1)$$

It is natural to consider the weak formulation of (1) in which $u \in H^1(\Omega)$ is a weak solution to (1). Given a potential $\phi \in H^{1/2}(\partial\Omega)$ on the boundary, the induced potential $u \in H^1(\Omega)$ solves the Dirichlet problem

Fig. 1 10-day-old spontaneously breathing neonate lying in the prone position with the head turned to the left. Sixteen medical grade Ag/AgCl electrodes were placed in a transverse plane and connected to a Geo MF-II EIT system [57]

$$\begin{cases} L_\gamma u = 0 & \text{in } \Omega, \\ u|_{\partial\Omega} = \phi. \end{cases} \quad (2)$$

The currents and voltages measurements taken on the surface of Ω , $\partial\Omega$, are given by the so-called Dirichlet-to-Neumann map (associated with γ) or voltage-to-current map

$$\Lambda_\gamma : u|_{\partial\Omega} \in H^{1/2}(\partial\Omega) \longrightarrow \gamma \frac{\partial u}{\partial v} \in H^{-1/2}(\partial\Omega).$$

Here, v denotes the unit outer normal to $\partial\Omega$ and the restriction to the boundary is considered in the sense of the trace theorem on Sobolev spaces. Here, $\partial\Omega$ must be at least Lipschitz continuous and $\gamma \in L^\infty(\Omega)$ with $\text{ess inf Re } \gamma = m > 0$.

The *forward problem* under consideration is the map $\gamma \in \mathcal{D}_m \mapsto \Lambda_\gamma$, where $\mathcal{D}_m = \{\gamma \in L^\infty(\Omega) | \text{ess infy} \geq m\}$. The *inverse problem* for complete data is then the recovery of γ from Λ_γ . As is usual in inverse problems, consideration will be given to questions of (1) uniqueness of solution (or from a practical point of view sufficiency of data), (2) stability/instability with respect to errors in the data, and (3) practical algorithms for reconstruction. It is also worth pointing out to the reader who is not very familiar with EIT the well-known fact that the behavior of materials under the influence of external electric fields is determined not only by the electrical conductivity γ but also by the electric permittivity ϵ so that the determination of the complex valued function $\gamma(x, \omega) = \sigma(x) + i\omega\epsilon(x)$ would be the more general and realistic problem, where $i = \sqrt{-1}$ and ω is the frequency. The simple case where $\omega = 0$ will be treated in this work. For a description of the formulation of the inverse problem for the complex case, refer for example to [20]. Before addressing questions (1)–(3) mentioned above, it is interesting to consider how the problem arises in practice.

Measurement Systems and Physical Derivation

For the case of direct current, that is the voltage applied is independent of time, the derivation is simple. Of course here $\Omega \subset \mathbb{R}^3$. First suppose that it is possible to apply an arbitrary voltage $\phi \in H^{1/2}(\Omega)$ to the surface. It is typical to assume that the exterior $\mathbb{R}^3 \setminus \Omega$ is an electrical insulator. An electric potential (voltage) u results in the interior and the current \mathbf{J} that flows satisfies the continuum Ohm's law $\mathbf{J} = -\gamma \nabla u$; the absence of current sources in the interior is expressed by the continuum version of Kirchoff's law $\nabla \cdot \mathbf{J} = 0$ which together result in (1). The boundary conditions are controlled or measured using a system of conducting electrodes which are typically applied to the surface of the object. In some applications, especially geophysical, these may be spikes that penetrate the object, but it is common to model these as points on the surface. Most EIT systems are designed to apply a known current on (possibly a subset) or electrodes and measure the voltage that results on electrodes (again possibly a subset, in some cases disjoint from those carrying a nonzero current). In other cases it is a predetermined voltage applied to electrodes and the current measured; there being practical reasons determined by electronics or safety for choosing one over the other. In medical EIT applying known currents and measuring voltages is typical. One reason for this is the desire to limit the maximum current for safety reasons. In practice the circuit that delivers a predetermined current can only do so while the voltage required to do that is within a certain range so both maximum current and voltage are limited. For an electrode (let us say indexed by ℓ) not modeled by a point but covering a region $E_\ell \subset \partial\Omega$ the current to that electrode is the integral

$$I_\ell = \int_{E_\ell} -\mathbf{J} \cdot \mathbf{v} \, dx. \quad (3)$$

Away from electrodes,

$$\gamma \frac{\partial u}{\partial \mathbf{v}} = 0, \quad \text{on } \partial\Omega \setminus \bigcup_{\ell=1}^L E_\ell \quad (4)$$

as the air surrounding the object is an insulator. On the conducting electrode, $u|_{E_\ell} = V_\ell$ a constant, or as a differential condition

$$\mathbf{v} \times \nabla u = 0 \quad \text{on } \partial\Omega \setminus \bigcup_{\ell=1}^L E_\ell. \quad (5)$$

Taken together, (3)–(5) are called the *shunt model*. This ideal of a perfectly conducting electrode is of course only an approximation. Note that while the condition $u \in H^1(\Omega)$ is a sensible condition, which ensures finite total dissipated power, it is not sufficient to ensure (3) is well defined. Indeed for smooth γ and

smooth ∂E_ℓ the condition results in a square root singularity in the current density on the electrode. A more realistic model of electrodes is given later.

It is more common to use alternating current in geophysical and process monitoring applications, and essential in medical applications. Specifically the direction of the current must be reversed within a sufficiently short time to avoid electrochemical effects. This also means that the time average of the applied current should be zero. In medical applications, current in one direction for sufficient duration would result in transport of ions, and one of the effects of this can be stimulation of nerves. It would also degrade electrode behavior due to charge build up and ionic changes in the electrode. As a general rule higher levels of current and voltage are considered safer at higher temporal frequencies. The simplest EIT system therefore operates at a fixed frequency using an oscillator or digital signal processing to produce a sinusoidal current. Measurements are then taken of the magnitude, or in some cases the components that are in phase and $\pi/2$ out of phase with the original sine wave. When an EIT system switches from stimulating one set of electrodes to the next set in a stimulation pattern, the measurements adapt to the new pattern over a finite time, and typical EIT systems are designed to start measuring after this transient term has decayed so as to be negligible.

In geophysics a technique that is complementary to EIT called *induced polarization tomography* IPT is used to find polarizable minerals. In effect this uses a square wave pulse and measures the transient response [85]. In process tomography a technique known as electrical capacitance tomography is designed for imaging insulating materials with different dielectric permittivities, for example oil and gas in a pipe [60, 101]. Again square waves or pulses are used.

In medical and geophysical problems the response of the materials may vary with frequency. For example in a biological cell higher frequency current might penetrate a largely capacitive membrane and so be influenced by the internal structures of the cell, while lower frequency currents pass around the cell. This has led to electrical impedance tomography spectroscopy (EITS) [47], and in geophysics spectral induced polarization tomography (SIPT) [85]. The spectral response can be established either by using multiple sinusoidal frequencies or by sampling the transient response to a pulse.

Our starting point for the case of alternating current is the time harmonic Maxwell equations at a fixed angular frequency ω . Here it is assumed that the transient components of all fields are negligible and represent the time harmonic electric and magnetic vector fields using the complex representation $\mathcal{F}(x, t) = \text{Re}(\mathbf{F} \exp(i\omega t))$, yielding

$$\nabla \times \mathbf{E} = -i\omega \mathbf{B}, \quad (6)$$

$$\nabla \times \mathbf{H} = \mathbf{J} + i\omega \mathbf{D}. \quad (7)$$

The electric and magnetic fields \mathbf{E} and \mathbf{H} are related to the current density \mathbf{J} , electric displacement \mathbf{D} , and magnetic flux \mathbf{B} by the material properties conductivity σ , permittivity ϵ , and permeability μ by

$$\mathbf{J} = \sigma \mathbf{E}, \mathbf{D} = \epsilon \mathbf{E}, \mathbf{B} = \mu \mathbf{H}. \quad (8)$$

The fields \mathbf{E} and \mathbf{H} are evaluated on directed curves, while the “fluxes” \mathbf{J} , \mathbf{D} and \mathbf{B} on surfaces. In biomedical applications one can typically take μ to be constant and to be the same inside the body as outside in air. In non-destructive testing and geophysical applications there may well be materials with differing permeability. Here (8) assumes linear relations. For example the first is the continuum Ohm’s law. Here, the material properties may be frequency dependent. This *dispersion* is important in EIS and SIPT. For the moment a first approximation is to assume isotropy (so that the material properties are scalars).

There are many inverse problems governed by time harmonic Maxwell’s equations.. These occur at large values of ω and include optical and microwave tomographic techniques and scattering problems such as radar which are not discussed in this chapter. There are also systems where the fields arise from alternating current in a coil, and measurements are made either with electrodes or with other coils. Mutual (or magnetic) induction tomography (MIT) falls into this category and has been tried in medical and process monitoring applications [46]. In these cases the eddy current approximation [9] to Maxwell’s equations is used. While for direct current EIT (i.e., ERT) the object is assumed surrounded by an insulator, in MIT one must account for the magnetic fields in the surrounding space, there being no magnetic “shielding.”

The assumptions used to justify the usual mathematical model of EIT make it distinct from many other inverse problems for Maxwell’s equations. Given

Assumption 1. Transients components of all fields are negligible.

This assumption simply means that a sufficient “settling time” has been given before making measurements.

The interest in relatively low frequencies, where magnetic effects can be neglected, translates into two assumptions

Assumption 2. $\omega\sqrt{\epsilon\mu}$ is small compared with the size of Ω .

This means that the wavelength of propagating waves in the material is large. A measurement accuracy of $2^{-12} = 1/4096$ is ambitious at higher frequencies means that for wave effects to be negligible

$$d \omega \sqrt{\epsilon\mu} < \cos^{-1} \frac{4095}{4096}, \quad (9)$$

where d is the diameter of the body. Taking the relative permittivity to be 10 and $R = 0.3$ m gives a maximum frequency of 1 MHz.

Assumption 3. $\sqrt{\omega\sigma\mu/2}$ is small compared with the size of Ω .

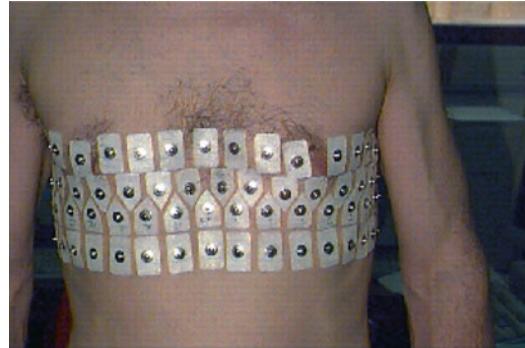

Fig. 2 A system of electrodes used for chest EIT at Oxford Brookes University. The positions of the electrodes were measured manually with a tape measure and the cross-sectional shape was also determined by manual measurements. These electrodes have a disk of jell containing silver chloride solution that makes contact with the skin. Each electrode was attached to the EIT system by a screened lead, not shown in this picture for clarity

The quantity

$$\delta = \sqrt{\frac{2}{\omega\sigma\mu}} \quad (10)$$

is known as the skin depth. For a frequency of 10 kHz and a conductivity of 0.5 Sm^{-1} typical in medical applications, the skin depth is 7 m. In geophysics lower frequencies are typical but length scales are larger. In a conducting cylinder the electric field decays with distance r from the boundary at a rate $e^{-r/\delta}$ due to the opposing magnetic field. At EIT frequencies this simple example suggests that accurate forward modeling of EIT should take account of this effect although it is currently not thought to be a dominant source of error.

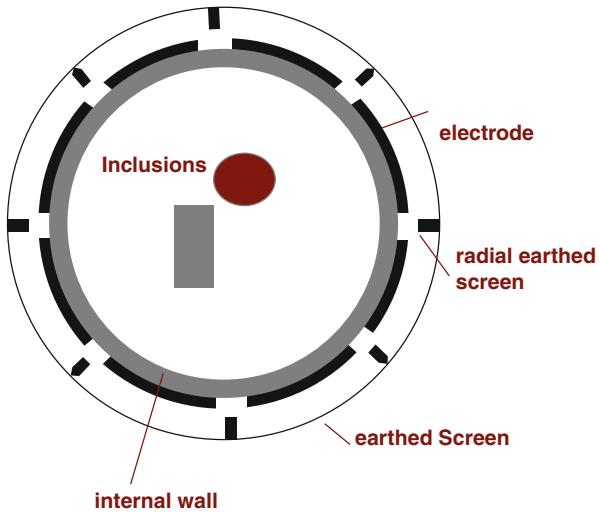

The effect of Assumptions 2 and 3 combined together is that it is reasonable to neglect $\nabla \times E$ in Maxwell's equations resulting in the standard equation for complex EIT

$$\nabla \cdot (\sigma + i\omega\epsilon) \nabla u = 0. \quad (11)$$

Here the expression $\gamma = \sigma + i\omega\epsilon$ is called complex conductivity, or logically the *admittivity*, while $1/\sigma$ is called *resistivity* and the rarely-used complex $1/\gamma$ *impedivity*. A scaling argument is given for the approximation (11) in [31], and numerical checks on the validity of the approximation in [37, 104] (Fig. 2).

It is often not so explicitly stated but while in the direct current case one can neglect the conductivity of the air surrounding the body, for the alternating current case the electrodes are coupled capacitively and, while σ can be assumed to be

Fig. 3 A cross section through a typical ECT sensor around a pipe (internal wall) showing the external screen with radial screens designed to reduce the external capacitive coupling between electrodes

zero for air, the permittivity of any material is no smaller than that of a vacuum $\epsilon_0 = 8.85 \times 10^{-12}$, although dry air approaches that value. One requires then

Assumption 4. $\omega\epsilon$ in the exterior is negligible compared to $|\sigma + i\omega\epsilon|$ in the interior.

For example, with a conductivity of 0.2 Sm^{-1} , the magnitude of the exterior admittance reaches 2^{-12} of that value for a frequency of 0.88 MHz . For a more detailed calculation the capacitance between the electrodes externally could be compared with the impedance between electrodes. In ECT frequencies above 1 MHz are used and the exterior capacitance cannot be neglected. Indeed an exterior grounded shield is used so that the exterior capacitive coupling is not affected by the surroundings (see Fig. 3).

The Concentric Anomaly: A Simple Example

A simple example helps us to understand the instability in the inverse conductivity problem. Let Ω be the unit disk in \mathbb{R}^2 with polar coordinates (r, θ) and consider a concentric anomaly in the conductivity of radius $\rho < 1$

$$\gamma(x) = \begin{cases} a_1, & |x| \leq \rho \\ a_0, & \rho < |x| \leq 1. \end{cases} \quad (12)$$

From separation of variables, matching Dirichlet and Neumann boundary conditions at $|x| = \rho$, for $n \in \mathbb{Z}$

$$\Lambda_\gamma e^{in\theta} = |n| \frac{1 + \mu \rho^{2|n|}}{1 - \mu \rho^{2|n|}} e^{in\theta}, \quad (13)$$

where $\mu = (a_1 - a_0)/(a_1 + a_0)$. From this one sees the effect of the Dirichlet to Neumann map on the complex Fourier series, and the effect on the real Fourier series is easily deduced. This example was considered in [64] as an example of the eigenvalues and eigenfunctions of Λ_γ , and also by [2] as an example of instability. Thus $\|\gamma - a_0\|_{L^\infty(\Omega)} = |a_1 - a_0|$ independently of ρ and yet $\Lambda_\gamma \rightarrow \Lambda_{a_0}$ in the operator norm. Hence if an inverse map $\Lambda_\gamma \mapsto \gamma$ exists, it cannot be continuous in this topology. Similar arguments can be used to show instability of inversion in other norms.

This example reveals many other features of the more general problem. For example experimentally one observes *saturation*: for an object placed away from the boundary, changes in the conductivity of an object with a conductivity close to the background are fairly easily detected, but for an object of very high or low conductivity further changes in conductivity of that object have little effect. This saturation effect was explored for offset circular objects (using conformal mappings) by Seagar [98]. This is also an illustration of the nonlinearity of $\gamma \rightarrow \Lambda_\gamma$. One can also see in this example that smaller objects (with the same conductivity) produce smaller changes in measured data as one might expect.

On the unit circle S^1 one can define an equivalent norm on the Sobolev space $H_\diamond^s(S^1)$ (see definitions in the section ‘‘The Neumann-to-Dirichlet Map’’) by

$$\left\| \sum_{n=-\infty, n \neq 0}^{\infty} c_n m r e^{in\theta} \right\|_s^2 = \sum_{n=-\infty, n \neq 0}^{\infty} n^{2s} c_n^2. \quad (14)$$

It is clear for this example that $\Lambda_\gamma : H_\diamond^s(S^1) \rightarrow H_\cdot^{s-1}(S^1)$, for any s . Roughly the current is a derivative of potential and one degree of differentiability less smooth. Technically Λ_γ (for any positive $\gamma \in C^\infty(\Omega)$) is a *first order pseudo-differential operator* [80]. The observation that for the example $e^{-in\theta} \Lambda_\gamma e^{in\theta} = |n| + o(n^{-p})$ as $|n| \rightarrow \infty$ for any $p > -1$ illustrates that the change in conductivity and radius of the interior object is of somewhat secondary importance! In the language of pseudodifferential operators for a general γ such that $\gamma - 1$ vanishes in a neighborhood of the boundary, Λ_γ and Λ_1 differ by a *smoothing operator*.

Since (13), Λ_γ^{-1} is also a well-defined operator on $L^2 \rightarrow L^2$ with eigenvalues $O(|n|^{-1})$ and is therefore a Hilbert–Schmidt operator. This is also known for the general case [36].

Early work on medical applications of EIT [58, 74] hoped that the forward problem in EIT would be approximated by generalized ray transform – that is integrals along current stream lines. The example of a concentric anomaly was used to illustrate that EIT is *nonlocal* [99]. If one applies the voltage $\cos(\theta + \alpha)$, which for a homogeneous disk would result in current streamlines that are straight and parallel, a change in conductivity in a small radius ρ from the center changes

all measured currents, not just on lines passing through the region of changed conductivity $|x| \leq \rho$. In the 1980s a two-dimensional algorithm that backprojected filtered data along equipotential lines was popularized by Barber and Brown [11]. Berenstein [17] later showed that the linearized EIT problem in a unit disc can be interpreted as the Radon transform with respect to the Poincaré metric and a convolution operator and that Barber and Brown's algorithm is an approximate inverse to this.

In process applications of EIT and related techniques the term *soft field imaging* is used, which by analogy to soft field X-rays means a problem that is nonlinear and nonlocal. However in the literature when the “soft field effect” is invoked, it is often not clear if it is the nonlinear or nonlocal aspect to which they refer and, in the authors' opinion, the term is best avoided.

Measurements with Electrodes

A typical electrical imaging system uses a system of conducting electrodes attached to the surface of the body under investigation. One can apply current or voltage to these electrodes and measure voltage or current respectively. For one particular measurement the voltages (with respect to some arbitrary reference) are V_ℓ and the currents I_ℓ , which are arranged in vectors as \mathbf{V} and $\mathbf{I} \in \mathbb{C}^L$. The discrete equivalent of the Dirichlet-to-Neumann Λ_γ map is the transfer admittance, or mutual admittance matrix \mathbf{Y} which is defined by $\mathbf{I} = \mathbf{Y}\mathbf{V}$.

It is easy to see that the vector $\mathbf{1} = (1, 1, \dots, 1)^T$ is in the null space of \mathbf{Y} , and that the range of \mathbf{Y} is orthogonal to the same vector. Let S be the subspace of \mathbb{C}^L perpendicular to $\mathbf{1}$; then it can be shown that $\mathbf{Y}|_S$ is invertible from S to S . The generalized inverse (see chapter ▶ [Linear Inverse Problems](#)) $\mathbf{Z} = \mathbf{Y}^\dagger$ is called the transfer impedance. This follows from uniqueness of solution of *shunt model* boundary value problem.

The transfer admittance, or equivalently transfer impedance, represents a complete set of data which can be collected from the L electrodes at a single frequency for a stationary linear medium. It can be seen from the weak formulation of (11) that \mathbf{Y} and \mathbf{Z} are symmetric (but for $\omega \neq 0$ *not Hermitian*). In electrical engineering this observation is called *reciprocity*. The dimension of the space of possible transfer admittance matrices is clearly no bigger than $L(L - 1)/2$, and so it is unrealistic to expect to recover more unknown parameters than this. In the analogous case of planar resistor networks with L “boundary” electrodes the possible transfer admittance matrices can be characterized completely [33], a characterization which is known at least partly to hold in the planar continuum case [63]. A typical electrical imaging system applies current or voltage patterns which form a basis of the space S , and measures some subset of the resulting voltages which as they are only defined up to an additive constant can be taken to be in S .

The shunt model is nonphysical; in medical application with electrodes applied to skin and in “phantom” tanks used to test EIT systems with ionic solutions in contact with metal electrodes, a contact impedance layer exists between the solution or skin

and the electrode. This modifies the shunting effect so that the voltage under the electrode is no longer constant. The voltage on the electrode is still a constant V_ℓ so now on E_ℓ there is a voltage drop across the contact impedance layer

$$\phi + z_\ell \sigma \frac{\partial \phi}{\partial v} = V_\ell, \quad (15)$$

where the contact impedance z_ℓ could vary over E_ℓ but is usually assumed constant. Experimental studies have shown [56] that a contact impedance on each electrode is required for an accurate forward model. This new boundary condition together with (3) and (4) form the *Complete Electrode Model* or CEM. For experimental validation of this model see [30], theory [103], and numerical calculations [96, 111]. A nonzero contact impedance removes the singularity in the current density, although high current densities still occur at the edges of the electrodes (Fig. 4). For further details on the singularity in the current density, see [32]. While “point electrodes,” in which the current density is a sum of delta functions, are a limiting case of the CEM, they are not physically realistic as they result in nonphysical potentials not in $H^1(\Omega)$. The trace on the boundary cannot be evaluated at a point, so point measurements of voltage are undefined. However it can be shown that if the conductivity is changed only in the compliment of a neighborhood of $\partial\Omega$ the resulting *voltage difference* at the boundary can be evaluated at points [52].

The set of imposed current patterns, or *excitation patterns*, is designed to span S , or at least that part of it that can be accurately measured in a given situation. In medical EIT, with process ERT following suit, early systems designed at Sheffield [11] assumed a two-dimensional circular domain. Identical electrodes were equally spaced on the circumference and, taking them to be numbered anticlockwise, the excitation patterns used were adjacent pairs, that is proportional to

$$I_\ell^i = \begin{cases} 1, & i = \ell \\ -1, & i = \ell + 1 \\ 0, & \text{otherwise,} \end{cases} \quad (16)$$

for $i = 1, \dots, L-1$. The electronics behind this is balanced current source connected between two electrodes [59, Chap. 2], and this is somewhat easier to achieve in practice than a variable current source at more than two electrodes. For general geometries, where the electrodes are not placed on a closed curve, other pairs of electrodes are chosen. For example $I_1^i = -1$, while $I_\ell^i = \delta_{i\ell}, \ell \neq 1$.

Measurements of voltage can only be differential and so voltage measurements are taken between pairs of electrodes, for example adjacent pairs, or between each and some fixed electrode. In pair drive systems, similar to the original Sheffield system, voltages on electrodes with nonzero currents are not measured, resulting in incomplete knowledge of \mathbf{Z} .

In geophysical surface resistivity surveys it is common to use a pair drive and pair measurement system, using electrodes in a line where a two-dimensional approximation is used, or laid out in a rectangular or triangular grid where the

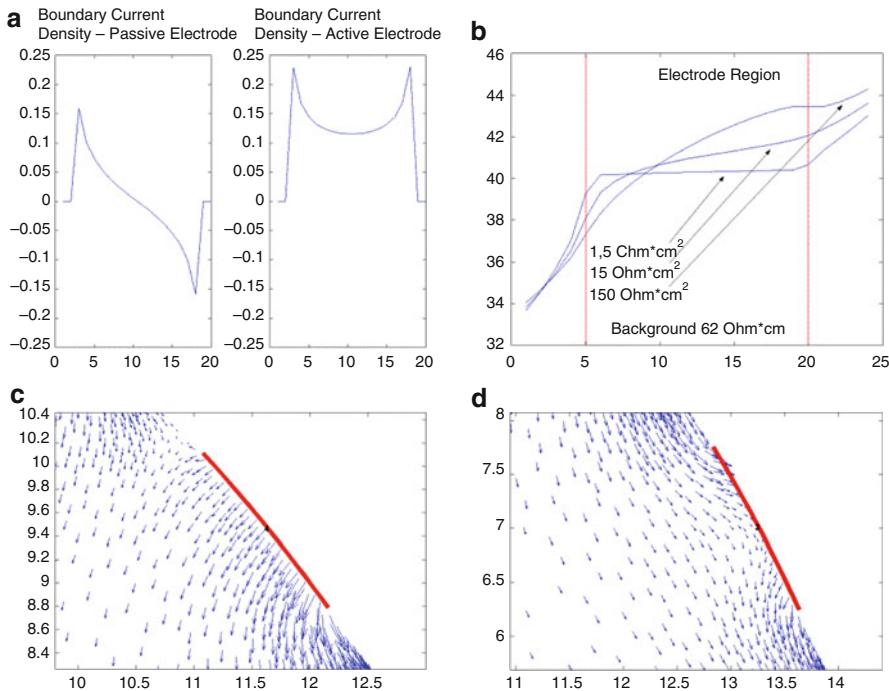

Fig. 4 The current density on the boundary with the CEM is greatest at the edge of the electrodes, even for passive electrodes. This effect is reduced as the contact impedance increases. Diagrams courtesy of Andrea Borsic. (a) Current density on the boundary for passive and active electrodes. In fact there is a jump discontinuity at the edge of electrodes for nonzeros contact impedance although the plotting routine has joined the left and right limits. (b) The effect of contact impedance on the potential beneath an electrode. The potential is continuous. (c) Interior current flux near an active electrode. (d) Interior current flux near a passive electrode

full three-dimensional problem is solved. Measurements taken between pairs of non-current carrying electrodes. The choice of measurement strategy is limited by the physical work involved in laying out the cables and by the switching systems. Often electrodes will be distributed along one line and a two-dimensional approximate reconstruction is used as this gives adequate information for less cost. A wider spacing of the current electrodes is used where the features of interest is located at a greater depth below the ground. In another geophysical configuration, cross borehole tomography, electrodes are deployed down several vertical cylindrical holes in the ground, typically filled with water, and current passed between electrodes in the same or between different bore holes. Surface electrodes may be used together with those in the bore holes. In some systems the current is measured to account for a non-ideal current source.

In capacitance tomography a basis of voltage patterns is applied and the choice $V_\ell^i = \delta_{i\ell}$ is almost universal. The projection of these vectors to S (denoted as an “electrode-wise basis”) is convenient computationally as a current pattern.

Given a *multiple drive system* capable of driving an arbitrary vector of currents in S (in practice with in some limits on the maximum absolute current and on the maximum voltage) there remains a choice of excitation patterns. While exact measurements of $\mathbf{Z}\mathbf{I}^i$ for \mathbf{I}^i in any basis for S is clearly sufficient, the situation is more complicated with measurements of finite precision in the presence of noise. If a redundant set of currents is taken, the problem of estimating \mathbf{Z} becomes one of *multivariate linear regression*. The choice of current patterns is then a *design matrix*. Another approach seeks the minimum set of current patterns that results in usable measurements. Applying each current pattern and taking a set of measurements take a finite time, during which the admittivity changes. Without more sophisticated statistical methods (such as Kalman filters [112]), there are diminishing returns in applying redundant current patterns. Suppose that the total power $\mathbf{V}^*\mathbf{Z}\mathbf{I}$ is constrained (to keep the patient electrically safe) and the current best estimate of the admittivity gives a transfer admittance \mathbf{Z}_{calc} , then it is reasonable to apply currents \mathbf{I} such that $(\mathbf{Z} - \mathbf{Z}_{\text{calc}})\mathbf{I}$ is above the threshold of voltages that can be accurately measured and modeled. One approach is to choose current patterns that are the right generalized singular vectors of $\mathbf{Z} - \mathbf{Z}_{\text{calc}}$ with singular values bigger than an error threshold. The generalized singular values are with respect to the norm $\|\mathbf{I}\|_{\mathbf{Z}} := \|\mathbf{Z}\mathbf{I}\|$ on S and are the extrema of the *distinguishability* defined as

$$\frac{\|(\mathbf{Z} - \mathbf{Z}_{\text{calc}})\mathbf{I}\|}{\|\mathbf{I}\|_{\mathbf{Z}}}, \quad (17)$$

for $\mathbf{I} \in S$. These excitation patterns are called “optimal current patterns” [45] and can be calculated from an iterative procedure involving repeated measurement. For circular disk with rotationally symmetric admittivity and equally spaced identical electrodes, the singular vectors will be discrete samples of a Fourier basis and these *trigonometric patterns* are a common choice for multiple drive systems using a circular array of electrodes.

2 Uniqueness and Stability of the Solution

Uniqueness of solution is very important in inverse problems, although when talking to engineers it is often better to speak of *sufficiency of data* to avoid confusion. Interestingly it is generally true that results that show *insufficiency of data*, that one cannot recover an unknown function even if an infinite number of measurements of arbitrary precision are taken, have more impact in applied areas. While there are still unsolved problems in the uniqueness theory for the EIT inverse problem, there has been considerable progress over the last three decades and many important questions have been answered. While for an isotropic real conductivity γ (with certain smoothness assumptions for dimensions $n \geq 3$), γ is uniquely determined by the complete data Λ_γ (see [10, 24, 107]), an anisotropic conductivity tensor is not uniquely determined by the boundary data, although some progress on what can be determined in this case has been made (see [3, 6, 43, 79]). Aside from

knowing what can and cannot be determined with ideal data, there are two important ways the theoretical work has a practical impact. Firstly in some cases the proof of uniqueness of solution suggests a reconstruction algorithm. As for the two-dimensional case (below) the most effective approach (the so-called $\bar{\partial}$ -method) to uniqueness theory has now been implemented as a fast, practical algorithm. The other is an understanding of the instability and conditional stability of the inverse problem. This helps us to determine what a priori information is helpful in reducing the sensitivity of the solution to errors in the data.

In 1980 Calderón published a paper with the title “On a inverse boundary value problem” [26], where he addressed the problem of whether it is possible to determine the conductivity of a body by making current and voltage measurements at the boundary. It seems that Calderón thought of this problem when he was working as an engineer in Argentina for the Yacimientos Petrolíferos Fiscales (YPF), but it was only decades later that he decided to publish his results. This short paper is considered the first mathematical formulation of the problem. For a reprinted version of this manuscript, refer to [27]. The authors wish to recall also the work due to Druskin (see [38–40]) which has been carried on independently from Calderón’s approach and has been devoted to the study of the problem from a geophysical point of view.

The Isotropic Case

Calderón’s Paper

Calderón considered a domain Ω in \mathbb{R}^n , $n \geq 2$, with Lipschitz boundary $\partial\Omega$. He took γ be a real bounded measurable function in Ω with a positive lower bound. Let Q_γ be the quadratic form (associated with Λ_γ) defined by

$$Q_\gamma(\phi) = \langle \phi, \Lambda_\gamma \phi \rangle = \int_{\Omega} \gamma |\nabla u|^2 dx, \quad (18)$$

where $u \in H^1(\Omega)$ solves the Dirichlet problem (2). Physically $Q_\gamma(\phi)$ is the Ohmic power dissipated when the boundary voltage ϕ is applied. The bilinear form associated with Q_γ is then obtained by using the polarization identity

$$\begin{aligned} B_\gamma(\phi, \psi) &= \frac{1}{2} \left\{ Q_\gamma(\phi + \psi) - Q_\gamma(\phi) - Q_\gamma(\psi) \right\} \\ &= \frac{1}{2} \left\{ \int_{\Omega} (\gamma |\nabla(u + v)|^2 - \gamma |\nabla u|^2 - \gamma |\nabla v|^2) dx \right\} \\ &= \int_{\Omega} \gamma \nabla u \cdot \nabla v dx, \end{aligned} \quad (19)$$

where $L_\gamma v = 0$ in Ω and $v|_{\partial\Omega} = \psi \in H^{\frac{1}{2}}(\partial\Omega)$. Clearly a complete knowledge of any of Λ_γ , Q_γ and B_γ are equivalent. Calderón considered the “forward” map

$$\mathbf{Q}: \gamma \longrightarrow Q_\gamma$$

and proved that \mathbf{Q} is bounded and analytic in the subset of $L^\infty(\Omega)$ consisting of functions γ which are real and have a positive lower bound. He then investigated the injectivity of the map and in order to do so, he linearized the problem. He in fact proved the injectivity of the Fréchet derivative of \mathbf{Q} at $\gamma = 1$. Here, a few details of the linearization for a general γ are given. Let u be the solution to (2) and $U = u + w$ satisfy $L_{\gamma+\delta} U = 0$, with $U|_{\partial\Omega} = \phi$. The perturbation in potential satisfies $w|_{\partial\Omega} = 0$, by considering the Dirichlet data fixed and investigating how the Neumann data varies when γ is perturbed to $\gamma + \delta$. This yields

$$L_\delta u + L_\gamma w + L_\delta w = 0. \quad (20)$$

Now let $G : H^{-1}(\Omega) \rightarrow H_0^1(\Omega)$ be the Green’s operator that solves the equivalent of Poisson’s equation for L_γ with zero Dirichlet boundary conditions. That is for $g \in H^{-1}(\Omega)$, $L_\gamma Gg = g$ and $G(g)|_{\partial\Omega} = 0$, the operator equation is given

$$(1 + GL_\delta)w = -GL_\delta u. \quad (21)$$

An advantage of using the L^∞ norm is that it is clear $\|L_\delta\| \rightarrow 0$ in the $H^1(\Omega) \rightarrow H^{-1}(\Omega)$ operator norm as $\|\delta\|_\infty \rightarrow 0$. This means one can choose δ small enough that $\|GL_\delta\| < 1$ (in the operator norm on $H^1(\Omega)$) and this ensures that the term in the bracket in (21) is invertible and the operator series in

$$w = - \left(\sum_{k=1}^{\infty} (-GL_\delta)^k \right) u \quad (22)$$

is convergent. This proves that the map $\gamma \mapsto u$ and hence \mathbf{Q} is not just C^∞ but analytic with (22) its Taylor series. Thus, the linearization of the map $\gamma \mapsto \Lambda_\gamma$ is

$$\Lambda_{\gamma+\delta}\phi = \Lambda_\gamma\phi + \gamma \frac{\partial}{\partial\nu} GL_\delta u + \delta \frac{\partial u}{\partial\nu} + O(\|\delta\|_\infty^2). \quad (23)$$

A strength of this argument is that it gives the Fréchet derivative in these norms, rather than just the Gateaux derivative. It is easy to deduce that the Fréchet derivative of \mathbf{Q} at γ in the direction δ is given by

$$d\mathbf{Q}(\gamma)\delta(\phi) = \int_{\Omega} \delta |\nabla u|^2 dx. \quad (24)$$

In many practical situations it is more common to fix the Neumann boundary conditions and measure the change in boundary voltage as the conductivity changes. Suppose $L_\gamma u = 0$, $L_{\gamma+\delta} U = 0$, $w = U - u$ with

$$\gamma \partial u / \partial v = (\gamma + \delta) \partial U / \partial v = g \in H_-^{-1/2}(\partial\Omega)$$

then a similar argument to the above shows

$$\int_{\partial\Omega} w \gamma \frac{\partial u}{\partial v} dx = - \int_{\Omega} \delta |\nabla u|^2 dx + O(||\delta||_\infty^2). \quad (25)$$

The polarization identity is often applied to (25) giving

$$\int_{\partial\Omega} w \gamma \frac{\partial v}{\partial v} dx = - \int_{\Omega} \delta \nabla u \cdot \nabla v dx + O(||\delta||_\infty^2), \quad (26)$$

where $L_\gamma v = 0$. This is often used in practice with

$$\gamma \frac{\partial v}{\partial v} = \chi_{E_i}/|E_i| - \chi_{E_j}/|E_j|, \quad (27)$$

which represents the difference in the characteristic functions of a pair of electrodes. In the case of the shunt model this makes the left-hand side of (25) equal to change that occurs in the difference between voltages on that pair of electrodes when the conductivity is perturbed. The formula (25) and its relatives are referred to as the Geselowitz Sensitivity Theorem in the bioengineering literature. With the CEM (25) still holds, but with u and v satisfying (15) [97].

Returning to Calderón's argument: for $\gamma = 1$ one has $L_1 u = \nabla^2 u$. To prove the injectivity of $d\mathbf{Q}(1)$ one must show that if the integral appearing in (24) vanishes for all the harmonic functions in Ω , then $\delta = 0$ in Ω . Suppose the integral in (24) vanishes for all $u \in H^1(\Omega)$ such that $\nabla^2 u = 0$ in Ω , then

$$\int_{\Omega} \delta \nabla u \cdot \nabla v = 0, \quad (28)$$

whenever $\nabla^2 u = \nabla^2 v = 0$ in Ω . For any $z \in \mathbb{R}^n$ consider $a \in \mathbb{R}^n$ such that $|a| = |z|$, $a \cdot z = 0$ and consider the harmonic functions

$$\begin{aligned} u(x) &= e^{\pi i(z \cdot x) + \pi(a \cdot x)}, \\ v(x) &= e^{\pi i(z \cdot x) - \pi(a \cdot x)}, \end{aligned} \quad (29)$$

which is equivalent to choosing

$$u(x) = e^{x \cdot \rho}, \quad v(x) = e^{-x \cdot \bar{\rho}},$$

where $\rho \in \mathbb{C}^n$ with

$$\rho \cdot \rho = 0.$$

Here the real dot product on complex vectors is used $\rho \cdot \rho := \rho^T \rho$. With the choice made in (29), (28) leads to

$$2\pi|z|^2 \int \delta(x)e^{2\pi i(z \cdot x)} dx = 0, \quad \text{for each } z,$$

therefore $\delta(x) = 0$, for all $x \in \Omega$. Calderón also observed that if the linear operator $d\mathbf{Q}(1)$ had a closed range, then one could have concluded that Q itself was injective in a sufficiently small neighborhood of $\gamma=\text{constant}$. However conditions on the range of $d\mathbf{Q}(1)$, that would allow us to use the implicit function theorem, are either false or not known. Furthermore if the range was closed, one could have also concluded that the inverse of $d\mathbf{Q}(1)$ was a bounded linear operator by the open mapping theorem. Calderón concluded the paper by giving an approximation for the conductivity γ if

$$\gamma = 1 + \delta$$

and δ is small enough in the L^∞ norm, by making use of the same harmonic functions (29). Calderón's technique is based on the construction of low frequency oscillating solutions. Sylvester and Uhlmann proved in their fundamental paper [107] a result of uniqueness using high frequencies oscillating solutions of $L_\gamma u = 0$. Their solutions are of type

$$u(x, \xi, t) = e^{x \cdot \xi} \gamma^{-\frac{1}{2}} (1 + \psi(x, \xi, t)),$$

which behaves (for high frequencies ξ) in the same way as the solutions used by Calderón. These oscillating solutions have come to be known as *complex geometrical optics (CGO) solutions*. Before going into more details of the use of CGO solutions, an earlier result using a different approach is given.

Uniqueness at the Boundary

In 1984 Kohn and Vogelius [75] proved that boundary values, and derivatives at the boundary, of a smooth isotropic conductivity γ could be determined from the knowledge of Q_γ . Their result is given by the following theorem.

Theorem 1. *Let Ω be a domain in \mathbb{R}^n ($n \geq 2$) with smooth boundary $\partial\Omega$. Suppose $\gamma_i \in C^\infty(\bar{\Omega})$, $i = 1, 2$ is strictly positive and that there is a neighborhood B of some $x^* \in \partial\Omega$ so that*

$$Q_{\gamma_1}(f) = Q_{\gamma_2}(f), \quad \text{for all } f, \quad f \in H^{\frac{1}{2}}(\partial\Omega), \quad \text{supp}(f) \subset B.$$

Then

$$\frac{\partial^{|\alpha|}}{\partial x^\alpha} \gamma_1(x^*) = \frac{\partial^{|\alpha|}}{\partial x^\alpha} \gamma_2(x^*), \quad \forall \alpha.$$

Theorem 1 is a local result in the sense that one only need to know \mathcal{Q}_γ in a open set of the boundary in order to determine the Taylor series of γ on that open set. The global reformulation of this result given in terms of Λ_γ is given below.

Theorem 2. Let $\gamma_i \in C^\infty(\bar{\Omega})$, $i = 1, 2$ be strictly positive. If $\Lambda_1 = \Lambda_2$, then

$$\frac{\partial^{|\alpha|}}{\partial x^\alpha} \gamma_1 = \frac{\partial^{|\alpha|}}{\partial x^\alpha} \gamma_2, \text{ on } \partial\Omega, \quad \forall \alpha.$$

For a sketch of the proof of Theorem 2 see [110, Sketch of proof of Theorem 4.1, pp 6]. This result settled the identifiability question in the real-analytic category of conductivities. Kohn and Vogelius have extended this result to piecewise real-analytic (e.g., piecewise constant) conductivities in [76]. The proof of this result is based on [75] together with the Runge approximation theorem for solutions of $L_\gamma u = 0$.

CGO Solutions for the Schrödinger Equation

In 1987 Sylvester and Uhlmann [106, 107] constructed in dimension $n \geq 2$ CGO solutions in the whole space for the Schrödinger equation with potential q . Before giving their result, the well-known relation between the conductivity equation and the Schrödinger equation will be derived. This relationship is also important in diffuse optical tomography (see chapter ▶ [Optical Imaging](#)).

Lemma 1. Let $\gamma \in C^2(\bar{\Omega})$ be strictly positive, yielding

$$\gamma^{-\frac{1}{2}} L_\gamma(\gamma^{-\frac{1}{2}}) = \nabla^2 - q, \quad (30)$$

where

$$q = \frac{\nabla^2(\gamma^{\frac{1}{2}})}{\gamma^{\frac{1}{2}}}.$$

Proof of Lemma 1.

$$L_\gamma u = \gamma \nabla^2 u + \nabla \gamma \cdot \nabla u \quad (31)$$

therefore

$$\gamma^{-\frac{1}{2}} L_\gamma u = \gamma^{\frac{1}{2}} \nabla^2 u + \frac{\nabla \gamma \cdot \nabla u}{\gamma^{\frac{1}{2}}}.$$

Consider for $w = \gamma^{\frac{1}{2}}u$

$$\begin{aligned}
\nabla^2 w - q w &= \nabla^2 \left(\gamma^{\frac{1}{2}} u \right) - \left(\nabla^2 \gamma^{\frac{1}{2}} \right) u \\
&= \nabla \cdot \left(\nabla (\gamma^{\frac{1}{2}} u) \right) - \left(\nabla^2 \gamma^{\frac{1}{2}} \right) u \\
&= \nabla \cdot \left((\nabla \gamma^{\frac{1}{2}} u) + \gamma^{\frac{1}{2}} (\nabla u) \right) - \left(\nabla^2 \gamma^{\frac{1}{2}} \right) u \\
&= (\nabla^2 \gamma^{\frac{1}{2}}) u + 2\nabla \gamma^{\frac{1}{2}} \cdot \nabla u + \gamma^{\frac{1}{2}} \nabla^2 u - (\nabla^2 \gamma^{\frac{1}{2}}) u \\
&= \gamma^{\frac{1}{2}} \nabla^2 u + \frac{\nabla \gamma \cdot \nabla u}{\gamma^{\frac{1}{2}}} \\
&= \gamma^{-\frac{1}{2}} L_\gamma u,
\end{aligned}$$

which proves (30). \square

The term q is usually called the *potential* of the Schrödinger equation, by analogy with the potential energy in quantum mechanics, this definition being somehow confusing given that in EIT u is the electric potential. The results in [106, 107] state the existence of CGO solutions for the Schrödinger equation with potential q bounded and compactly supported in \mathbb{R}^n . This result is as given in [110], which relies on the weighted L^2 space $L_\delta^2(\mathbb{R}^n) = \{f : \int_{\mathbb{R}^n} (1+|x|^2)^\delta |f(x)|^2 dx\}$. For $\delta < 0$ this norm controls the “growth at infinity.” The Sobolev spaces $H_\delta^k(\mathbb{R}^n)$ are formed in the standard way from $L_\delta^2(\mathbb{R}^n)$

$$H_\delta^k(\mathbb{R}^n) = \{f \in W^k(\mathbb{R}^n) \mid D^\alpha f \in L_\delta^2(\mathbb{R}^n), \text{ for all } |\alpha| \leq k\},$$

where α is a multi-index, $D^\alpha f$ denotes the α th weak derivative of f and $W^k(\mathbb{R}^n)$ is the set of k times weakly differentiable functions on \mathbb{R}^n .

Theorem 3. *Let $q \in L^\infty(\mathbb{R}^n)$, $n \geq 2$, with $q(x) = 0$ for $|x| \geq R > 0$ and $-1 < \delta < 0$. Then there exists $\epsilon(\delta)$ and such that for every $\rho \in \mathbb{C}^n$ satisfying*

$$\rho \cdot \rho = 0$$

and

$$\frac{\|(1+|x|^2)^{1/2}q\|_{L^\infty(\mathbb{R}^n)} + 1}{|\rho|} \leq \epsilon$$

there exists a unique solution to

$$(\nabla^2 - q)u = 0 \tag{32}$$

of the form

$$u(x, \rho) = e^{x \cdot \rho} (1 + \psi_q(x, \rho)), \quad (33)$$

with $\psi_q(\cdot, \rho) \in L^2_\delta(\mathbb{R}^n)$. Moreover $\psi_q(\cdot, \rho) \in H^2_\delta(\mathbb{R}^n)$ and for $0 \leq s \leq 2$ there exists $C = C(n, s, \delta) > 0$ such that

$$\|\psi_q(\cdot, \rho)\|_{H^2} \leq \frac{C}{|\rho|^{1-s}}. \quad (34)$$

Sketch of the proof of Theorem 3. Let u be a solution of (32) of type (33), then ψ_q must satisfy

$$(\nabla^2 + 2\rho \cdot \nabla - q)\psi_q = q. \quad (35)$$

The idea is that Eq.(35) can be solved for ψ_q by constructing an inverse for $(\nabla^2 + 2\rho \cdot \nabla)$ and solving the integral equation

$$\psi_q = (\nabla^2 + 2\rho \cdot \nabla)^{-1} (q(1 + \psi_q)) \quad (36)$$

for ψ_q . For more details about how to solve the above equation, refer to [110, Lemma 5.2] where it is shown that the integral equation (36) can only be solved in $L^2_\delta(\mathbb{R}^n)$ for large $|\rho|$. \square

Other approaches for the construction of CGO solutions for the Schrödinger equation have been considered in [36, 49]. The reader may refer to [110] for more details about references on this topic and a more in-depth explanation about the constructions of this kind of solutions.

Dirichlet-to-Neumann Map and Cauchy Data for the Schrödinger Equation

If 0 is not a Dirichlet eigenvalue for the Schrödinger equation, then the Dirichlet-to-Neumann map associated with a potential q can be defined by

$$\tilde{\Lambda}_q(f) = \frac{\partial u}{\partial \nu}|_{\partial\Omega},$$

where u solves the Dirichlet problem

$$\begin{cases} (\nabla^2 - q)u = 0 & \text{in } \Omega \\ u|_{\partial\Omega} = f. \end{cases}$$

As a consequence of Lemma 1, for any $q = \frac{\nabla^2 \gamma^{1/2}}{\gamma^{1/2}}$,

$$\begin{aligned}
\tilde{\Lambda}_q(f) &= \frac{\partial}{\partial \nu} (\gamma^{\frac{1}{2}} \gamma^{-\frac{1}{2}} u)|_{\partial\Omega} \\
&= \left(\frac{\partial \gamma^{\frac{1}{2}}}{\partial \nu} (\gamma^{-\frac{1}{2}} u) + \gamma^{\frac{1}{2}} \frac{\partial (\gamma^{-\frac{1}{2}} u)}{\partial \nu} \right)|_{\partial\Omega} \\
&= \left(\frac{1}{2} \gamma^{-\frac{1}{2}} \frac{\partial \gamma}{\partial \nu} \gamma^{-\frac{1}{2}} + \gamma^{\frac{1}{2}} \frac{\partial (\gamma^{-\frac{1}{2}} u)}{\partial \nu} \right)|_{\partial\Omega} \\
&= \frac{1}{2} \left(\gamma^{-1} \frac{\partial \gamma}{\partial \nu} \right)|_{\partial\Omega} f + \gamma^{\frac{1}{2}}|_{\partial\Omega} \Lambda_\gamma(\gamma^{-\frac{1}{2}}|_{\partial\Omega} f).
\end{aligned}$$

So the two Dirichlet-to-Neumann maps $\tilde{\Lambda}_q$ and Λ_γ are related in the following way

$$\tilde{\Lambda}_q(f) = \frac{1}{2} \left(\gamma^{-1} \frac{\partial \gamma}{\partial \nu} \right)|_{\partial\Omega} f + \gamma^{\frac{1}{2}}|_{\partial\Omega} \Lambda_\gamma(\gamma^{-\frac{1}{2}}|_{\partial\Omega} f), \quad (37)$$

for any $f \in H^{\frac{1}{2}}(\partial\Omega)$. For $q \in L^\infty(\partial\Omega)$, the Cauchy data are defined as the set

$$\mathbf{C}_q = \left\{ \left(u|_{\partial\Omega}, \frac{\partial u}{\partial \nu}|_{\partial\Omega} \right) \mid u \in H^1(\Omega), \quad (\nabla^2 - q)u = 0 \quad \text{in } \Omega \right\}.$$

If 0 is not an eigenvalue of $\nabla^2 - q$, then \mathbf{C}_q is the graph given by

$$\mathbf{C}_q = \left\{ (f, \tilde{\Lambda}_q(f)) \in H^{\frac{1}{2}}(\partial\Omega) \times H^{-\frac{1}{2}}(\partial\Omega) \right\}.$$

The result so far is very general and holds in any dimension $n \geq 2$. In the rest of the discussion on the uniqueness of Calderón's problem, a distinction is made between the higher dimensional case $n \geq 3$ and the two-dimensional one.

Global Uniqueness for $n \geq 3$

Sylvester and Uhlmann proved in [107] a result of global uniqueness for $C^2(\bar{\Omega})$ conductivities by solving in this way the identifiability question with the following result. Their result follows in dimension $n \geq 3$ from a more general one for the Schrödinger equation, which is useful in its own right for other inverse problems.

Theorem 4. *Let $q_i \in L^\infty(\Omega)$, $i=1, 2$. Assume $\mathbf{C}_{q_1} = \mathbf{C}_{q_2}$, then $q_1 = q_2$.*

Proof of Theorem 4. This result has been proved by constructing oscillatory solutions of $(\nabla^2 - q_i)u_i = 0$ in \mathbb{R}^n with high frequencies. Beginning with the following equality

$$\int_{\Omega} (q_1 - q_2)u_1 u_2 = 0 \quad (38)$$

is true for any $u_i \in H^1(\Omega)$ solution to

$$(\nabla^2 - q_i)u_i = 0 \quad \text{in } \Omega, \quad i = 1, 2.$$

Equality (38) follows by

$$\int_{\Omega} (q_1 - q_2)u_1 u_2 = \int_{\partial\Omega} \left(\frac{\partial u_1}{\partial \nu} u_2 - u_1 \frac{\partial u_2}{\partial \nu} \right) dS,$$

which can be easily obtained by the divergence theorem. This extends q_i on the whole \mathbb{R}^n by taking $q_i = 0$ on $\mathbb{R}^n \setminus \Omega$ and taking solutions of

$$(\nabla^2 - q_i)u_i = 0 \quad \text{in } \mathbb{R}^n, \quad i = 1, 2$$

of the form

$$u_i = e^{x \cdot \rho_i} (1 + \psi_{q_i}(x, \rho_i)), \quad i = 1, 2, \quad (39)$$

with $|\rho_i|$ large. This type of solutions are known as CGO solutions. $\rho_i, i = 1, 2$ is chosen of type

$$\begin{aligned} \rho_1 &= \frac{\eta}{2} + i \left(\frac{k+l}{2} \right) \\ \rho_2 &= -\frac{\eta}{2} + i \left(\frac{k-l}{2} \right), \end{aligned} \quad (40)$$

with $\eta, k, l \in \mathbb{R}^n$ and satisfying

$$\eta \cdot k = k \cdot k = \eta \cdot l = 0, \quad |\eta|^2 = |k|^2 + |l|^2, \quad (41)$$

the choices of η, k, l having been made so that $\rho_i \cdot \rho_i = 0, i = 1, 2$. With these choices of $\rho_i, i = 1, 2$,

$$\begin{aligned} u_1 u_2 &= \left[e^{x \cdot \frac{\eta}{2} + ix \cdot \left(\frac{k+l}{2} \right)} + e^{x \cdot \frac{\eta}{2} + ix \cdot \left(\frac{k+l}{2} \right)} \psi_{q_1} \right] \\ &\quad \cdot \left[e^{-x \cdot \frac{\eta}{2} + ix \cdot \left(\frac{k-l}{2} \right)} + e^{-x \cdot \frac{\eta}{2} + ix \cdot \left(\frac{k-l}{2} \right)} \psi_{q_2} \right] \\ &= e^{ix \cdot k} (1 + \psi_{q_1} + \psi_{q_2} + \psi_{q_1} \psi_{q_2}) \end{aligned}$$

and therefore

$$\widehat{(q_1 - q_2)}(-k) = - \int_{\Omega} e^{ix \cdot k} (q_1 - q_2)(\psi_{q_1} + \psi_{q_2} + \psi_{q_1} \psi_{q_2}) dx. \quad (42)$$

By recalling that

$$\|\psi_{q_i}\|_{L^2(\Omega)} \leq \frac{C}{|\rho_i|}$$

and letting $|l| \rightarrow \infty$ one obtains $q_1 = q_2$ (see [110, proof of Theorem 6.2, pp 10]). \square

As a consequence of this result, the result [107] stated below is finally obtained.

Theorem 5. *Let $\gamma_i \in C^2(\bar{\Omega})$, γ_i strictly positive, $i=1, 2$. If $\Lambda_{\gamma_1} = \Lambda_{\gamma_2}$, then $\gamma_1 = \gamma_2$ in $\bar{\Omega}$.*

Theorem 5 has been proved in [107] in a straightforward manner by constructing highly oscillatory solutions to $L_\gamma u = 0$ in Ω . In this chapter, the line of [110] is followed in the exposition of such result as a consequence of the more general Theorem 4. Such a choice has been made because of the clearer exposition made in [110].

One can proceed by showing that Theorem 4 implies Theorem 5 for the sake of completeness. The reader can find it also in [110]. The argument used is the following. Let $\gamma_i \in C^2(\bar{\Omega})$ be strictly positive and $\Lambda_{\gamma_1} = \Lambda_{\gamma_2}$. Then by [75],

$$\begin{aligned} \gamma_1|_{\partial\Omega} &= \gamma_2|_{\partial\Omega}, \\ \frac{\partial\gamma_1}{\partial\nu}|_{\partial\Omega} &= \frac{\partial\gamma_2}{\partial\nu}|_{\partial\Omega}, \end{aligned}$$

therefore (37) implies $C_{q_1} = C_{q_2}$ i.e., $q_1 = q_2 =: q$ because of Theorem 4. Recall that

$$q_i = \frac{\nabla^2 \gamma_i^{1/2}}{\gamma_i^{1/2}}, \quad i = 1, 2,$$

which leads to

$$\begin{aligned} \nabla^2 \gamma_1^{\frac{1}{2}} - q \gamma_1^{\frac{1}{2}} &= 0 \\ \nabla^2 \gamma_2^{\frac{1}{2}} - q \gamma_2^{\frac{1}{2}} &= 0 \end{aligned}$$

i.e.,

$$\nabla^2 \left(\gamma_1^{\frac{1}{2}} - \gamma_2^{\frac{1}{2}} \right) - q \left(\gamma_1^{\frac{1}{2}} - \gamma_2^{\frac{1}{2}} \right) = 0$$

with

$$\left(\gamma_1^{\frac{1}{2}} - \gamma_2^{\frac{1}{2}} \right) |_{\partial\Omega} = 0.$$

Therefore it must be that

$$\gamma_1 = \gamma_2 \quad \text{in } \Omega,$$

by uniqueness of the solution of the Cauchy problem.

The identifiability question was then pushed forward to the case of $\gamma \in C^{1,1}(\bar{\Omega})$ with an affirmative answer by Nachman et al. in 1988 [90]. Nachman extended then this result to domains with $C^{1,1}$ boundaries (see [88]). The condition on the boundary was relaxed to $\partial\Omega$ Lipschitz by Alessandrini in 1990 in [3]; he proved uniqueness at the boundary and gave stability estimates for $\gamma \in W^{1,p}(\Omega)$, with $p > n$ by making use of singular solutions with an isolated singularity at the center of a ball. This method enables one to construct solutions of $L_\gamma u = 0$ on a ball behaving asymptotically like the singular solutions of the Laplace–Beltrami equation with separated variables. His results hold in dimension $n \geq 2$. Results of global uniqueness in the interior were also found in [3] among piecewise analytic perturbations of γ , giving an extension of Kohn and Vogelius result in [76] to Lipschitz domains.

Going back to the issue of global uniqueness, Brown [22] relaxed the regularity of the conductivity to $\frac{3}{2} + \varepsilon$ derivatives, which was followed by the uniqueness result of Päivärinta et al. [95] for $W^{\frac{3}{2},\infty}$ conductivities. Their result is based on the construction of CGO solutions for conductivities $\gamma \in W^{1,\infty}(\mathbb{R}^n)$ ($n \geq 2$). Recalling in what follows, their construction of the CGO followed by their uniqueness result.

Theorem 6 ([95]). *Let $\gamma \in W^{1,\infty}(\mathbb{R}^\times)$, γ strictly positive and $\gamma = 1$ outside a large ball. Let $-1 < \delta < 0$, then for $|\rho|$ sufficiently large there is a unique solution of*

$$\operatorname{div}(\gamma \nabla u) = 0 \quad \text{in } \mathbb{R}^\times$$

of the form

$$u = e^{x \cdot \rho} \left(\gamma^{-\frac{1}{2}} + \psi_\gamma(x, \rho) \right), \quad (43)$$

with $\psi_\gamma \in L^2_\delta(\mathbb{R}^n)$. Moreover, ψ_γ has the form

$$\psi_\gamma(x, \rho) = \left(\omega_0(x, \rho) - \gamma^{-\frac{1}{2}} \right) + \omega_1(x, \rho), \quad (44)$$

where ω_0, ω_1 satisfy

$$\lim_{|\rho| \rightarrow \infty} \|\omega_0(x, \rho) - \gamma^{-\frac{1}{2}}\|_{H_\delta^1} = 0 \quad (45)$$

and

$$\lim_{|\rho| \rightarrow \infty} ||\omega_1(x, \rho)||_{L^2_\delta} = 0. \quad (46)$$

Here, the idea behind the proof of the above Theorem 6 is recalled. The first step is to rewrite the conductivity equation

$$\operatorname{div}(\gamma \nabla u) = 0 \quad \text{in } \mathbb{R}^n$$

as

$$\Delta u + A \cdot \nabla u = 0 \quad \text{in } \mathbb{R}^n,$$

where

$$A + \nabla \log \gamma \in L^\infty(\mathbb{R}^n)$$

has compact support. By introducing

$$\Phi_\varepsilon = \varepsilon^{-n} \left(\frac{x}{\varepsilon} \right),$$

with $\Phi(x)$ a mollifier, one can define

$$\begin{aligned} \varphi_\varepsilon &= \Phi_\varepsilon * \log \gamma \\ A_\varepsilon &= \Phi_\varepsilon * A \\ \omega_0(x, \varepsilon) &= e^{-\frac{\varphi_\varepsilon(x)}{2}} \end{aligned}$$

and with the above choice of ω_0 one can show that

$$\lim_{\varepsilon \rightarrow 0} ||\omega_0 - \gamma^{-\frac{1}{2}}||_{H^1_\delta} = 0. \quad (47)$$

Let $\rho \in \mathbb{C}^n$ be such that $\rho \cdot \rho = 0$ and define the operators

$$\Delta_\rho u := e^{-x \cdot \rho} \Delta (e^{x \cdot \rho} u) = \Delta u + 2\rho \cdot \nabla u \quad (48)$$

$$\nabla_\rho u := e^{-x \cdot \rho} \nabla (e^{x \cdot \rho} u) = \nabla u + \rho u. \quad (49)$$

One can then define for any $f \in C_0^\infty(\mathbb{R}^n)$

$$\Delta_\rho^{-1} f = \frac{1}{(2\pi)^n} \int e^{ix \cdot \xi} \frac{\hat{f}(\xi)}{-|\xi|^2 + 2i\rho \cdot \xi} d\xi,$$

which can then be extended to a bounded operator

$$\Delta_\rho^{-1} : H_{\delta+1}^s(\mathbb{R}^n) \rightarrow H_\delta^s(\mathbb{R}^n),$$

for any $-1 < \delta < 0$ and $s \geq 0$. Moreover

$$\|\Delta_\rho^{-1}\|_{H_{\delta+1}^s \rightarrow H_\delta^s} \leq \frac{C(s, \delta, n)}{|\rho|},$$

for some $C > 0$. The idea is now to construct ω_1 solution to

$$(\Delta_\rho + A \cdot \nabla_\rho)\omega_1 = -(\Delta_\rho + A \cdot \nabla_\rho)\omega_0, \quad (50)$$

recalling that $\omega_0(x, \varepsilon) = e^{-\frac{\varphi_\varepsilon(x)}{2}}$ and therefore depends on ε . If one sets now

$$\omega_1 = \Delta_\rho^{-1} \tilde{\omega},$$

one can then rewrite (50) as

$$\underbrace{(I + A \cdot \nabla_\rho \Delta_\rho^{-1})}_{:= T_\rho(\gamma)} \tilde{\omega} = f_\varepsilon, \quad (51)$$

where

$$\begin{aligned} f_\varepsilon &:= -(\Delta_\rho + A \cdot \nabla_\rho)\omega_0 \\ &= -e^{-\frac{\varphi_\varepsilon}{2}} \left(-\frac{1}{2} \Delta \varphi_\varepsilon + \frac{1}{4} (\nabla \varphi_\varepsilon)^2 - \frac{1}{2} A \cdot \nabla \varphi_\varepsilon + (A - A_\varepsilon) \cdot \rho \right). \end{aligned}$$

An approximate inverse of $T_\rho(\gamma)$ is given by

$$\begin{aligned} S_\rho(\gamma) &:= \gamma^{-\frac{1}{2}} (I - A \cdot \nabla_\rho \Delta_\rho^{-1}) \gamma^{\frac{1}{2}} \\ &= \gamma^{-\frac{1}{2}} T_\rho(\gamma^{-1}) \gamma^{\frac{1}{2}}, \end{aligned}$$

therefore (51) has a unique solution in an appropriate space. To study now the behavior of ω_1 as $\varepsilon \rightarrow 0$ and $|\rho| \rightarrow \infty$, recall that

$$\omega_1(x, \varepsilon, \rho) = \Delta_\rho^{-1} S_\rho f_\varepsilon + \underbrace{\Delta_\rho^{-1} (T_\rho^{-1} - S_\rho) f_\varepsilon}_{:= h_\rho} \quad (52)$$

and now one can show that

$$\lim_{|\rho| \rightarrow \infty} \|h_\rho\|_{H_\delta^1(\mathbb{R}^n)} = 0, \quad (53)$$

which concludes the proof. Theorem 43 is then used in [95] to prove global uniqueness for conductivities $\gamma \in W^{\frac{3}{2},\infty}(\Omega)$, where Ω is a bounded domain in \mathbb{R}^n , with $n \geq 3$. More precisely they prove the following theorem.

Theorem 7. *Let $n \geq 3$. Let $\gamma_i \in W^{\frac{3}{2},\infty}(\Omega)$ be strictly positive on $\bar{\Omega}$, $i = 1, 2$. If*

$$\Lambda_{\gamma_1} = \Lambda_{\gamma_2},$$

then

$$\gamma_1 = \gamma_2 \quad \text{on } \Omega.$$

Again, the idea is to give to the reader a flavor of how Theorem 7 is proven in [95]. The main idea is that if $\gamma_i \in W^{1,\infty}(\Omega)$ and $\Lambda_{\gamma_1} = \Lambda_{\gamma_2}$, with $a_i = \sqrt{\gamma_i}$, $i = 1, 2$, then the identity

$$\int_{\Omega} (\nabla a_1 \cdot \nabla(u_1 v) - \nabla a_2 \cdot \nabla(u_2 v)) - \int_{\Omega} (\nabla(a_1 u_1) \cdot \nabla v - \nabla(a_2 u_2) \cdot \nabla v) \, dx = 0, \quad (54)$$

holds true $\forall v \in H^1(\Omega)$, $\forall u_i \in H^1(\Omega)$ solution to $\operatorname{div}(\gamma_i \nabla u_i) = 0$ in $\Omega = 1, 2$. The reader should notice that so far the results obtained hold true for conductivities of type $\gamma \in W^{1,\infty}(\Omega)$. It is at this stage that one needs to assume

$$\gamma \in W^{\frac{3}{2},\infty}(\mathbb{R}^n)$$

to show the following technical results for $\omega_1(x, \rho) = \omega_1(x, \varepsilon, \rho)$ as in (52), $\varepsilon = |\rho|^{-1}$

$$\lim_{|\rho| \rightarrow \infty} \int e^{ix \cdot \xi} \nabla \gamma^{\frac{1}{2}} \cdot \nabla \omega_1 \, dx = 0. \quad (55)$$

With this choice of ω_1 , by substituting the CGO solutions (44) into identity (54), one then can gain the desired uniqueness result.

The above result was then followed by uniqueness for $W^{\frac{3}{2},p}$ (with $p > 2n$) in [23]. Recently Haberman and Tataru [48] proved that uniqueness holds for C^1 conductivities and Lipschitz conductivities close to the identity. Their result is the following.

Theorem 8. *Let $n \geq 3$ and $\Omega \subset \mathbb{R}^n$ be a bounded domain with Lipschitz boundary. Let $\gamma_i \in W^{1,\infty}(\bar{\Omega})$ be a real conductivity, $i = 1, 2$. Suppose there exists a constant $C = C(n, \Omega)$ such that γ_i , $i = 1, 2$ satisfies either*

$$\|\nabla \log \gamma_i\|_{L^\infty(\bar{\Omega})} \leq C \quad (56)$$

or

$$\gamma_i \in C^1(\bar{\Omega}). \quad (57)$$

If

$$\Lambda_{\gamma_1} = \Lambda_{\gamma_2},$$

then

$$\gamma_1 = \gamma_2.$$

Global Uniqueness in the Two-Dimensional Case

The two-dimensional inverse conductivity problem must often be treated as a special case. Although results in [76] gave a positive answer to the identifiability question in the case of piecewise analytic conductivities, it was not until 1996 that Nachman [89] proved a global uniqueness result to Calderón problem for conductivities in $W^{2,p}(\Omega)$, for some $p > 1$. An essential part of his argument is based on the construction of the CGO solutions and the $\bar{\partial}$ -method (sometimes written “d-bar method”) in inverse scattering introduced in one dimension by Beals and Coifman (see [14, 15]). The result of [89] has been improved in 1997 for conductivities having one derivative in an appropriate sense (see [24]) and the question of uniqueness was settled in $L^\infty(\Omega)$ finally by Astala and Päiväranta [10] using $\bar{\partial}$ -methods. They proved

Theorem 9. *Let Ω be a bounded domain in \mathbb{R}^2 and $\gamma_i \in L^\infty$, $i = 1, 2$ be real functions such that for some constant M , $M^{-1} < \gamma_i < M$. Then*

$$\Lambda_{\gamma_1} = \Lambda_{\gamma_2} \implies \gamma_1 = \gamma_2.$$

Let us first explain the complex version of the problem used by [10]. Using the complex variable $z = x_1 + ix_2$, and the notation $\partial = \partial/\partial z$, $\bar{\partial} = \partial/\partial \bar{z}$. Then the following result is available [10]:

Lemma 2. *Let Ω be the unit disk in the plane and $u \in H^1(\Omega)$ be a solution of $L_\gamma u = 0$. Then there exists a real function $v \in H^1(\Omega)$, unique up to a constant, such that $f = u + iv$ satisfies the Beltrami equation*

$$\bar{\partial} f = \mu \overline{\partial f}, \quad (58)$$

where $\mu = (1 - \gamma)/(1 + \gamma)$.

Conversely if $f \in H^1(\Omega)$ satisfies (58), with a real valued μ , then $u = \operatorname{Re} f$ and $v = \operatorname{Im} f$ satisfy

$$L_\gamma u = 0 \quad \text{and} \quad L_{\gamma^{-1}} v = 0, \quad (59)$$

where $\gamma = (1 - \mu)/(1 + \mu)$.

Astala and Päiväranta reduce the general case of Ω to that of the disk, and show that the generalized Hilbert transform $\mathcal{H}_\mu : u|_{\partial\Omega} \mapsto v|_{\partial\Omega}$ uniquely determines, and is determined by Λ_γ . They go on to construct CGO solutions to (58) of the form

$$f_\mu(z, k) = e^{ikz} \left(1 + O\left(\frac{1}{z}\right) \right) \text{ as } |z| \rightarrow \infty \quad (60)$$

and using a result connecting pseudoanalytic functions with quasi-regular maps prove that \mathcal{H}_μ determines μ . The original method Nachman used to prove uniqueness has resulted in the development of $\bar{\partial}$ reconstruction methods which are described below (section “Direct Nonlinear Solution”). See also the work of Druskin [38], which provides some answers to the 2-D geophysical settings.

Some Open Problems for the Uniqueness

One of the main open problems in dimension $n \geq 3$ is to investigate whether global uniqueness holds for the minimal assumption $\gamma \in L^\infty(\Omega)$ or else to find what are the minimal assumptions on γ in order to guarantee uniqueness. The inverse conductivity problem makes sense for conductivities that are indeed merely L^∞ . There are neither proofs nor counter-examples for this in any dimension, to the authors’ knowledge, but it has been conjectured by Uhlmann that the optimal assumption is that the conductivities are Lipschitz. These open problems influence of course also the stability issue of finding appropriate assumptions (possibly on γ) in order to improve the unstable nature of EIT. This issue will be studied in the next section.

Stability of the Solution at the Boundary

The result of uniqueness at the boundary of Theorem 2 has been improved in [108] to a stability estimate. The result is the following.

Theorem 10. *Let $\gamma_i \in C^\infty(\bar{\Omega})$, $i = 1, 2$, satisfy*

$$0 < \frac{1}{E} \leq \gamma_i \leq E, \quad i = 1, 2 \quad (61)$$

$$\|\gamma_i\|_{C^2(\bar{\Omega})} \leq E, \quad i = 1, 2. \quad (62)$$

Given any $0 < \sigma < \frac{1}{n+1}$, there exists $C = C(\Omega, E, n, \sigma)$ such that

$$\|\gamma_1 - \gamma_2\|_{L^\infty(\partial\Omega)} \leq C \|\Lambda_{\gamma_1} - \Lambda_{\gamma_2}\|_* \quad (63)$$

and

$$\left\| \frac{\partial \gamma_1}{\partial \nu} - \frac{\partial \gamma_2}{\partial \nu} \right\|_{L^\infty(\partial\Omega)} \leq C \|\Lambda_{\gamma_1} - \Lambda_{\gamma_2}\|_*^\sigma, \quad (64)$$

where $\|\cdot\|_*$ denotes the norm in the space of bounded linear operators from $H^{\frac{1}{2}}(\partial\Omega)$ to $H^{-\frac{1}{2}}(\partial\Omega)$.

This result improves the one of Theorem 2 in the sense that it is no longer necessary to require $\gamma \in C^\infty(\bar{\Omega})$ to determine γ itself and its derivative at the boundary. It is only needed that γ be continuous on $\bar{\Omega}$ to determine the boundary values of γ , where if $\gamma \in C^1(\bar{\Omega})$ then one can determine γ and its first derivative on $\partial\Omega$ as well. Subsequent results of stability at the boundary along the same lines have been proved in [3, 7, 22, 43, 88, 91].

Global Stability for $n \geq 3$

In 1988 Alessandrini [2] proved that, in dimension $n \geq 3$, under an a priori assumption on γ of type

$$\|\gamma\|_{H^s(\Omega)} \leq E, \quad \text{for some } s > \frac{n}{2} + 2,$$

γ depends continuously on Λ_γ with a modulus of continuity of logarithmic type. The result is stated below.

Theorem 11. *Let $n \geq 3$. Suppose that $s > \frac{n}{2}$ and that $\gamma_i \in C^\infty(\bar{\Omega})$, $i = 1, 2$ is a conductivity satisfying*

$$0 < \frac{1}{E} \leq \gamma_i \leq E, \quad i = 1, 2 \quad (65)$$

$$\|\gamma_i\|_{H^{s+2}(\Omega)} \leq E, \quad i = 1, 2. \quad (66)$$

Then there exists $C = C(\Omega, E, n, s)$ and $\tau = \tau(n, s)$, with $0 < \tau < 1$ such that

$$\|\gamma_1 - \gamma_2\|_{L^\infty(\Omega)} \leq C (\|\log \|\Lambda_{\gamma_1} - \Lambda_{\gamma_2}\|_*\|^{-\tau} + \|\Lambda_{\gamma_1} - \Lambda_{\gamma_2}\|_*). \quad (67)$$

It has been proved [3, 4] that a similar stability estimate holds if (66) is replaced by

$$\|\gamma_i\|_{W^{2,\infty}(\Omega)} \leq E, \quad i = 1, 2. \quad (68)$$

Mandache [86] proved that logarithmic stability is optimal for dimension $n \geq 2$ if the a priori assumption is of the form

$$\|\gamma\|_{C^k(\bar{\Omega})} \leq E, \quad (69)$$

for any finite $k = 0, 1, 2, \dots$. One of the main open problems in the stability issue is then to improve this logarithmic-type stability estimate under some additional a priori condition. In [8] it has been shown that (67) can be improved to a Lipschitz-type estimate in the case in which γ is piecewise constant with jumps on a finite

number of domains. For piecewise constant complex conductivities a similar result has been proved in [16], where piecewise constant potentials of the Schrödinger equation have been investigated in [18] and Lipschitz stability estimates have been proved in this case as well. For more in-depth discussion about the stability in EIT and open problems in that regard refer to [5]. A similar estimate to (67) for the potential case can be found in [110].

Global Stability for the Two-Dimensional Case

Logarithmic-type stability estimates in dimension $n = 2$ were obtained by [12, 13, 82]. The results obtained in [82] last require only γ be Hölder continuous of positive exponent

$$\|\gamma\|_{C^\alpha(\bar{\Omega})} \leq E, \quad (70)$$

for some α , $0 < \alpha \leq 1$.

Some Open Problems for the Stability

The main open problem is to improve the logarithmic-type estimate found in [2] in any dimension $n \geq 2$. One approach would be to investigate whether the a priori regularity assumptions (68) can be further relaxed. On the other hand, since it has been observed [86] that this logarithmic type of estimate cannot be avoided under any a priori assumption of type (69) for any finite $k = 0, 1, 2, \dots$, it seems natural to think that another direction to proceed would be the one of looking for different a priori assumptions rather than the one of type (69). For a complete analysis of open problems in this area, refer to [5].

The Anisotropic Case

The Non-uniqueness

In anisotropic media the conductivity depends on the direction, therefore it is represented by a matrix $\gamma = (\gamma_{ij})_{i,j=1}^n$, which is symmetric and positive definite. Anisotropic conductivity appears in nature, for example as a homogenization limit in layered or fibrous structures such as rock stratum or muscle, as a result of crystalline structure or of deformation of an isotropic material. Let $\Omega \subset \mathbb{R}^n$ be a domain with smooth boundary $\partial\Omega$ (a Lipschitz boundary will be enough in most cases). The Dirichlet problem associated in the anisotropic case takes the form

$$\begin{cases} \sum_{i,j=1}^n \frac{\partial}{\partial x^i} (\gamma_{ij} \frac{\partial u}{\partial x^j}) = 0 \text{ in } \Omega \\ u|_{\partial\Omega} = f, \end{cases} \quad (71)$$

where $f \in H^{\frac{1}{2}}(\partial\Omega)$ is a prescribed potential at the boundary. The Dirichlet-to-Neumann map associated with γ is defined by

$$\Lambda_\gamma f = \gamma \nabla u \cdot v|_{\partial\Omega}, \quad (72)$$

for any u solution to (71). Here $\gamma \nabla u \cdot v = \sum_{i,j=1}^n (\gamma_{ij} \frac{\partial u}{\partial x^j}) v_i|_{\partial\Omega}$ and as usual $v = (v_i)_{i=1}^n$ is the unit outer normal to $\partial\Omega$. The weak formulation of (72) is commonly used and will be given below for the sake of completeness.

Definition 1. The Dirichlet-to-Neumann map associated with (71) is

$$\Lambda_\gamma : H^{\frac{1}{2}}(\partial\Omega) \longrightarrow H^{-\frac{1}{2}}(\partial\Omega)$$

given by

$$\langle \Lambda_\gamma f, \eta \rangle = \int_{\Omega} \sigma(x) \nabla u(x) \cdot \nabla \phi(x) dx, \quad (73)$$

for any $f, \eta \in H^{\frac{1}{2}}(\partial\Omega)$, $u, \phi \in H^1(\Omega)$, $\phi|_{\partial\Omega} = \eta$ and u is the weak solution to (71).

A conductor is isotropic when $\gamma = (\gamma_{ij})$ is rotation invariant, i.e., when at each point

$$R^T \gamma R = \gamma,$$

for all rotations R . This is the case exactly when $\gamma = \alpha I$, where $\alpha > 0$ is a scalar function and I the identity matrix.

In the section “The Isotropic Case,” the uniqueness problem for the isotropic case was considered solved; on the other hand, in the anisotropic case, Λ_γ does not in general determine γ . Tartar (see [75]) observed the following non-uniqueness result.

Proposition 1. If $\psi : \bar{\Omega} \longrightarrow \bar{\Omega}$ is a C^1 diffeomorphism such that $\psi(x) = x$, for each $x \in \partial\Omega$, then γ and $\tilde{\gamma} = \frac{(D\psi)\gamma(D\psi)^T}{\det(D\psi)} \circ \psi^{-1}$ have the same Dirichlet-to-Neumann map.

The proof of this result is given below as a tutorial for the first-time reader of this material.

Proof. Let us consider the change of variables $y = \psi(x)$ on the Dirichlet integral

$$\int_{\Omega} \gamma_{ij}(x) \frac{\partial u}{\partial x^i} \frac{\partial u}{\partial x^j} dx = \int_{\Omega} \tilde{\gamma}_{ij}(y) \frac{\partial \tilde{u}}{\partial y^i} \frac{\partial \tilde{u}}{\partial y^j} dx \quad (74)$$

where

$$\tilde{\gamma}(y) = \frac{(D\psi) \gamma(D\psi)^T}{\det(D\psi)} \circ \psi^{-1}(y)$$

and

$$\tilde{u}(y) = u \circ \psi^{-1}(y).$$

Notice that the solution u of the Dirichlet problem

$$\begin{cases} \nabla \cdot \gamma \nabla u = 0 & \text{in } \Omega \\ u|_{\partial\Omega} = f \end{cases}$$

minimizes the integral appearing on the left-hand side of (74), therefore $\tilde{u} = u \circ \psi^{-1}$ minimizes the Dirichlet integral appearing on the right-hand side of the same. One can then conclude that \tilde{u} solves

$$\begin{cases} \nabla \cdot (\tilde{\gamma} \nabla \tilde{u}) = 0 & \text{in } \Omega \\ \tilde{u}|_{\partial\Omega} = \tilde{f} = u \circ \psi^{-1}. \end{cases}$$

Let us consider now the solution v of

$$\begin{cases} \nabla \cdot (\gamma \nabla v) = 0 & \text{in } \Omega \\ v|_{\partial\Omega} = g \end{cases}$$

and let \tilde{v} be obtained by v by the change of variable, therefore \tilde{v} solves

$$\begin{cases} \nabla \cdot (\tilde{\gamma} \nabla \tilde{v}) = 0 & \text{in } \Omega \\ \tilde{v}|_{\partial\Omega} = \tilde{g} = g \circ \psi^{-1}. \end{cases}$$

By the change of variables in the Dirichlet integrals,

$$\int_{\Omega} \gamma_{ij} \frac{\partial u}{\partial x^i} \frac{\partial v}{\partial x^j} dx = \int_{\Omega} \tilde{\gamma}_{ij} \frac{\partial \tilde{u}}{\partial y^i} \frac{\partial \tilde{v}}{\partial y^j} dy,$$

which can be written as

$$\int_{\Omega} \gamma \nabla u \cdot \nabla v dx = \int_{\Omega} \tilde{\gamma} \nabla \tilde{u} \cdot \nabla \tilde{v} dy,$$

which is equivalent to

$$\int_{\Omega} \nabla \cdot (v \gamma \nabla u) dx - \int_{\Omega} v \nabla \cdot (\gamma \nabla u) dx = \int_{\Omega} \nabla \cdot (\tilde{v} \tilde{\gamma} \nabla \tilde{u}) dy - \int_{\Omega} \tilde{v} \nabla \cdot (\tilde{\gamma} \nabla \tilde{u}) dy$$

and by the divergence theorem

$$\int_{\partial\Omega} v\gamma \nabla u \cdot v \, ds = \int_{\partial\Omega} \tilde{v}\tilde{\gamma} \nabla \tilde{u} \cdot v \, ds,$$

but $\tilde{v} = v \circ \psi^{-1} = v = g$ and $\tilde{u} = u \circ \psi^{-1} = u = f$ at the boundary $\partial\Omega$, then

$$\int_{\partial\Omega} g\Lambda_\gamma(f) \, ds = \int_{\partial\Omega} g\Lambda_{\tilde{\gamma}}(f) \, ds$$

then $\Lambda_\gamma = \Lambda_{\tilde{\gamma}}$. □

Since Tartar's observation has been made, different lines of research have been pursued. One direction was to prove the uniqueness of γ up to diffeomorphisms that fix the boundary, whereas the other direction was to study conductivities with some a priori information. The first direction of research is summarized in what follows.

Uniqueness up to Diffeomorphism

The question here is to investigate whether Tartar's observation is the only obstruction to unique identifiability of the conductivity. A first observation is that the physical problem of determining the conductivity of a body is closely related to the geometrical problem of determining a Riemannian metric from its Dirichlet-to-Neumann map for harmonics functions [80].

Let (M, g) be a compact Riemannian manifold with boundary. The Laplace–Beltrami operator associated with the metric g is given in local coordinates by

$$\Delta_g := \sum_{i,j=1}^n (\det g)^{-\frac{1}{2}} \frac{\partial}{\partial x^i} \left\{ (\det g)^{\frac{1}{2}} g^{ij} \frac{\partial u}{\partial x^j} \right\}.$$

The Dirichlet-to-Neumann map associated with g is the operator Λ_g mapping functions $u|_{\partial M} \in H^{1/2}(\partial M)$ into $(n-1)$ -forms $\Lambda_g(u|_{\partial M}) \in H^{-1/2}(\Omega^{n-1}(\partial M))$

$$\Lambda_g(f) = i^*(*_g du), \quad (75)$$

for any $u \in H^1(M)$ solution to $\Delta_g u = 0$ in M , with $u|_{\partial M} = f$. Here i is the inclusion map $i : \partial M \rightarrow M$ and i^* denotes the pull-back of forms under the map i . In any local coordinates (75) becomes

$$\Lambda_g(f) = \sum_{i,j=1}^n v^i g^{ij} \frac{\partial u}{\partial x_j} \sqrt{\det g}|_{\partial M}. \quad (76)$$

The inverse problem is to recover g from Λ_g . In dimension $n \geq 3$, the conductivity γ uniquely determines a Riemannian metric g such that

$$\gamma = *_g, \quad (77)$$

where $*_g$ is the Hodge operator associated the metric g mapping 1-forms on M into $(n-1)$ -forms (see [42, 80, 81]). In any local coordinates (77) becomes

$$(g_{ij}) = (\det \gamma_{kl})^{\frac{1}{n-2}} (\gamma_{ij}) \quad \text{and} \quad (\gamma_{ij}) = (\det g_{kl})^{\frac{1}{2}} (g^{ij}), \quad (78)$$

where (g^{ij}) , (γ^{ij}) denotes the matrix inverse of (g_{ij}) and (γ_{ij}) respectively. It has been shown in [80] that if M is a domain in \mathbb{R}^n , then for $n \geq 3$

$$\Lambda_g = \Lambda_\gamma. \quad (79)$$

In dimension $n \geq 3$ if ψ is a diffeomorphism of \bar{M} that fixes the boundary,

$$\Lambda_{\psi^* g} = \Lambda_g, \quad (80)$$

where $\psi^* g$ is the pull-back of g under ψ . For the case $n = 2$ the situation is different as the two-dimensional conductivity determines a conformal structure of metrics under scalar field, i.e., there exists a metric g such that $\gamma = \varphi *_g$, for a positive function φ . Therefore in $n = 2$, if ψ is a diffeomorphism of \bar{M} that fixes the boundary,

$$\Lambda_{\varphi \psi^* g} = \Lambda_g, \quad (81)$$

for any smooth positive function such that $\varphi|_{\partial M} = 1$. It seems natural to think that (80) and (81) are the only obstructions to uniqueness for $n \geq 3$ and $n = 2$ respectively. In 1989 Lee and Uhlmann [80] formulated the following two conjectures.

Conjecture 1. Let \bar{M} be a smooth, compact n -manifold, with boundary, $n \geq 3$ and let g , \tilde{g} be smooth Riemannian metrics on \bar{M} such that

$$\Lambda_g = \Lambda_{\tilde{g}}.$$

Then there exists a diffeomorphism $\psi : \bar{M} \rightarrow \bar{M}$ with $\psi|_{\partial M} = Id$, such that $g = \psi^* \tilde{g}$.

Conjecture 2. Let \bar{M} be a smooth, compact 2-manifold with boundary, and let g , \tilde{g} be smooth Riemannian metrics on \bar{M} such that

$$\Lambda_g = \Lambda_{\tilde{g}}.$$

Then there exists a diffeomorphism $\psi : \bar{M} \rightarrow \bar{M}$ with $\psi|_{\partial M} = Id$, such that $\psi^* \tilde{g}$ is a conformal multiple of g , in other words there exists $\phi \in C^\infty(\bar{M})$ such that

$$\psi^* \tilde{g} = \phi g.$$

Conjecture 1 has been proved in [80] in a particular case. The result is the following.

Theorem 12. *Let \bar{M} be a compact, connected, real-analytic n -manifold with connected real-analytic boundary, and assume that $\pi_1(\bar{M}, \partial M) = 0$ (this assumption means that every closed path in \bar{M} with base point in ∂M is homotopic to some path that lies entirely in ∂M). Let g and \tilde{g} be real-analytic metrics on \bar{M} such that*

$$\Lambda_g = \Lambda_{\tilde{g}},$$

and assume that one of the following conditions holds:

1. \bar{M} is strongly convex with respect to both g and \tilde{g} ;
2. either g or \tilde{g} extends to a complete real-analytic metric on a non-compact real-analytic manifold \tilde{M} (without boundary) containing \bar{M} .

Then there exists a real-analytic diffeomorphism $\psi : \bar{M} \rightarrow \tilde{M}$ with $\psi|_{\partial M} = Id$, such that $g = \psi^ \tilde{g}$.*

Theorem 12 has been proved by showing that one can recover the full Taylor series of the metric at the boundary from Λ_g . The diffeomorphism ψ is then constructed by analytic continuation from the boundary. As previously mentioned, the full Taylor series of γ was recovered by Kohn and Vogelius in [75] from the knowledge of Λ_γ in the isotropic case and then a new proof was given in [106] by showing that the full symbol of the pseudodifferential operator Λ_γ determines the full Taylor series of γ at the boundary. In [80] a simpler method suggested by R. Melrose consisting of factorizing Δ_g , is used. In 1990 Sylvester proved in [105] Conjecture 2 in a particular case. His result is the following.

Theorem 13. *Let Ω be a bounded domain in \mathbb{R}^2 with a C^3 boundary and let γ_1, γ_2 be anisotropic C^3 conductivities in $\bar{\Omega}$ such that*

$$\|\log(\det \gamma_i)\|_{C^3} < \varepsilon(M, \Omega), \quad \text{for } i = 1, 2, \tag{82}$$

with $M \geq \|\gamma_i\|_{C^3}$, for $i=1, 2$ and $\varepsilon(M, \Omega)$ sufficiently small. If

$$\Lambda_{\gamma_1} = \Lambda_{\gamma_2},$$

then there exists a C^3 diffeomorphism ψ of $\bar{\Omega}$ such that $\psi|_{\partial\Omega} = Id$ and such that

$$\psi_* \gamma_1 = \gamma_2.$$

Nachman [89] extended this result in 1995 by proving the same theorem but removing the hypothesis (82). In 1999 Lassas and Uhlmann [78] extended the result of [80]. They assumed that the Dirichlet-to-Neumann map is measured only on

a part of the boundary which is assumed to be real-analytic in the case $n \geq 3$ and C^∞ -smooth in the two-dimensional case. The metric is here recovered (up to diffeomorphism) and the manifold is reconstructed. Since a manifold is a collection of coordinate patches, the idea is to construct a representative of an equivalent class of the set of isometric Riemannian manifolds (M, g) . Recalling that if Γ is an open subset of ∂M , and defining

$$\Lambda_{g,\Gamma}(f) = \Lambda_g(f)|_\Gamma,$$

for any f with $\text{supp } f \subseteq \Gamma$. The main result of [78] is given below.

Theorem 14. *Let us assume that one of the following conditions is satisfied:*

1. *M is a connected Riemannian surface;*
2. *$n \geq 3$ and (M, g) is a connected real-analytic Riemannian manifold and the boundary ∂M is real-analytic in the nonempty set $\Gamma \subset \partial M$.*

Then

1. *For $\dim M = 2$ the $\Lambda_{g,\Gamma}$ -mapping and Γ determine the conformal class of the Riemannian manifold (M, g) .*
2. *For a real-analytic Riemannian manifold (M, g) , $\dim M > 2$ which boundary is real analytic in Γ , the $\Lambda_{g,\Gamma}$ -mapping and Γ determine the Riemannian manifold (M, g) .*

This result improved the one in [80] also because here the only assumption on the topology of the manifold is the connectedness, while in [80] the manifold was simply connected and the boundary of the manifold was assumed to be geodesically convex. Theorem 14 has been extended in [79] to a completeness hypothesis on \bar{M} .

Anisotropy Which Is Partially A Priori Known

Another approach to the anisotropic problem is to assume that the conductivity γ is a priori known to depend on a restricted number of unknown spatially dependent parameters. In 1984 Kohn and Vogelius (see [75]) considered the case where the conductivity matrix $\gamma = (\gamma_{ij})$ is completely known with the exception of one eigenvalue. The main result is the following.

Theorem 15. *Let $\gamma, \tilde{\gamma}$ be two symmetric, positive definite matrices with entries in $L^\infty(\Omega)$, and let $\{\gamma_i\}, \{\tilde{\gamma}_i\}$ and $\{e_i\}, \{\tilde{e}_i\}$ be the corresponding eigenvalues and eigenvectors. For $x_0 \in \partial\Omega$, let B be a neighborhood of x_0 relative to $\bar{\Omega}$, and suppose that*

$$\gamma, \tilde{\gamma} \in C^\infty(B); \quad (83)$$

$$\partial\Omega \cap B \quad \text{is} \quad C^\infty; \quad (84)$$

$$e_j = \tilde{e}_j, \quad \lambda_j = \tilde{\lambda}_j \quad in \quad B, \quad for \quad 1 \leq j \leq n-1; \quad (85)$$

$$e_n(x_0) \cdot v(x_0) \neq 0. \quad (86)$$

If

$$Q_\gamma(\phi) = Q_{\tilde{\gamma}}(\phi) \quad for \ every \quad \phi \in H^{\frac{1}{2}}(\partial\Omega),$$

with $\text{supp } \phi \subset B \cap \partial\Omega$, then

$$D^k \tilde{\lambda}_n(x_0) = D^k \lambda_n(x_0),$$

for every $k = (k_1, \dots, k_n)$, $k_i \in \mathbb{Z}^+$, $i = 1, \dots, n$.

In 1990 Alessandrini [3] considered the case in which γ is a priori known to be of type

$$\gamma(x) = A(a(x)),$$

where $t \rightarrow A(t)$ is a given matrix-valued function and $a = a(x)$ is an unknown scalar function. He proved results of uniqueness and stability at the boundary and then uniqueness in the interior among the class of piecewise real-analytic perturbations of the parameter $a(x)$. The main hypothesis he used is the so-called monotonicity assumption

$$D_t A(t) \geq C I,$$

where $C > 0$ is a constant. In 1997 Lionheart [81] proved that the parameter $a(x)$ can be uniquely recovered for a conductivity γ of type

$$\gamma(x) = a(x) A_0(x),$$

where $A_0(x)$ is given. Results in [3] have been extended in 2001 by Alessandrini and Gaburro [6] to a class of conductivities

$$\gamma(x) = A(x, a(x)),$$

where $A(x, t)$ is given and satisfies the monotonicity condition with respect to the parameter t

$$D_t A(x, t) \geq C I,$$

where $C > 0$ is a constant (see [6] or [41] for this argument). In [6] the authors improved results of [3] since they relaxed the hypothesis on $A(\cdot, t)$ for the global uniqueness in the interior and the result there obtained can be applied to [81] as well.

The technique of [6] can also be applied to the so-called one-eigenvalue problem introduced in [75]. Results of [6] have been recently extended to manifolds [43] and to the case when the local Dirichlet-to-Neumann map is prescribed on an open portion of the boundary [7].

Some Remarks on the Dirichlet-to-Neumann Map

EIT with Partial Data

In many applications of EIT one can actually only take measurements of voltages and currents on some portion of the boundary. In such situation the Dirichlet-to-Neumann map can only be defined locally.

Let $\Omega \subseteq \mathbb{R}^n$ be a domain with conductivity γ . If Γ is a nonempty open portion of $\partial\Omega$, the subspace of $H^{\frac{1}{2}}(\partial\Omega)$ is introduced

$$H_{co}^{\frac{1}{2}}(\Gamma) = \{f \in H^{\frac{1}{2}}(\partial\Omega) \mid \text{supp } f \subset \Gamma\}. \quad (87)$$

Definition 2. The local Dirichlet-to-Neumann map associated with γ and Γ is the operator

$$\Lambda_\gamma^\Gamma : H_{co}^{\frac{1}{2}}(\Gamma) \longrightarrow (H_{co}^{\frac{1}{2}}(\Gamma))^* \quad (88)$$

defined by

$$\langle \Lambda_\gamma^\Gamma f, \eta \rangle = \int_\Omega \gamma \nabla u \cdot \nabla \phi \, dx, \quad (89)$$

for any $f, \eta \in H_{co}^{\frac{1}{2}}(\Gamma)$, where $u \in H^1(\Omega)$ is the weak solution to

$$\begin{cases} \nabla \cdot (\gamma(x) \nabla u(x)) = 0, & \text{in } \Omega, \\ u = f, & \text{on } \partial\Omega, \end{cases}$$

and $\phi \in H^1(\Omega)$ is any function such that $\phi|_{\partial\Omega} = \eta$ in the trace sense.

Note that, by (89), it is easily verified that Λ_σ^Γ is self adjoint. The inverse problem is to recover γ from Λ_γ^Γ .

The procedure of reconstructing the conductivity by local measurements has been studied first by Brown [22], where the author gives a formula for reconstructing the isotropic conductivity pointwise at the boundary of a Lipschitz domain Ω without any a priori smoothness assumption of the conductivity. Nakamura and Tanuma [91] give a formula for the pointwise reconstruction of a conductivity continuous at one point x^0 of the boundary from the local D-N map when the boundary is C^1 near x^0 . Under some additional regularity hypothesis the authors

give a reconstruction formula for the normal derivatives of γ on $\partial\Omega$ at $x^0 \in \partial\Omega$ up to a certain order. A direct method for reconstructing the normal derivative of the conductivity from the local Dirichlet-to-Neumann (D-N) map is presented in [92]. The result in [91] has been improved by Kang and Yun [70] to an inductive reconstruction method by using only the value of γ at x^0 . The authors derive here also Hölder stability estimates for the inverse problem to identify Riemannian metrics (up to isometry) on the boundary via the local D-N map. An overview on reconstructing formulas of the conductivity and its normal derivative can be found in [93].

For related uniqueness results in the case of local boundary data, refer to Alessandrini and Gaburro [7], Bukhgeim and Uhlmann [25], Kenig et al. [73] and Isakov [68], and, for stability, [7] and Heck and Wang [55]. Recent results are also provided by Kenig and Salo [71, 72]. It is worth noting that [72] generalizes the results obtained in both [73] and [68] by making use of improved Carleman estimates with boundary terms, CGO solutions involving reflected Gaussian beam quasimodes and invertibility of (broken) geodesics ray transforms. Results of stability for cases of piecewise constant conductivities and local boundary maps have also been obtained by Alessandrini and Vessella [8], and by Di Cristo [35]. Another useful reference is [110, Sect. 7].

The Neumann-to-Dirichlet Map

In many applications of EIT especially in medical imaging, rather than the local Dirichlet-to-Neumann map, one should consider the so-called local Neumann-to-Dirichlet (N-D) map. That is, the map associating the specified current densities supported on a portion of $\Gamma \subset \partial\Omega$ to the corresponding boundary voltages, also measured on the same portion Γ of $\partial\Omega$. Usually electrodes are only applied to part of the body. Geophysics, of course, gives an extreme example where Γ is a small portion of the surface of the earth Ω . It seems appropriate at this stage to recall the definition of the N-D map and its local version for the sake of completeness [7].

Let us introduce the following function spaces (see [7])

$$\begin{aligned} H_\diamond^{\frac{1}{2}}(\partial\Omega) &= \left\{ \phi \in H^{\frac{1}{2}}(\partial\Omega) \mid \int_{\partial\Omega} \phi = 0 \right\}, \\ H_\diamond^{-\frac{1}{2}}(\partial\Omega) &= \left\{ \psi \in H^{-\frac{1}{2}}(\partial\Omega) \mid \langle \psi, 1 \rangle = 0 \right\}. \end{aligned}$$

Observe that, if considering the (global) D-N map Λ_γ , that is the map introduced in (88) Λ_γ^Γ in the special case when $\Gamma = \partial\Omega$, then it maps onto $_0H^{-\frac{1}{2}}(\partial\Omega)$, and, when restricted to $H_\diamond^{\frac{1}{2}}(\partial\Omega)$, it is injective with bounded inverse. Then one can define the global Neumann-to-Dirichlet map as follows.

Definition 3. The Neumann-to-Dirichlet map associated with γ , $N_\gamma : H_\diamond^{-\frac{1}{2}}(\partial\Omega) \longrightarrow H_\diamond^{\frac{1}{2}}(\partial\Omega)$ is given by

$$N_\gamma = \left(\Lambda_\gamma|_{_0H^{\frac{1}{2}}(\partial\Omega)} \right)^{-1}. \quad (90)$$

Note that N_γ can also be characterized as the self-adjoint operator satisfying

$$\langle \psi, N_\gamma \psi \rangle = \int_{\Omega} \gamma(x) \nabla u(x) \cdot \nabla u(x) dx, \quad (91)$$

for every $\psi \in H_\diamond^{-\frac{1}{2}}(\partial\Omega)$, where $u \in H^1(\Omega)$ is the weak solution to the Neumann problem

$$\begin{cases} L_\gamma u = 0, & \text{in } \Omega, \\ \gamma \nabla u \cdot \nu|_{\partial\Omega} = \psi, & \text{on } \partial\Omega, \\ \int_{\partial\Omega} u = 0. \end{cases} \quad (92)$$

At this point, it is useful to introduce the local version of the N-D map. Let Γ be an open portion of $\partial\Omega$ and let $\Delta = \partial\Omega \setminus \bar{\Gamma}$. Here, $H_{00}^{\frac{1}{2}}(\Delta)$ denotes the closure in $H^{\frac{1}{2}}(\partial\Omega)$ of the space $H_{co}^{\frac{1}{2}}(\Delta)$ previously defined in (87) and introducing

$$H_\diamond^{-\frac{1}{2}}(\Gamma) = \left\{ \psi \in H_\diamond^{-\frac{1}{2}}(\partial\Omega) \mid \langle \psi, f \rangle = 0, \text{ for any } f \in H_{00}^{\frac{1}{2}}(\Delta) \right\}, \quad (93)$$

that is the space of distributions $\psi \in H^{-\frac{1}{2}}(\partial\Omega)$ which are supported in $\bar{\Gamma}$ and have zero average on $\partial\Omega$. The local N-D map is then defined as follows.

Definition 4. The local Neumann-to-Dirichlet map associated with γ , Γ is the operator $N_\gamma^\Gamma : {}_0H^{-\frac{1}{2}}(\Gamma) \longrightarrow ({}_0H^{-\frac{1}{2}}(\Gamma))^* \subset {}_0H^{\frac{1}{2}}(\partial\Omega)$ given by

$$\langle N_\gamma^\Gamma i, j \rangle = \langle N_\gamma i, j \rangle, \quad (94)$$

for every $i, j \in {}_0H^{-\frac{1}{2}}(\Gamma)$.

3 The Reconstruction Problem

Locating Objects and Boundaries

The simplest form of the inverse problem is to locate a single object with a conductivity contrast in a homogeneous medium. Some real situations approximate this, such as a weakly electric fish locating a single prey or the location of an insulating land mine in homogeneous soil. Typically the first test done on an EIT system experimentally is to locate a cylindrical or spherical object in a cylindrical tank. Linearization about $\gamma = 1$ simplifies to

$$\nabla^2 w = -\nabla \delta \cdot \nabla u + O(\|\delta\|_{L^\infty}^2). \quad (95)$$

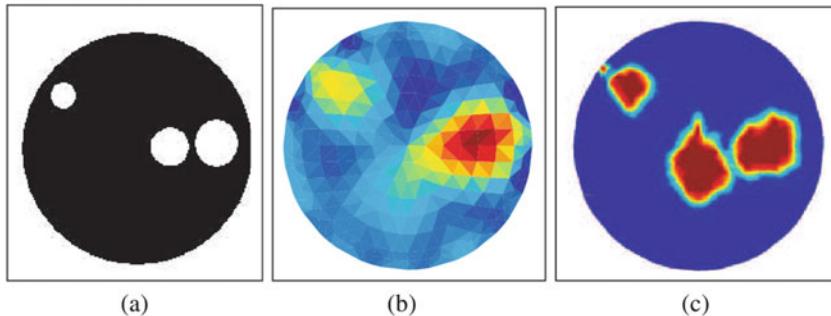

Here, the disturbance in the potential w is, to first order, the solution of Poisson's equation with a dipole source centered on the object oriented in the direction of the unperturbed electric field. With practice experienced experimenters (like electric fish) can roughly locate the object from looking at a display of the voltage changes. When it is known a priori that there is a single object, either small or with a known shape, the reconstruction problem is simply fitting a small number of model parameters (e.g., position, diameter, conductivity contrast) to the measured voltage data, using an analytical or numerical forward solver. This can be achieved using standard nonlinear optimization methods. For the two-dimensional case a fast mathematically rigorous method of locating an object (not required to be circular) from one set of Cauchy data is presented by Hanke [50]. Results on the recovery of the support of the difference between two piecewise analytic conductivities by solving the linearized problem are given in [53].

In the limiting case where the object is insulating, object location becomes a free boundary problem, where the Dirichlet-to-Neumann map is known on the known boundary and only zero Neumann data known on the unknown boundary. This is treated theoretically for example by [61] and numerically in [62]. A practical example is the location of the air core of a hydrocyclone, a device used in chemical engineering [114].

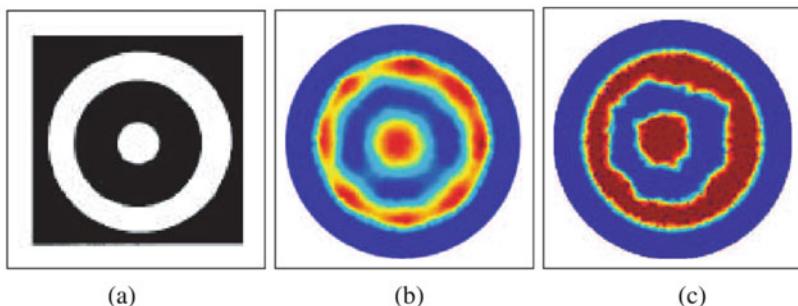

In more complex cases the conductivity may be piecewise constant with a jump discontinuity on a smooth surface. In that case there are several methods that have been tested at least on laboratory data for locating the surface of the discontinuity. One would expect in general that the location of a surface can be achieved more accurately or with less data than the recovery of a spatially varying function and this is confirmed by numerical studies.

A natural method of representing the surface of discontinuity is as a level set of a smooth surface (see chapter ▶ [Level Set Methods for Structural Inversion and Image Reconstruction](#)). This approach has the advantage that no change in parameterization is required as the number of connected components changes, in contrast for example to representing a number of star-shaped objects using spherical polar coordinates. The approach to using the level set method in EIT is exactly the same as its use in scattering problems apart from the forward problem (see chapter ▶ [Inverse Scattering](#)). Level set methods have been tested on experimental ERT and ECT data by Soleimani et al. [102]. Here some of their results are reproduced in Fig. 5.

Another approach to locating a discontinuity, common with other inverse boundary value problems for PDEs are “sampling and probe methods” in which a test is performed at each point in a grid to determine if that point is in the object. Linear sampling and factorization methods are treated in the chapter ▶ [Sampling Methods](#). Theory and numerical results for the application of Linear Sampling to ERT for a half space are given by Hanke and Schappel [51]. Sampling methods generally require the complete transfer impedance matrix and where only incomplete measurements are available they must be interpolated.

(a) Level set reconstruction (c) from experimental ERT data for high contrast objects (a) compared with generalized Tikhonov regularization.

(b) Level set reconstruction (c) from experimental ECT data for a pipe (a) compared with generalized Tikhonov regularization.

Fig. 5 Comparison of level set reconstruction of 2D experimental data compared to generalized Tikhonov regularization using a Laplacian smoothing matrix (EIDORS-2D [113]). Thanks to Manuchehr Soleimani for reconstruction results, and Wu Quaing Yang and colleagues for the ECT data [116], the experimental ERT data was from [113]

Also in the spirit of probe methods is the *monotonicity method* of Tamburrino and Rubinacci [109]. This method follows from the observation that for γ real the map $\gamma \mapsto \mathbf{Z}_\gamma$ is monotone in the sense that $\gamma_1 \leq \gamma_2 \Rightarrow \mathbf{Z}_{\gamma_1} - \mathbf{Z}_{\gamma_2} \geq 0$, where a matrix $Z \geq 0$ if its eigenvalues are non-negative. Suppose that for some partition $\{\Omega_i\}$ of Ω (e.g., pixels or voxels)

$$\gamma = \sum_i \gamma_i \chi_{\Omega_i} \quad (96)$$

and each $\gamma_i \in \{m, M\}$, $0 < m < M$. For each i let \mathbf{Z}_i^m be the transfer impedance for a conductivity that is M on Ω_i and m elsewhere. Supposing $\mathbf{Z} - \mathbf{Z}_i^m$ has a negative eigenvalue, then $\gamma_i = m$. For each set in the partition the test is repeated, and it is inferred that some of the conductivity values are definitely m . The equivalent procedure is repeated for each \mathbf{Z}_i^M . In practice, for large enough sets in the partition and $M - m$ big enough, most conductivity values in the binary image are determined,

although this is not guaranteed. In practice the method is very fast as \mathbf{Z}_i^m and \mathbf{Z}_i^M can be precomputed and one only needs to find the smallest eigenvalue of two modestly sized matrices for each set in the partition. In the presence of noise, of course, one needs a sufficiently negative eigenvalue to be sure of the result of the test, and the method does assume that the conductivity is of the given form (96). Recently a partial converse of the monotonicity result has been found [54] and this promises more accurate fast methods of reconstructing the shape of an inclusion.

If conductivities on some sets are undetermined, they can then be found using other methods. For example [115] use a Markov Chain Monte Carlo method to determine the expected value and variance of undetermined pixels in ECT.

Forward Solution

Most reconstruction algorithms for EIT necessitate solution of the forward problem, that is to predict the boundary data given the conductivity. In addition, methods that use linearization typically require electric fields in the interior. The simplest case is an algorithm that uses a linear approximation calculated at a homogenous background conductivity. For simple geometries this might be done using an analytical method, while for arbitrary boundaries Boundary Element Method is a good choice, and is also suitable for the case where the conductivity is piecewise constant with discontinuities on smooth surfaces. For general conductivities the choice is between finite difference, finite volume and finite element methods (FEMs). All have been used in EIT problems. FEM has the advantage that the mesh can be adapted to a general boundary surface and to the shape and location of electrodes, whereas regular grids in finite difference/volume methods can result in more efficient computation, traded off against the fine discretization needed to represent irregular boundaries. One could also use a hybrid method such as finite element on a bounded domain of variable conductivity coupled to BEM for a homogeneous (possibly unbounded) domain.

In reconstruction methods that iteratively adjust the conductivity and resolve the forward problem, a fast forward solution is needed, whereas in methods using a linear approximation, the forward solution can be solved off-line and speed is much less important.

The simplest, and currently in EIT the most widely used, FE method is first order tetrahedral elements. Here a polyhedral approximation Ω_h to Ω is partitioned into a finite set of tetrahedra T_k , $k = 1, \dots, n_t$ which overlap at most in a shared face, and with vertices x_i , $i = 1 < n_v$. The potential is approximated as a sum

$$u_h(x) = \sum u_i \phi_i(x), \quad (97)$$

where the ϕ_i are piecewise linear continuous functions with $\phi_i(x_j) = \delta_{ij}$. The finite element system matrix $K \in \mathbb{C}^{n_v \times n_v}$ is given by

$$K_{ij} = \int_{\Omega_p} \gamma \nabla \phi_i \cdot \nabla \phi_j \, dx. \quad (98)$$

On each tetrahedron $\nabla \phi_i$ is constant which reduces calculation of (98) in the isotropic case to the mean of γ on each tetrahedron. One then chooses an approximation to the conductivity in some space spanned by basis functions $\psi_i(x)$

$$\gamma = \sum_i \gamma_i \psi_i. \quad (99)$$

One can choose these functions to implement some a priori constraints such as smoothness and to reduce the number of unknowns in the discrete inverse problem. Or one can choose basis functions just as the characteristic functions of the tetrahedra, which makes the calculation, and updating, of the system matrix very simple. In this case, all a priori information must be incorporated later, such as by a regularization term. In general the integrals

$$\int_{\Omega_p} \psi_l \nabla \phi_i \cdot \nabla \phi_j \, dx \quad (100)$$

are evaluated using quadrature if they cannot be done explicitly. If the inverse solution uses repeated forward solutions with updated conductivity but with a fixed mesh, the coefficients (100) can be calculated once for each mesh and stored. For a boundary current density $j = \gamma \nabla u \cdot v$ the current vector $\mathbf{Q} \in \mathbb{R}^{n_v}$ is defined by

$$q_i = \int_{\partial \Omega} j \phi_i \, dx \quad (101)$$

and the FE system is

$$\mathbf{Ku} = \mathbf{Q}, \quad (102)$$

where \mathbf{u} is the vector of u_i . One additional condition is required for a unique solution, as the voltage is only determined up to an additive constant. One way to do this is to choose one (“grounded”) vertex i_g and enforce $u_{i_g} = 0$ by deleting the i_g row and column from the system (102). It is clear from (98) that for a pair of vertices indexed by i, j that are not both in any tetrahedron, $K_{ij} = 0$. The system (102) is equivalent to Ohm’s and Kirchoff’s law for a resistor network with resistors connecting nodes i and j when the corresponding vertices in the FE mesh share an edge (where some dihedral angles are obtuse, there is the possibility of negative conductances). It is worth noting that whatever basis is used to represent the approximate conductivity (including an anisotropic conductivity) the finite element system has only one degree of freedom per edge and one cannot hope, even with

perfect data and arithmetic, to recover more than n_e (the number of edges) unknowns from the discretization of the inverse problem.

The above formulation implements the shunt model. The CEM with specified currents can be implemented following Vauhkonen [111] using an augmented matrix. Defining

$$K_{ij}^{\circ} = K_{ij} + \sum_{l=1}^L \frac{1}{z_l} \int_{E_l} \phi_i \phi_j dx, \quad (103)$$

where, here, $|E_l|$ denotes the area of the l th electrode, and

$$K_{\ell\ell}^{\partial} = \frac{1}{z_\ell} |E_\ell| \quad \text{for } \ell = 1, \dots, L, \quad (104)$$

$$K_{i\ell}^{\circ\partial} = - \int_{E_l} \frac{1}{z_\ell} \phi_i dx \quad i = 1, \dots, n, \ell = 1, \dots, L. \quad (105)$$

The system matrix for the CEM, $\mathbf{K}^{\text{CEM}} \in \mathbb{C}^{(n_v+L) \times (n_v+L)}$ is

$$\mathbf{K}^{\text{CEM}} = \begin{bmatrix} K^{\circ} & K^{\circ\partial} \\ K^{\circ\partial T} & K^{\partial} \end{bmatrix}. \quad (106)$$

In this notation, the linear system of equations has the form

$$\mathbf{K}^{\text{CEM}} \tilde{\mathbf{u}} = \tilde{\mathbf{Q}}, \quad (107)$$

where $\tilde{\mathbf{u}} = (u_1, \dots, u_{n_v}, V_1, \dots, V_L)^T$ and $\tilde{\mathbf{Q}} = (0, \dots, 0, I_1, \dots, I_L)^T$. The constraint $\mathbf{V} \in S$ (see section ‘‘Measurements with Electrodes’’) is often used to ensure uniqueness of solution. The transfer impedance matrix is obtained directly as

$$\mathbf{Z} = (K^{\partial} - K^{\circ\partial T} K^{\circ\partial \dagger} K^{\circ\partial})^{\dagger} \quad (108)$$

although it is usual to solve the system (106) as u in the interior is used in the calculation of the linearization. This formulation should only be used for reasonably large z_ℓ , as small z_ℓ will result in the block K^∂ dominating the matrix. For an accurate forward model it is necessary to estimate the contact impedance accurately. This is more important when measurements from current carrying electrodes are used in the reconstruction, or when the electrodes are large (even if they are ‘‘passive’’ $I_\ell = 0$). The CEM boundary condition is rather unusual and most commercial FE systems will not include the boundary condition easily. This is one of the reasons forward solution code for EIT is generally written specifically for the purpose, such as the EIDORS project [1]. It is possible to calculate the transadmittance matrix $\mathbf{Y} = \mathbf{Z}^\dagger$ more easily with standard solvers. One sets Robin boundary $u + z_\ell \gamma \partial u / \partial v = V_\ell$ on each E_ℓ and the zero Neumann condition (4) using \mathbf{V} forming a basis for S , one then takes the integral of the current over each

electrode as the current $\mathbf{I} = \mathbf{Y}\mathbf{V}$. For a given current pattern \mathbf{I} one applies the Robin conditions $\mathbf{V} = \mathbf{Y}^\dagger \mathbf{I}$ and the solver gives the correct u . Advantages of commercial solver are that they might contain a wide variety of element types, fast solvers, and mesh generators. Disadvantages are that they may be hard to integrate as part of a nonlinear inverse solver, and it might be harder to calculate the linearization efficiently.

In fact implementing code to assemble a system matrix is quite straightforward; much harder for EIT is the generation of three-dimensional meshes. For human bodies with irregular boundaries of inaccurately known shape this is a major problem. To apply boundary conditions accurately without overfine meshes it is also important that the electrodes are approximated by unions of faces of the elements. While the accuracy of the FEM is well understood in terms of the error in the solution u , in EIT it is necessary to require that the dependence of the boundary data on the conductivity be accurate, something that is not so well understood. In addition if the conductivities vary widely it may be necessary to remesh to obtain the required accuracy, and ideally this capability will be integrated with the inverse solver [87].

Regularized Linear Methods

Methods based on linearization are popular in medical and process versions of EIT. The reasons are twofold. Process and medical applications benefit from very rapid data acquisition times with even early systems capable measuring a transfer impedance matrix in less than 0.04 s, and it was often required to produce an image in real time. The application of a precomputed (regularized) inverse of the linearized forward problem required only about $\frac{1}{2}L^2(L - 1)^2$ floating point operations. For reasons of both speed and economy early systems also assumed a two-dimensional object with a single ring of electrodes arranged in a plane. The second reason for using a linear approximation is that in medical applications especially there is uncertainty in the body shape, electrode position and contact impedance. This means that a computed forward solution, based on an assumed conductivity (typically constant), has a much larger error than the errors inherent in the measurements. A compromise called *difference imaging* (by contrast to *absolute imaging*) uses a forward solution to calculate the linearization (25) and then forms an image of the difference of the conductivities between two different times, for example inspiration and expiration in a study of the lungs. Alternatively measurements can be taken simultaneously at two frequencies and a difference image formed of the permittivity.

Given a basis of applied current patterns \mathbf{I}_i and a chosen set of measurements \mathbf{M}_i expressed as a set of independent vectors in S that are $1/|E_l|$ for one electrode E_l , $-1/|E_k|$ for another electrode E_k (the two electrodes between which the voltage is measured), and a set of functions ψ_i with the approximate admittivity satisfying $\tilde{\gamma} = \sum \gamma_k \psi_k$, the discretization of the Fréchet derivative is the Jacobian matrix

$$J_{(ij)k} = \frac{\partial}{\partial \gamma_k} \mathbf{M}_i^T \mathbf{Z} \mathbf{I}_j = - \int_{\Omega} \psi_k \nabla v_i \cdot \nabla u_j \, dx, \quad (109)$$

where $L_{\tilde{\gamma}} u_i = L_{\tilde{\gamma}} v_j = 0$ (at least approximately) with u_i satisfying the CEM with current \mathbf{I}_i and v_j with \mathbf{M}_j . If the finite element approximation is used to solve the forward problem it has the interesting feature that the natural approximation to the Fréchet derivative in the FE context coincides with the Fréchet derivative of them FE approximation. The indices (ij) are bracketed together as they are typically “flattened” so the matrix of measurements becomes a vector and J a matrix (rather than a tensor). Let $\tilde{\mathbf{V}}$ be the vector of all voltage measurements, $\tilde{\mathbf{V}}_{\text{calc}}$ the calculated voltages, and $\boldsymbol{\gamma}$ the vector of γ_i . Our regularized least-squares version of the linearized problem is now

$$\boldsymbol{\gamma}_{\text{reg}} = \arg \min_{\boldsymbol{\gamma}} \|\mathbf{J}\boldsymbol{\gamma} - (\tilde{\mathbf{V}} - \tilde{\mathbf{V}}_{\text{calc}})\|^2 + \alpha^2 \Psi(\boldsymbol{\gamma}), \quad (110)$$

where Ψ is a penalty function and α a regularization parameter. The same formulation is used for difference imaging where $\tilde{\mathbf{V}}_{\text{calc}}$ is replaced by measured data at a different time or frequency. Typical choices for Ψ are quadratic penalties such a weighted sum of squares of the γ_i , the two norm of (a discretization) a partial differential operator \mathbf{R} applied to $\boldsymbol{\gamma} - \boldsymbol{\gamma}_0$, for some assumed background $\boldsymbol{\gamma}_0$. $\|\mathbf{R}(\boldsymbol{\gamma} - \boldsymbol{\gamma}_0)\|^2$. Another common choice is a weighted sum of squares, i.e., L a positive diagonal matrix. In Total Variation regularization Ψ approximates $\|\nabla(\boldsymbol{\gamma} - \boldsymbol{\gamma}_0)\|_1$, and can be used where discontinuities are expected in the conductivity. Where there is a jump discontinuity on a surface (a curve in the two-dimensional case) the total variation is the integral of the absolute value of the jump over the surface (curve). The choice of regularization parameter α , the choice of penalty function, and the solution methods are covered in the chapters [► Linear Inverse Problems](#) and “Total Variation in Imaging.” The singular values of J are found to decay faster than exponentially (see Fig. 9), so it is a *severely illconditioned* problem and regularization is needed even for very accurate data. There are also to some extent diminishing returns in increasing the number of electrodes without also increasing the measurement accuracy.

For a quadratic penalty function the minimization problem with $\Psi(\boldsymbol{\gamma}) = \|\mathbf{R}(\boldsymbol{\gamma} - \boldsymbol{\gamma}_0)\|^2$ the solution to (110) is given by the well-known Tikhonov inversion formula

$$\boldsymbol{\gamma}_{\text{reg}} - \boldsymbol{\gamma}_0 = (\mathbf{J}^* \mathbf{J} + \alpha^2 \mathbf{R}^* \mathbf{R})^{-1} \mathbf{J}^* (\tilde{\mathbf{V}} - \tilde{\mathbf{V}}_{\text{calc}}). \quad (111)$$

For a total variation penalty $\Psi(\boldsymbol{\gamma}) = \|\mathbf{R}(\boldsymbol{\gamma} - \boldsymbol{\gamma}_0)\|_1$ minimization is more difficult, and standard gradient based optimization methods have difficulty with the singularity in Ψ where a component of $\mathbf{R}\boldsymbol{\gamma}$ vanishes. One way around this is to use the Primal Dual Interior Point Method; for details, see [21] and for comparison of TV and a quadratic penalty applied to a difference image of the chest, see Fig. 6.

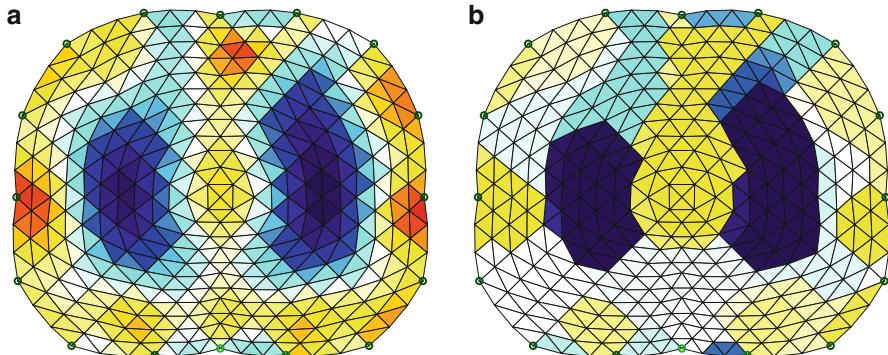

Fig. 6 Time difference EIT image of a human thorax during breathing, comparison of generalized Tikhonov $\|\mathbf{R}\mathbf{y}\|_2^2$ and of the TV $\|\mathbf{R}\mathbf{y}\|_1$ regularized algorithms. Both are represented on the same color scale and in arbitrary conductivity units. See [21] for details (a) Generalized Tikhonov (b) Total variation

Regularized Iterative Nonlinear Methods

As the problem is nonlinear clearly a solution based on linearization is inaccurate. Intuitively there are two aspects to the nonlinearity that are lost in a linear approximation. If one considers an object of constant conductivity away from the boundary the norm of the voltage data will exhibit a sigmoid curve as the conductivity of that object varies, as seen in the example of a concentric anomaly and illustrated numerically in Fig. 10. This means that voltage measurements *saturate*, or tends to a limiting value, as the conductivity contrast to the background tends to zero or infinity. Typically this means that linear approximations underestimate conductivity contrast. One has to be careful in communications between mathematicians and engineers: the latter will sometimes take linearity (e.g., of $\mathbf{Y}(\mathbf{y})$) to mean a function that is homogenous of degree one, ignoring the requirement for “superposition of solutions.” Considering two small spherical objects in a homogeneous background, it is known from (22) that to first order the change in u due to the objects is approximately the sum of two dipole fields. The effect of nonlinearity, the higher order terms in (22) can be thought of as interference between these two fields, analogous to higher order scattering in wave scattering problems. The practical effect is that linear approximations are poor not only at getting the correct conductivity contrast, but also at resolving a region between two objects that are close together. Many nonlinear solution methods calculate an update of the admittivity from solving a linear system, that update is applied to the conductivity in the model and the forward solution solved again. One severe problem with linear reconstruction methods that do not include a forward solver is that one cannot test if the updated admittivity even fits the data better than the initial assumption (e.g., of a constant admittivity). Such algorithms tend to produce some plausible image even if the data are erroneous.

The usual approach taken in geophysical and medical EIT to nonlinear reconstruction is to numerically perform the (nonlinear generalized Tikhonov) minimization

$$\boldsymbol{\gamma}_{\text{reg}} = \arg \min_{\boldsymbol{\gamma}} \|\tilde{\mathbf{V}}_{\text{calc}}(\boldsymbol{\gamma}) - \mathbf{V}\|^2 + \alpha^2 \Psi(\boldsymbol{\gamma}) \quad (112)$$

using standard numerical optimization techniques. As the Jacobian is known explicitly it is efficient to use gradient optimization methods such as Gauss–Newton, and in that context the update step is very similar to the solution of the linear problem (110), and is a linear system for quadratic Ψ . Assuming conductivity initialized as the background level $\boldsymbol{\gamma}_0$ a typical iterative update scheme for successive approximations to the conductivity is

$$\boldsymbol{\gamma}_{n+1} = \boldsymbol{\gamma}_n + (\mathbf{J}_n^* \mathbf{J}_n + \alpha^2 \mathbf{L}^* \mathbf{L})^{-1} \left(\mathbf{J}_n^* (\tilde{\mathbf{V}} - \tilde{\mathbf{V}}_{\text{calc}}(\boldsymbol{\gamma}_n)) + \alpha^2 \mathbf{L}^* \mathbf{L}(\boldsymbol{\gamma}_0 - \boldsymbol{\gamma}_n) \right). \quad (113)$$

In contrast to the linearized problem, the nonlinear problem requires repeated solution of the forward solution $\tilde{\mathbf{V}}_{\text{calc}}(\boldsymbol{\gamma}_n)$ for variable conductivity, typically using the finite element or finite difference method. One also has to constrain the conductivity $\operatorname{Re} \gamma$ to be positive and this is made easier by a choice of ϕ_i as the characteristic functions of a partition on Ω . This could be a rectangular grid or a courser tetrahedral mesh than that used for u . Accurate modeling of electrodes requires a fine discretization near electrodes, and yet one cannot hope to recover that level of detail in the admittivity near an electrode. In many practical situations a priori bounds are known for the conductivity and permittivity and as the logarithmic stability result predicts, enforcing these bounds has a stabilizing effect on the reconstruction. The positivity constraint can be enforced by a change of variables to $\log \gamma$ and this is common practice, with the Jacobian adjusted accordingly. It is generally better to perform a line search in the update direction from (113) to minimize the cost function in (112) rather than simply applying the update. Most commonly this search is approximated, for example, by fitting a few points to a low order polynomial although implementation details of this are rarely well documented. It is also worth mentioning that most absolute reconstruction algorithms start by finding a homogeneous conductivity $\boldsymbol{\gamma}_0$ best fitting the data before the iterative method starts.

In geophysical ERT nonlinear solution is well established. Although it is more common, for reasons of economy, to measure only along a line and reconstruct on the plane beneath that line, fully three-dimensional reconstruction is also widely used. The most common reconstruction code used is RES3DINV [44] which builds on the work of Loke and Barker at the University of Birmingham [84]. The code is available commercially from Loke's company Geotomo Software. RES3DINV has a finite difference forward solver used when the ground is assumed flat, and a finite element solver for known non-flat topography. In geophysical applications there is the advantage that obtaining a triangulation of the surface is a common surveying practice. The Jacobian is initialized using an analytical initial solution

assuming homogeneous conductivity. Regularized nonlinear inversion is performed using Gauss–Newton, with recalculation of Jacobian [44], or using a quasi-Newton method in which a rank one update is performed on the Jacobian. The penalty function used in the regularization is of the form $\Psi(\gamma) = \|\mathbf{R}\gamma\|_2^2$ where \mathbf{R} is an approximate differential operator that penalizes horizontal and vertical variations differently. Total variation regularization $\Psi(\gamma) = \|\mathbf{R}\gamma\|_1$ is also an option in this code. When data is likely to be noisy one can select a “robust error norm,” in which the one-norm is used also to measure the fit of the data to the forward solution. A maximum and minimum value of the regularization parameter can be set by the user, but in a manner similar to the classical Levenburg–Marquardt method for well-posed least squares problems the parameter can be varied within that range depending on the residual at each iteration.

Although it is common in inverse problems to think of (112) as a *regularization scheme* a more rational justification for the method is probabilistic. Here, error in the measured data is considered to be sampled from a zero mean, possibly correlated, random variables. The a priori belief about the distribution of γ is then represented as a probability distribution. The minimization (112) is the Maximum a posteriori (MAP) estimate for the case of independent Gaussian error and with prior distribution with log probability density proportional to $-\Psi(\gamma)$. A more sophisticated approach goes beyond Gauss distributions and MAP estimates and samples the posterior distribution using Markov Chain Monte Carlo methods [69]. As this involves a large number of forward problem solutions, this is infeasible for large scale three-dimensional EIT problems. However as computers increase in speed and memory size relative to price, it is reasonable to expect this will eventually become a feasible approach. It will make it easier to approach EIT with a specific question such as “what is the volume of the region with a specified conductivity” with the answer expressed as an estimate of the probability distribution. Going back to (112) the regularization parameter α^2 controls the ratio of the variances of the prior and error distribution. In practice this choice of this parameter is somewhat subjective, and the usual techniques in choice of regularization parameter, and the caution in their application, are relevant (Fig. 7).

Results of a geophysical ERT study are shown in Fig. 8, thanks to the Geophysical Tomography Team, British Geological Survey (<http://www.bgs.ac.uk/research/tomography>) for this figure and the description of the survey summarized below. In this case ERT was used to identify the concentrations of *leachate*, the liquid that escapes from buried waste in a landfill site. The leachate can be extracted and recirculated to enhance the production of landfill gas, which can ultimately be used for electricity generation. It was important to use a non-invasive technique – the more standard practice of drilling exploratory wells could lead to new flow paths. Data were collected sequentially on 64 parallel survey lines, using a regular grid of electrode positions. The inter-line spacing was 15 m with a minimum electrode spacing of 5 m along line. For the current sources, electrode spacings between 15 m and 95 m were used, while electrode spacings for the measurement electrodes were between 5 m and 225 m (Figs. 9 and 10).

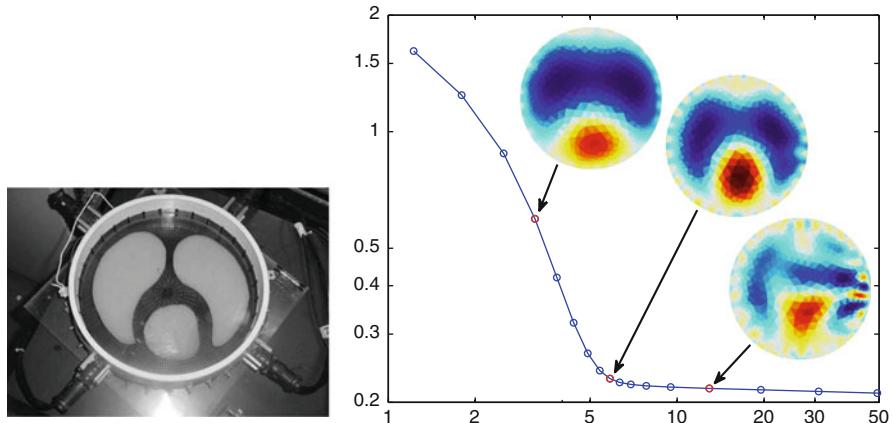

Fig. 7 An “L-curve”: data mismatch $\|\mathbf{V} - \mathbf{V}_{\text{calc}}(\mathbf{y})\|_2$ (vertical) versus regularization norm $\|\mathbf{R}(\mathbf{y} - \mathbf{y}_0)\|_2$ (horizontal) for a range of six orders of magnitude of the regularization. In each case, a single step of the iterative solution was taken. Three representative images are shown illustrating the “overregularization,” appropriate regularization, and “underregularization.” The data are from the RPI chest phantom [65] shown left

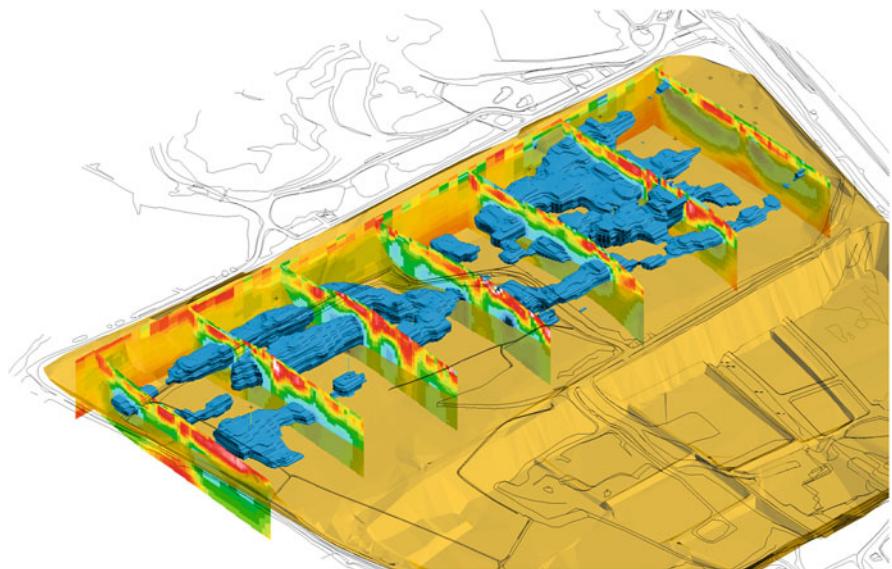

Fig. 8 A three-dimensional ERT survey of a commercial landfill site to map the volumetric distribution of leachate (opaque blue). Leachate is abstracted and reproduction of any BGS materials does not amount to an endorsement by NERC or any of its employees of any product or service and no such endorsement should be stated or implied

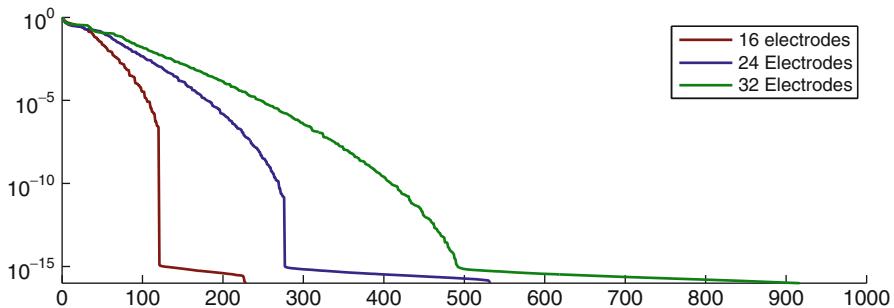

Fig. 9 Normalized singular values of the Jacobian matrix from circular 2D model with $L = 16, 24$, and 32 electrodes. EIT measurements are made with trigonometric patterns such that the number of independent measurements from L electrodes is $\frac{1}{2}(L - 1)L$. Note the use of more degrees of freedom in the conductivity than the data so as to be able to study the effect of different numbers of electrodes using SVD

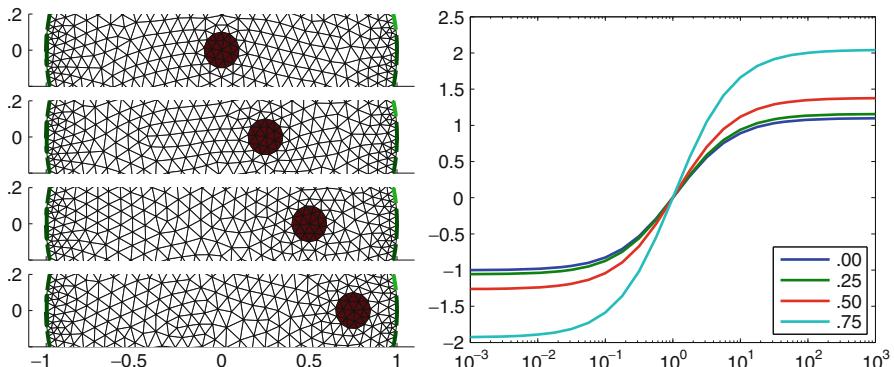

Fig. 10 Saturation of EIT signals as a function of conductivity contrast. *Left:* Slices through a finite element model of a 2D circular medium with a circular conductivity target at four horizontal positions. EIT voltages are simulated at 32 electrodes for 31 trigonometric current patterns. *Right:* change in a voltage difference as a function of conductivity contrast (target vs. background) for each horizontal position (*horizontal center of contrast specified in legend*). Vertical axis is normalized with respect to the maximum change from the central target, and scaled by the sign of conductivity change

The inversion was performed using RES3DINV with the FE forward solver with a mesh generated using the measured surface topography. The two norm was used for both penalty term and error norm. Due to the large number of datum points (approx 85,000 in total), the dataset was split in four approximately equal volumes for subsequent inversion. The resulting resistivity models were then merged to produce a final model for the entire survey area. The resulting 3D resistivity model was used to identify a total of 14 drilling locations for intrusive investigation. Eight wells were drilled and the results (i.e., initial leachate strikes within these wells) were used to calibrate the resistivity model. Based on this ground-truth

calibration a resistivity threshold value of $4 \Omega\text{m}$ was used to represent the spatial distribution of leachate for volumetric analysis within the waste mass. A commercial visualization package was used to display cross sections, iso-resistivity surfaces as well as topography and features on the surface and the boreholes. For other similar examples of geophysical ERT see [28, 29].

Experiments on tanks in process tomography or as simulated bodies for medical EIT show that several iterations of a nonlinear method can improve the accuracy of conductivity and the shape of conductivity contours for known objects. In medical EIT it has yet to be demonstrated that the shape and electrode position can be measured and modeled with sufficient accuracy that the error in the linear approximation is greater than the modeling error. These technical difficulties are not, hopefully, insurmountable (Fig. 11).

Direct Nonlinear Solution

Nachman's [88, 89] (see also [94]) uniqueness result for the two-dimensional case was essentially constructive and has resulted in a family of reconstruction algorithms called $\bar{\partial}$ -methods or scattering transform methods. Nachman's method was implemented by Siltanen et al. [100] in 2000. Of course there are few practical situations in which the two-dimensional approximation is a good one – both the conductivity and the electrodes have to be translationally invariant. Flow in a pipe with long electrodes is one example in which it is a good approximation. The main steps in the method are sketched (following Knudsen et al. [77]) and the interested reader referred to the references for details.

Assuming Ω is the unit disk for simplicity and starting with the Faddeev Green's function

$$G_k(x) := e^{ikx} g_k(x), \quad g_k(x) = \frac{1}{(2\pi)^2} \int_{\mathbb{R}^2} \frac{e^{ix \cdot \xi}}{|\xi|^2 + 2k(\xi_1 + i\xi_2)} d\xi \quad (114)$$

Fig. 11 (continued) Iteration (*horizontal axis*) and regularization parameter selection (*vertical axis*) for two choices of regularization matrix \mathbf{R} . Data are from the RPI chest phantom [65]. The regularization parameter [α in (113)] in the *middle row* (1) was selected at the “knee” of the L-curve, indicating an appropriate level of regularization. Overregularization (*top row*) is shown for 10α , and underregularization (*bottom row*) for 0.1α . Columns indicate 1, 3, or 5 iteration of (113). With increased iteration, one can see improved separation of targets and more accurate conductivity estimates, although these improvements trade off against increased electrode artifacts due to model mismatch. The difference between the Laplacian and weighted diagonal regularization is shown in the increased smoothness of (a), especially in the underregularized case. (a) Laplacian regularization. (b) Weighted diagonal regularization

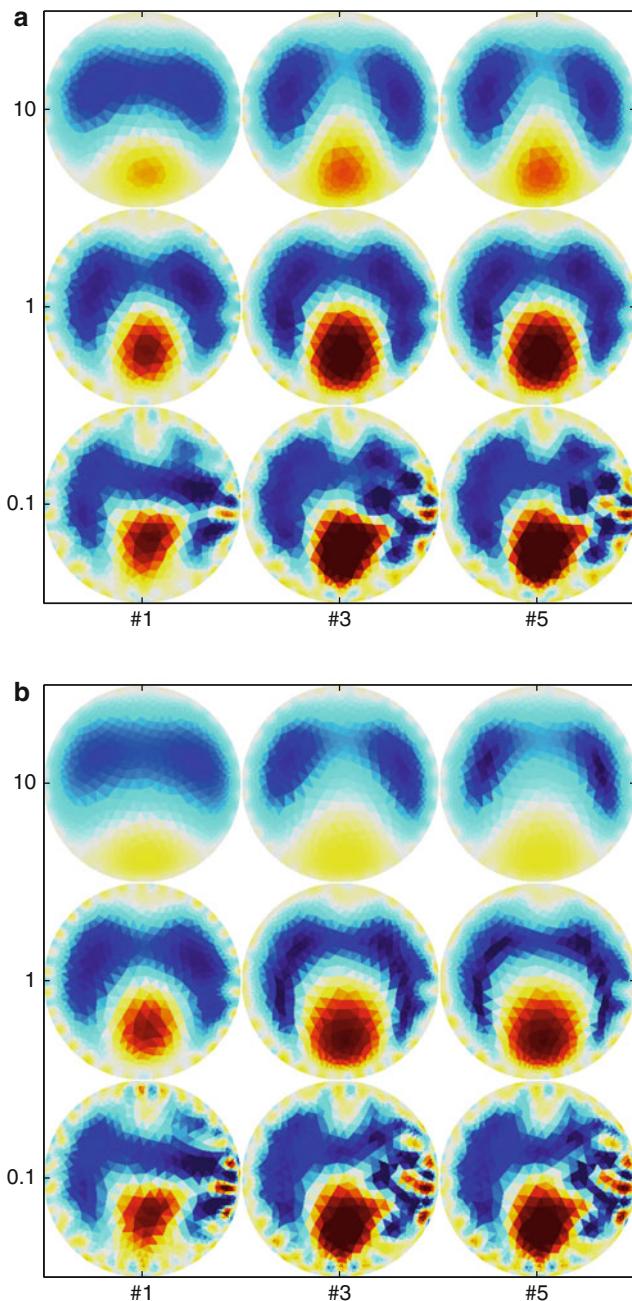

Fig. 11 (continued)

and the single layer potential

$$(S_k \phi)(x) := \int_{\partial\Omega} G_k(x - y)\phi(y) d\theta(y). \quad (115)$$

Here $k = k_1 + ik_2$ and, by abuse of notation, considering x as a vector in $x \cdot \xi$ and a complex number $x_1 + ix_2$ in the complex product kx . Here $\theta(y)$ means the angular polar coordinate of y . Here, it is assumed that the measured Dirichlet-to-Neumann map Λ_γ is available and, of course, that Λ_1 is known. The first step in the algorithm is for each fixed k to solve the linear Fredholm integral equation for a function $\psi(\cdot, k)$ on the boundary.

$$\psi(\cdot, k)|_{\partial\Omega} = e^{ikx} - S_k(\Lambda_\gamma - \Lambda_1)\psi(\cdot, k)|_{\partial\Omega}. \quad (116)$$

This is an explicit calculation of the Complex Geometries Optics solution of Theorem 3. It is fed into the calculation of what is called the *non-physical scattering transform* $\mathbf{t} : \mathbb{C} \rightarrow \mathbb{C}$ defined by

$$\mathbf{t}(k) = \int_{\partial\Omega} e^{\bar{k}\bar{x}}(\Lambda_\gamma - \Lambda_1)\psi(\cdot, k) d\theta. \quad (117)$$

Note here that (116) is a linear equation to solve the resulting ψ depends nonlinearly on the data Λ_γ , and of course as ψ depends on the data \mathbf{t} is a nonlinear function of the data. The second step is to find the conductivity from the scattering data as follows. Let $e_x(k) := \exp(i(kx + \bar{k}\bar{x}))$. For each fixed x another integral equation is solved

$$V(x, k) = 1 + \frac{1}{(2\pi)^2} \int_{\mathbb{R}^2} \frac{\mathbf{t}(k')}{(k - k')\bar{k}'} e_{-x}(k') \overline{V(x, k')} dk'_1 dk'_2 \quad (118)$$

finally setting $\gamma(x) = V(x, 0)^2$. The integral equation (118) is the solution to the partial differential equation

$$\bar{\partial}_k V(x, k) = \frac{1}{4\pi k} \mathbf{t}(k) e_{-x}(k) \overline{V(x, k)}, \quad k \in \mathbb{C}, \quad (119)$$

where $\bar{\partial}_k = \partial/\partial\bar{k}$. Equation (119) is referred to as the $\bar{\partial}$ equation hence the name of the method.

The reconstruction procedure is therefore a direct nonlinear method in which the steps are the solution of linear equations. The only forward modeling required is the construction of Λ_1 . In some practical realizations of this methods [65] an approximation to the scattering transform is used in which ψ is replaced by an exponential

$$\mathbf{t}^{\text{exp}}(k) = \int_{\partial\Omega} e^{\bar{k}\bar{x}} (\Lambda_\gamma - \Lambda_1) d\theta. \quad (120)$$

In practical reconstruction schemes \mathbf{t} or \mathbf{t}^{exp} are replaced by an approximation truncated to zero for $|k| > R$ for some $R > 0$, which effectively also truncates the domain of integration in (118) to the disk of radius R . Reconstruction of data from a two-dimensional agar phantom simulating a chest was performed in [65] using truncated \mathbf{t}^{exp} , and in [66] a difference imaging version of the $\bar{\partial}$ -method is implemented using a truncated scattering transform and applied to chest data. A rigorous regularization scheme for two-dimensional $\bar{\partial}$ -reconstruction is given in [77]. In this case the regularization is applied to the *data*, in a similar spirit to X-ray CT reconstruction in which the data is filtered and then backprojected (see chapter ▶ [Tomography](#)) and the regularization is applied in the filter on the data. In this sense it is harder to understand the regularized algorithm in terms of systematic a priori information applied to the image. As in CT this is traded off against having a fast explicit reconstruction algorithm that avoids iteration.

So far the discussion of $\bar{\partial}$ -methods has been confined to two-dimensional problems. At the time of writing three-dimensional direct reconstruction methods are in their infancy. A three-dimensional $\bar{\partial}$ -algorithm for small conductivities is outlined in [34], and it is yet to be seen if this will result in practical implementation with noisy data on a finite array of electrodes. See the thesis of Bikowski [19] for the latest steps in this direction. If these efforts are successful, the impact on EIT is likely to be revolutionary.

4 Conclusion

Electrical impedance tomography and its relatives are among the most challenging inverse problems in imaging as the problem is nonlinear and highly illposed. The problem has inspired detailed theoretical and numerical study, and this has had an influence across a wide range of related inverse boundary value problems for (systems of) partial differential equations. Medical and industrial process applications have yet to realize their potential as routine methods while the equivalent methods in geophysics are well established. A family of direct nonlinear solution techniques until recently only valid for the two-dimensional problem may soon be extended to practical three-dimensional algorithms. If this happens fast three-dimensional nonlinear reconstruction may be possible on relatively modest computers. In some practical situations in medical and geophysical EIT the conductivity is anisotropic, in which case the solution is non-unique. A specification of the a priori information needed for a unique solution is poorly understood and practical reconstruction algorithms have yet to be proposed in the anisotropic case.

For a more complete summary of uniqueness results, the reader is referred to the review article of Uhlmann [110]. Similarly, for a review of biomedical applications of EIT, see the book by Holder [59], while subsequent progress in the medical area

can generally be found in special issues of the journal *Physiological Measurement* arising from the annual conferences on Biomedical Applications of EIT. A good reference for the details of geophysical EIT reconstruction can be found in the manual [44] and the notes by Loke [83]. For applications in process tomography see [117] and the proceedings of the biennial World Congress on Industrial Process Tomography (<http://www.isipt.org/wcipt>).

Abstract

The purpose of this chapter is to explain the basics of radar imaging and to list a variety of associated open problems. After a short section on the historical background, the chapter includes a derivation of an approximate scalar model for radar data. The basics in inverse synthetic aperture radar (ISAR) are discussed, and a connection is made with the Radon transform. Two types of synthetic aperture radar (SAR), namely, spotlight SAR and stripmap SAR, are outlined. Resolution analysis is included for ISAR and spotlight SAR. Some numerical algorithms are discussed. Finally, the chapter ends with a listing of open problems and a bibliography for further reading.

1 Introduction

“Radar” is an acronym for RAdio Detection And Ranging. Radar was originally developed [7, 8, 64, 67, 72] as a technique for detecting objects and determining their positions by means of *echolocation*, and this remains the principal function of modern radar systems. However, radar systems have evolved over more than seven decades to perform an additional variety of very complex functions; one such function is imaging [9, 20–22, 26, 29, 35, 41, 59, 61].

Radar-based imaging is a technology that has been developed mainly within the engineering community. There are good reasons for this: some of the critical challenges are (1) transmitting microwave energy at high power, (2) detecting microwave energy, and (3) interpreting and extracting information from the received signals. The first two problems are concerned with the development of appropriate hardware; however, these problems have now largely been solved, although there is ongoing work to make the hardware smaller and lighter. The third problem essentially encompasses a set of mathematical challenges, and this is the area where most of the current effort is taking place.

Radar imaging shares much in common with optical imaging: both processes involve the use of electromagnetic waves to form images. The main difference between the two is that the wavelengths of radar are much longer than those of optics. Because the resolving ability of an imaging system depends on the ratio of the wavelength to the size of the aperture, radar imaging systems require an aperture many thousands of times larger than optical systems in order to achieve comparable resolution. Since kilometer-sized antennas are not practicable, fine-resolution radar imaging has come to rely on the so-called synthetic apertures in which a small antenna is used to sequentially sample a much larger measurement region.

2 Historical Background

Radar technology underwent rapid development during World War II; most of this work concerned developing methods to transmit radio waves and detect scattered

waves. The invention of synthetic aperture radar (SAR) is generally credited to Carl Wiley, of the Goodyear Aircraft Corporation, in 1951. The mid-1950s saw the development of the first operational systems, under the sponsorship of the US Department of Defense. These systems were developed by a collaboration between universities, such as the University of Illinois and the University of Michigan, together with companies such as Goodyear Aircraft, General Electric, Philco, and Varian. In the late 1960s, the National Aeronautics and Space Administration (NASA) began sponsoring unclassified work on SAR. Around this time, the first digital SAR processors were developed (earlier systems having used analogue optical processing). In 1978, the SEASAT-A satellite was sent up, and even though it operated only for 100 days, the images obtained from it were so useful that it became obvious that more such satellites were needed. In 1981, the shuttle imaging radar (SIR) series began, and many shuttle missions since then have involved radar imaging of the earth. In the 1990s, satellites were sent up by many countries (including Canada, Japan, and the European Space Agency), and SAR systems were sent to other planets and their moons, including Venus, Mars, and Titan. Since the beginning of the new millennium, more satellites have been launched, for example, the new European Space Agency satellite ENVISAT and the TerraSAR-X satellite, which was developed and launched by a (mainly European) public–private partnership.

Code letters for the radar frequency bands were originally used during wartime, and the usage has persisted. These abbreviations are listed in Table 1. The HF band usually carries radio signals; VHF carries radio and broadcast television; the UHF band carries television, navigation radar, and cell phone signals. Some radar systems operate at VHF and UHF; these are typically systems built for penetrating foliage, soil, and buildings. Most of the satellite synthetic aperture radar systems operate in the L-, S-, and C-bands. The S-band carries wireless Internet. Many military systems operate at X-band.

Table 1 Radar frequency bands

| Band designation | Approximate frequency range | Approximate wavelengths |
|---------------------------|-----------------------------|-------------------------|
| HF (high frequency) | 3–30 MHz | 50 m |
| VHF (very high frequency) | 30–300 MHz | 5 m |
| UHF (ultrahigh frequency) | 300–1,000 MHz | 1 m |
| L-band | 1–2 GHz | 20 cm |
| S-band | 2–4 GHz | 10 cm |
| C-band | 4–8 GHz | 5 cm |
| X-band | 8–12 GHz | 3 cm |
| Ku-band (under K) | 12–18 GHz | 2 cm |
| K-band | 18–27 GHz | 1.5 cm |
| Ka-band (above K) | 27–40 GHz | 1 cm |
| mm-wave | 40–300 GHz | 5 mm |

3 Mathematical Modeling

SAR relies on a number of very specific simplifying assumptions about radar scattering phenomenology and data-collection scenarios:

1. Most imaging radar systems make use of the *start-stop approximation* [29], in which both the radar sensor and scattering object are assumed to be stationary during the time interval over which the pulse interacts with the target.
2. The target or scene is assumed to behave as a rigid body.
3. SAR imaging methods assume a linear relationship between the data and scene.

Scattering of Electromagnetic Waves

The present discussion considers only scattering from targets that are stationary.

For linear materials, Maxwell's equations can be used [34] to obtain an inhomogeneous wave equation for the electric field \mathcal{E} at time t and position \mathbf{x} :

$$\nabla^2 \mathcal{E}(t, \mathbf{x}) - \frac{1}{c^2(\mathbf{x})} \frac{\partial^2 \mathcal{E}(t, \mathbf{x})}{\partial t^2} = s(t, \mathbf{x}) \quad (1)$$

and a similar equation for the magnetic field \mathcal{B} . Here $c(\mathbf{x})$ denotes the speed of propagation of the wave (throughout the atmosphere, this speed is approximately independent of position and equal to the constant vacuum speed c) and s is a source term that, in general, can involve \mathcal{E} and \mathcal{B} . For typical radar problems, the wave speed is constant in the region between the source and the scattering objects (targets) and varies only within the target volume. Consequently, here scattering objects are modeled solely via the source term $s(t, \mathbf{x})$.

One Cartesian component of Eq. (1) is

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) \mathcal{E}(t, \mathbf{x}) = s(t, \mathbf{x}), \quad (2)$$

where atmospheric propagation between source and target has been assumed.

Basic Facts About the Wave Equation

A *fundamental solution* [69] of the inhomogeneous wave equation is a generalized function [30, 69] satisfying

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) g(t, \mathbf{x}) = -\delta(t)\delta(\mathbf{x}). \quad (3)$$

The solution of (3) that is useful is

$$g(t, \mathbf{x}) = \frac{\delta(t - |\mathbf{x}|/c)}{4\pi|\mathbf{x}|} = \int \frac{e^{-i\omega(t-|\mathbf{x}|/c)}}{8\pi^2|\mathbf{x}|} d\omega, \quad (4)$$

where in the second equality the identity

$$\delta(t) = \frac{1}{2\pi} \int e^{-i\omega t} d\omega \quad (5)$$

was used. The function $g(t, \mathbf{x})$ can be physically interpreted as the field at (t, \mathbf{x}) due to a source at the origin $\mathbf{x} = \mathbf{0}$ at time $t = 0$ and is called the *outgoing fundamental solution* or (*outgoing*) *Green's function*.

The Green's function [62] can be used to solve the constant-speed wave equation with *any* source term. In particular, the outgoing solution of

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) u(t, \mathbf{x}) = s(t, \mathbf{x}), \quad (6)$$

is

$$u(t, \mathbf{x}) = - \iint g(t - t', \mathbf{x} - \mathbf{y}) s(t', \mathbf{y}) dt' d\mathbf{y}. \quad (7)$$

In the frequency domain, the equations corresponding to (3) and (4) are

$$(\nabla^2 + k^2) G = -\delta \quad \text{and} \quad G(\omega, \mathbf{x}) = \frac{e^{ik|\mathbf{x}|}}{4\pi|\mathbf{x}|}, \quad (8)$$

where the wave number k is defined as $k = \omega/c$.

Basic Scattering Theory

In constant-wave velocity radar problems, the source s is a sum of two terms, $s = s^{\text{in}} + s^{\text{sc}}$, where s^{in} models the transmitting antenna and s^{sc} models the scattering object. The solution \mathcal{E} to Eq. (1), which is written as \mathcal{E}^{tot} , therefore splits into two parts: $\mathcal{E}^{\text{tot}} = \mathcal{E}^{\text{in}} + \mathcal{E}^{\text{sc}}$. The first term, \mathcal{E}^{in} , satisfies the wave equation for the known, prescribed source s^{in} . This part is called the *incident* field, because it is incident upon the scatterers. The second term, \mathcal{E}^{sc} , is due to target scattering, and this part is called the *scattered* field. We use the same decomposition in the simplified scalar model.

One approach to finding the scattered field is to simply solve (2) directly, using, for example, numerical time-domain techniques. For many purposes, however, it is convenient to reformulate the scattering problem in terms of an integral equation.

The Lippmann–Schwinger Integral Equation

In scattering problems the source term s^{sc} (typically) represents the target's *response* to an incident field. This part of the source function will generally depend on the geometric and material properties of the target and on the form and strength of the incident field. Consequently, s^{sc} can be quite complicated to describe analytically, and in general, it will not have the same direction as s^{in} . Fortunately, for this article, it is not necessary to provide a detailed analysis of the target's response; for stationary objects consisting of linear materials, the scalar model s^{sc} is written as the time-domain convolution

$$s^{\text{sc}}(t, \mathbf{x}) = \int v(t - t', \mathbf{x}) \mathcal{E}^{\text{tot}}(t', \mathbf{x}) dt', \quad (9)$$

where $v(t, \mathbf{x})$ is called the reflectivity function and depends on target orientation. In general, this function also accounts for polarization effects.

The expression (9) is used in (7) to express \mathcal{E}^{sc} in terms of the *Lippmann–Schwinger integral equation* [47]

$$\mathcal{E}^{\text{sc}}(t, \mathbf{x}) = \int g(t - \tau, \mathbf{x} - \mathbf{z}) \iint v(\tau - t', \mathbf{z}) \mathcal{E}^{\text{tot}}(t', \mathbf{z}) dt' d\tau dz. \quad (10)$$

The Lippmann–Schwinger Equation in the Frequency Domain

In the frequency domain, the electric field and reflectivity function become

$$E(\omega, \mathbf{x}) = \int e^{i\omega t} \mathcal{E}(t, \mathbf{x}) dt \quad \text{and} \quad V(\omega, \mathbf{z}) = \int e^{i\omega t} v(t, \mathbf{z}) dt, \quad (11)$$

respectively. Thus the frequency-domain version of (2) is

$$\left(\nabla^2 + \frac{\omega^2}{c^2} \right) E(\omega, \mathbf{x}) = S(\omega, \mathbf{x}) \quad (12)$$

and of (10) is

$$E^{\text{sc}}(\omega, \mathbf{x}) = - \int G(\omega, \mathbf{x} - \mathbf{z}) V(\omega, \mathbf{z}) E^{\text{tot}}(\omega, \mathbf{z}) dz. \quad (13)$$

The reflectivity function $V(\omega, \mathbf{x})$ can display a sensitive dependence on ω [34, 36, 53]. When the target is small in comparison with the wavelength of the incident field, for example, V is proportional to ω^2 (this behavior is known as “Rayleigh scattering”). At higher frequencies (shorter wavelengths), the dependence on ω is typically less pronounced. In the so-called optical region, $V(\omega, \mathbf{x})$ is often approximated as being independent of ω (see, however, [56]); the optical approximation is used in this chapter, and the ω dependence is simply dropped.

In the time domain, this corresponds to $v(t, z) = \delta(t)V(z)$, and the delta function can be used to carry out the t' integration in (10).

The Born Approximation

For radar imaging, the field \mathcal{E}^{sc} is measured at the radar antenna, and from these measurements, the goal is to determine V . However, both V and \mathcal{E}^{sc} in the neighborhood of the target are unknown, and in (10) these unknowns are multiplied together. This nonlinearity makes it difficult to solve for V . Consequently, almost all work on radar imaging relies on the *Born approximation*, which is also known as the *weak-scattering* or *single-scattering* approximation [38, 47]. The Born approximation replaces \mathcal{E}^{tot} on the right side of (10) by \mathcal{E}^{in} , which is known. This results in a linear formula for \mathcal{E}^{sc} in terms of V :

$$\mathcal{E}^{\text{sc}}(t, \mathbf{x}) \approx \mathcal{E}_B(t, \mathbf{x}) \equiv \iint g(t - \tau, \mathbf{x} - \mathbf{z}) V(\mathbf{z}) \mathcal{E}^{\text{in}}(\tau, \mathbf{z}) d\tau dz. \quad (14)$$

In the frequency domain, the Born approximation is

$$E_B^{\text{sc}}(\omega, \mathbf{x}) = - \int \frac{e^{ik|\mathbf{x}-\mathbf{z}|}}{4\pi|\mathbf{x}-\mathbf{z}|} V(\mathbf{z}) E^{\text{in}}(\omega, \mathbf{z}) dz. \quad (15)$$

The Born approximation is very useful because it makes the imaging problem linear. It is not, however, always a good approximation; see Sect. 6.

The Incident Field

The incident field \mathcal{E}^{in} is obtained by solving (2), where s^{in} is taken to be the relevant component of the current density on the source antenna and s^{sc} is zero. This article uses a simplified point-like antenna model, for which $s^{\text{in}}(t, \mathbf{x}) = p(t)\delta(\mathbf{x} - \mathbf{x}^0)$, where p is the waveform transmitted by the antenna. Typically p consists of a sequence of time-shifted pulses, so that $p(t) = \sum p_0(t - t_n)$.

In the frequency domain, the corresponding source for (12) is $S^{\text{in}}(\omega, \mathbf{x}) = P(\omega)\delta(\mathbf{x} - \mathbf{x}^0)$, where P denotes the inverse Fourier transform of p :

$$p(t) = \frac{1}{2\pi} \int e^{-i\omega t} P(\omega) d\omega. \quad (16)$$

Use of (8) shows that the incident field in the frequency domain is

$$\begin{aligned} E^{\text{in}}(\omega, \mathbf{x}) &= - \int G(\omega, \mathbf{x} - \mathbf{y}) P(\omega) \delta(\mathbf{y} - \mathbf{x}^0) dy \\ &= -P(\omega) \frac{e^{ik|\mathbf{x}-\mathbf{x}^0|}}{4\pi|\mathbf{x}-\mathbf{x}^0|}. \end{aligned} \quad (17)$$

Model for the Scattered Field

In monostatic radar systems, the transmit and receive antennas are colocated – often the same antenna is used. Use of (17) in (15) shows that the Born-approximated scattered field at the transmitter location \mathbf{x}^0 is

$$E_B^{sc}(\omega, \mathbf{x}^0) = P(\omega) \int \frac{e^{2ik|\mathbf{x}^0 - \mathbf{z}|}}{(4\pi)^2 |\mathbf{x}^0 - \mathbf{z}|^2} V(\mathbf{z}) d\mathbf{z}. \quad (18)$$

Fourier transforming (18) results in an expression for the time-domain field:

$$\begin{aligned} \mathcal{E}_B^{sc}(t, \mathbf{x}^0) &= \iint \frac{e^{-i\omega(t-2|\mathbf{x}^0 - \mathbf{z}|/c)}}{2\pi(4\pi|\mathbf{x}^0 - \mathbf{z}|)^2} P(\omega) V(\mathbf{z}) d\omega d\mathbf{z} \\ &= \int \frac{p(t - 2|\mathbf{x}^0 - \mathbf{z}|/c)}{(4\pi|\mathbf{x}^0 - \mathbf{z}|)^2} V(\mathbf{z}) d\mathbf{z}. \end{aligned} \quad (19)$$

Under the Born approximation, the scattered field is a superposition of scattered fields from point-like targets $V(\mathbf{z}') \propto \delta(\mathbf{z}' - \mathbf{z}')$.

The Matched Filter

An important aspect of (19) is the $1/R^2$ geometrical decay (where $R = |\mathbf{x}^0 - \mathbf{z}|$). When R is large (which it usually is), this decay factor results in a received signal that is extremely small – so small, in fact, that it can be dominated by thermal noise in the receiver. Thus it is difficult even to detect the presence of a target. Target detection is typically accomplished by means of a *matched filter* [19, 25, 50].

Below the matched filter is derived for scattering from a single fixed, point-like target. For such a target, by Eqs. (9) and (19), the signal scattered is simply a time-delayed version of the transmitted waveform:

$$s_{\text{rec}}(t) = \rho s(t - \tau) + n(t),$$

where τ corresponds to the $2R/c$ delay, ρ is a proportionality factor related to the scatterer reflectivity $V(\mathbf{z})$ and the geometric decay $(4\pi|\mathbf{x}^0 - \mathbf{z}|)^{-2}$, and n denotes noise.

The strategy is to apply a filter (convolution operator) to s_{rec} in order to improve the signal-to-noise ratio. The filter's impulse response (convolution kernel) is denoted by h , which implies that the filter output is

$$\eta(t) = (h * s_{\text{rec}})(t) = \rho \eta_s(t) + \eta_n(t), \quad (20)$$

where

$$\eta_s(t) = \int h(t - t')s(t' - \tau) dt' \quad \text{and} \quad \eta_n(t) = \int h(t - t')n(t') dt'.$$

The signal output $\eta_s(\tau)$ at time τ should be as large as possible, relative to the noise output $\eta_n(\tau)$.

The noise is modeled as a random process. Thermal noise in the receiver is well approximated by white noise, which means that $\langle n(t)n^*(t') \rangle = N\delta(t - t')$, where N corresponds to the noise power and $\langle \cdot \rangle$ denotes expected value. Since the noise is random, so is η_n . Thus the signal-to-noise (SNR) ratio to be maximized is

$$\text{SNR} = \frac{|\eta_s(\tau)|^2}{\langle |\eta_n(\tau)|^2 \rangle}. \quad (21)$$

First, the denominator of (21) is

$$\begin{aligned} \langle |\eta_n(\tau)|^2 \rangle &= \left\langle \left| \int h(\tau - t')n(t') dt' \right|^2 \right\rangle \\ &= \left\langle \int h(\tau - t')n(t') dt' \left(\int h(\tau - t'')n(t'') dt'' \right)^* \right\rangle \\ &= \iint h(\tau - t')h^*(\tau - t'') \underbrace{\langle n(t')n^*(t'') \rangle}_{N\delta(t' - t'')} dt' dt'' \\ &= N \int |h(\tau - t')|^2 dt' = N \int |h(t)|^2 dt, \end{aligned}$$

where in the last line the change of variables $t = \tau - t'$ has been made and where the star denotes complex conjugation. Thus (21) becomes

$$\text{SNR} = \frac{\left| \int h(\tau - t')s(t' - \tau) dt' \right|^2}{N \int |h(t)|^2 dt} = \frac{\left| \int h(t)s(-t) dt \right|^2}{N \int |h(t)|^2 dt}, \quad (22)$$

where in the numerator the change of variables $t = \tau - t'$ has been made. To the numerator of (22), the Cauchy–Schwarz inequality can be used to conclude that the numerator, and therefore the quotient (22), is maximized when h is chosen, so that

$$h(t) = s^*(-t).$$

This is the impulse response of the matched filter. Thus to obtain the best signal-to-noise ratio, the received signal should be convolved with the time-reversed, complex-conjugated version of the expected signal.

With this choice, the filter (20) can be written as

$$\eta(t) = \int h(t-t'') s_{\text{rec}}(t'') dt'' = \int s^*(t''-t) s_{\text{rec}}(t'') dt'' = \int s^*(t') s_{\text{rec}}(t'+t) dt', \quad (23)$$

which is a *correlation* between s and s_{rec} . If $s = s_{\text{rec}}$, (23) is called an *autocorrelation*. Radar receivers which perform this kind of signal processing are known as “correlation receivers.”

The Effect of Matched Filtering on Radar Data When applied to (18), the output of the correlation receiver is

$$\begin{aligned} \eta(t, \mathbf{x}^0) &\approx \int p^*(t' - t) \mathcal{E}_B^{sc}(t', \mathbf{x}^0) dt' \\ &= \int \left(\frac{1}{2\pi} \int e^{i\omega'(t'-t)} P^*(\omega') d\omega' \right) \iint \frac{e^{-i\omega(t'-2|\mathbf{x}^0-\mathbf{z}|/c)}}{2\pi(4\pi|\mathbf{x}^0-\mathbf{z}|)^2} P(\omega) V(\mathbf{z}) d\omega d\mathbf{z} dt' \\ &= \iiint \underbrace{\frac{1}{2\pi} \int e^{i(\omega-\omega')t'} dt'}_{\delta(\omega'-\omega)} \frac{e^{-i\omega(t-2|\mathbf{x}^0-\mathbf{z}|/c)}}{(4\pi|\mathbf{x}^0-\mathbf{z}|)^2} P(\omega) P^*(\omega') V(\mathbf{z}) d\omega' d\omega d\mathbf{z} \\ &= \iint \frac{e^{-i\omega(t-2|\mathbf{x}^0-\mathbf{z}|/c)}}{(4\pi|\mathbf{x}^0-\mathbf{z}|)^2} |P(\omega)|^2 V(\mathbf{z}) d\omega d\mathbf{z}. \end{aligned} \quad (24)$$

Thus, the effect of matched filtering is simply to replace $P(\omega)$ in the first line of (19) by $2\pi|P(\omega)|^2$.

The Small-Scene Approximation

The *small-scene* approximation, namely,

$$|\mathbf{x} - \mathbf{y}| = |\mathbf{x}| - \hat{\mathbf{x}} \cdot \mathbf{y} + O\left(\frac{|\mathbf{y}|^2}{|\mathbf{x}|}\right), \quad (25)$$

where $\hat{\mathbf{x}}$ denotes a unit vector in the direction \mathbf{x} and is often applied to situations in which the scene to be imaged is small in comparison with its average distance from the radar. This approximation is valid for $|\mathbf{x}| \gg |\mathbf{y}|$.

Use of (25) in (4) gives rise to the large- $|\mathbf{x}|$ expansion of the Green’s function: [12, 19]

$$G(\omega, \mathbf{x} - \mathbf{y}) = \frac{e^{ik|\mathbf{x}-\mathbf{y}|}}{4\pi|\mathbf{x}-\mathbf{y}|} = \frac{e^{ik|\mathbf{x}|}}{4\pi|\mathbf{x}|} e^{-ik\hat{\mathbf{x}} \cdot \mathbf{y}} \left(1 + O\left(\frac{|\mathbf{y}|}{|\mathbf{x}|}\right) \right) \left(1 + O\left(\frac{k|\mathbf{y}|^2}{|\mathbf{x}|}\right) \right). \quad (26)$$

Here, the first-order term must be included in the exponential because $k\hat{\mathbf{x}} \cdot \mathbf{y}$ can take on values that are large fractions of 2π .

Small-Scene, Matched-Filtered Radar Data In (19), the origin of coordinates can be chosen to be in or near the target, and then the small-scene expansion (26) (with z playing the role of y) can be used in the matched-filtered version of (19). This results in the expression for the matched-filtered data:

$$\eta_B(t) = \frac{1}{(4\pi)^2 |\mathbf{x}^0|^2} \iint e^{-i\omega(t - 2|\mathbf{x}^0|/c + 2\hat{\mathbf{x}}^0 \cdot z/c)} |P(\omega)|^2 V(z) d\omega dz. \quad (27)$$

The inverse Fourier transform of (27) gives

$$D_B(\omega) = \frac{e^{2ik|\mathbf{x}^0|}}{(4\pi)^2 |\mathbf{x}^0|^2} |P(\omega)|^2 \underbrace{\int e^{-2i\hat{\mathbf{x}}^0 \cdot z} V(z) dz}_{\mathcal{F}[V](2k\hat{\mathbf{x}}^0)}. \quad (28)$$

Thus we see that each frequency component of the data provides us with a Fourier component of the reflectivity V .

The Range Profile

Signals with large bandwidth are commonly used in synthetic aperture imaging. When the bandwidth is large, the pulse p is said to be a *high-range-resolution* (HRR) pulse. An especially simple large-bandwidth signal is one for which $|P(\omega)|^2$ is constant over its support. In this case, the ω -integral in Eq. (27) reduces to a scaled sinc(t) function centered on

$$t = 2|\mathbf{x}^0|/c + 2\hat{\mathbf{x}}^0 \cdot z/c,$$

and the width of this sinc function is inversely proportional to the bandwidth. When the support of $|P(\omega)|^2$ is infinite, of course, this sinc(t) becomes a delta function. Thus large-bandwidth (HRR), matched-filtered data can be approximated by

$$\eta_B(t) \approx \frac{1}{(4\pi)^2 |\mathbf{x}^0|^2} \int \delta(t - 2|\mathbf{x}^0|/c + 2\hat{\mathbf{x}}^0 \cdot z/c) V(z) dz. \quad (29)$$

Since time delay and range are related in monostatic radar systems as $t = 2R/c$, Eq. (29) can be seen to be a relation between the radar data $\eta_B(t)$ and the integral of the target reflectivity function over the plane

$$R = |\mathbf{x}^0| + \hat{\mathbf{x}}^0 \cdot \mathbf{z}$$

(with respect to the radar). Such data are said to form a “range profile” of the target. An example of an HRR range profile is displayed in Fig. 1.

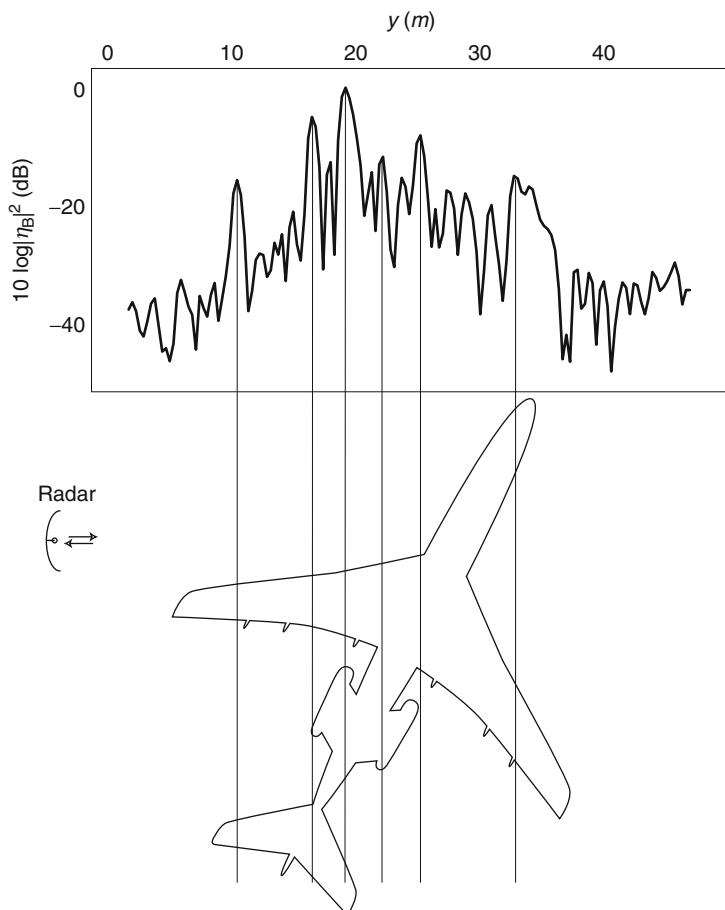

Fig. 1 Example of an HRR range profile of an aircraft (orientation displayed in *inset*)

4 Survey on Mathematical Analysis of Methods

The mathematical models discussed above assume that the target $V(z)$ is stationary during its interaction with a radar pulse. However, synthetic aperture imaging techniques assume that the target moves with respect to the radar *between* pulses.

Inverse Synthetic Aperture Radar (ISAR)

A fixed radar system staring at a rotating target is equivalent (by change of reference frame) to a stationary target viewed by a radar moving (from pulse to pulse) on a circular arc. This circular arc will define, over time, a synthetic

aperture, and sequential radar pulses can be used to sample those data that would be collected by a much larger radar antenna. Radar imaging based on such a data-collection configuration is known as *inverse synthetic aperture radar* (ISAR) imaging [5, 15, 41, 59, 66, 74]. This imaging scheme is typically used for imaging airplanes, spacecraft, and ships. In these cases, the target is relatively small and usually isolated.

Modeling Rotating Targets The target reflectivity function in a frame fixed to the target is denoted by q . Then, as seen by the radar, the reflectivity function is $V(\mathbf{x}) = q(\mathcal{O}(\theta_n)\mathbf{x})$, where \mathcal{O} is an orthogonal matrix and where $t_n = \theta_n$ denotes the time at the start of the n th pulse of the sequence.

For example, if the radar is in the plane perpendicular to the axis of rotation (so-called turntable geometry), then the orthogonal matrix \mathcal{O} can be written as

$$\mathcal{O}(\theta) = \begin{pmatrix} \cos \theta & -\sin \theta & 0 \\ \sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (30)$$

and $V(\mathbf{x}) = q(x_1 \cos \theta - x_2 \sin \theta, x_1 \sin \theta + x_2 \cos \theta, x_3)$.

Radar Data from Rotating Targets The use of $V(\mathbf{x}) = q(\mathcal{O}(\theta_n)\mathbf{x})$ in (28) provides a model for the data from the n th pulse:

$$D_B(\omega, \theta_n) = \frac{e^{2ik|\mathbf{x}^0|}}{(4\pi)^2|\mathbf{x}^0|^2} |P_0(\omega)|^2 \int e^{-2ik\hat{\mathbf{x}}^0 \cdot \mathbf{z}} \underbrace{q(\mathcal{O}(\theta_n)\mathbf{z})}_{\mathbf{y}} d\mathbf{z}. \quad (31)$$

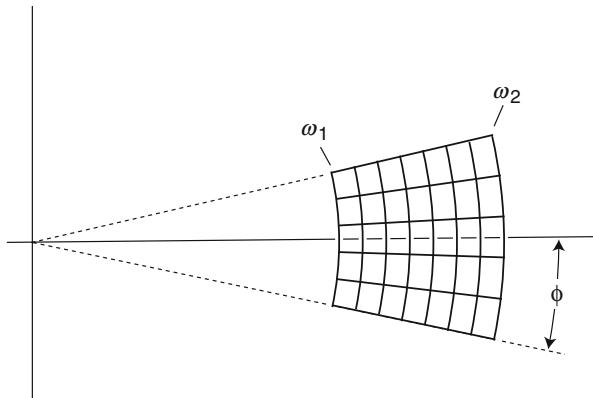

In (31), the change of variables $\mathbf{y} = \mathcal{O}(\theta_n)\mathbf{z}$ is made. Then use is made of the fact that the inverse of an orthogonal matrix is its transpose, which means that $\mathbf{x}^0 \cdot \mathcal{O}^{-1}(\theta_n)\mathbf{y} = \mathcal{O}(\theta_n)\mathbf{x}^0 \cdot \mathbf{y}$. The result is that (31) can be written in the form

$$D_B(\omega, \theta_n) = \frac{e^{2ik|\mathbf{x}^0|}}{(4\pi)^2|\mathbf{x}^0|^2} |P_0(\omega)|^2 \underbrace{\int e^{-2ik\mathcal{O}(\theta_n)\hat{\mathbf{x}}^0 \cdot \mathbf{y}} q(\mathbf{y}) d\mathbf{y}}_{\propto \mathcal{F}[q](2k\mathcal{O}(\theta_n)\hat{\mathbf{x}}^0)}. \quad (32)$$

Thus, the frequency-domain data are proportional to the inverse Fourier transform of q , evaluated at points in a domain defined by the angles of the sampled target orientation and the radar bandwidth (see Fig. 2). Consequently, a Fourier transform produces a target image.

The target rotation angle is usually not known. However, if the target is rotating with constant angular velocity, the image produced by the Fourier transform gives rise to a stretched or contracted image, from which the target is usually recognizable [5, 41, 66, 72].

Fig. 2 The data-collection manifold for turntable geometry

The Data-Collection Manifold

The Fourier components of the target that can be measured by the radar are those in the set

$$\Omega_z = \{2k\mathcal{O}(\theta_n)\hat{\mathbf{x}}^0\}, \quad (33)$$

where n ranges over the indices of pulses for which the point z is in the antenna beam and where $k = \omega/c$ with ω ranging over the angular frequencies received by the radar receiver. The region determined in this manner is called the *data-collection manifold*. The extent of the set of angles is called the *synthetic aperture*, and the extent of the set of frequencies is called the *bandwidth*. Typical synthetic apertures are on the order of a few degrees, and bandwidths of $2\pi \times 500 \times 10^6$ rad/s are not uncommon. Figure 2 shows an example of data-collection manifold corresponding to turntable geometry; Fig. 3 shows others that correspond to more complex motion. Typical SAR data-collection manifolds are two-dimensional manifolds. The larger the data-collection manifold at z , the better the resolution at z .

Examples of ISAR images are shown in Figs. 4 and 5.

ISAR in the Time Domain

Fourier transforming (32) into the time-domain results in

$$\eta_B(t, \theta_n) \propto \iint e^{-i\omega(t-2|\mathbf{x}^0|/c + 2\mathcal{O}(\theta_n)\hat{\mathbf{x}}^0 \cdot \mathbf{y}/c)} |P_0(\omega)|^2 d\omega q(\mathbf{y}) d\mathbf{y}. \quad (34)$$

Evaluation of η_B at a shifted time results in the simpler expression

$$\eta_B\left(t + \frac{2|\mathbf{x}^0|}{c}, \theta_n\right) = \iint e^{-i\omega(t+2\mathcal{O}(\theta_n)\hat{\mathbf{x}} \cdot \mathbf{y}/c)} |P_0(\omega)|^2 d\omega q(\mathbf{y}) d\mathbf{y}. \quad (35)$$

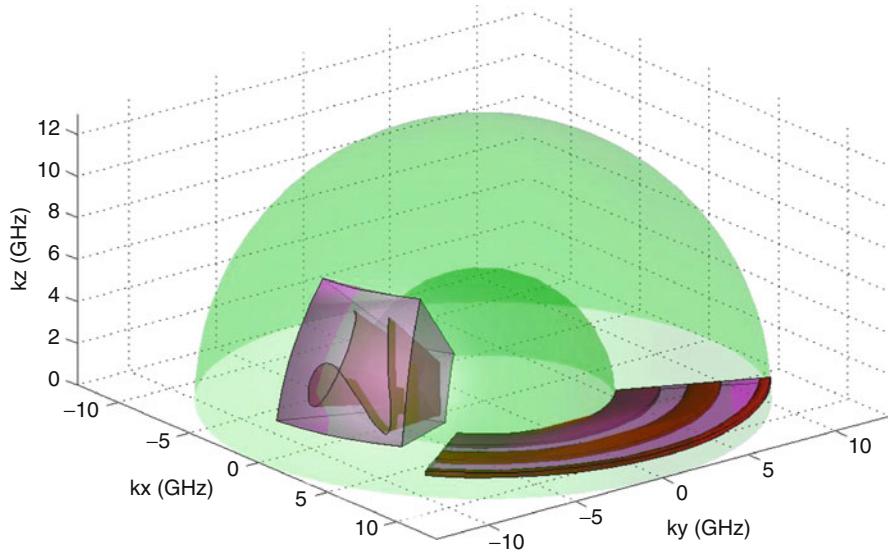

Fig. 3 The dark surfaces represent some typical data-collection manifolds that are subsets of a more complete “data dome”

With the temporary notation $\tau = -2\mathcal{O}(\theta_n)\hat{\mathbf{x}} \cdot \mathbf{y}/c$, the ω integral on the right side of (35) can be written as

$$\int e^{-i\omega(t-\tau)} |P_0(\omega)|^2 d\omega = \int \delta(s - \tau) \beta(t - s) ds, \quad (36)$$

where

$$\beta(t - s) = \int e^{-i\omega(t-s)} |P_0(\omega)|^2 d\omega.$$

With (36), η_B can be written

$$\begin{aligned} \eta_B \left(t + \frac{2|\mathbf{x}^0|}{c}, \theta_n \right) &= \int \beta(t - s) \int \delta \left(s + \frac{2\mathcal{O}(\theta_n)\hat{\mathbf{x}}}{c} \cdot \mathbf{y} \right) q(\mathbf{y}) d\mathbf{y} ds \\ &= \beta * \mathcal{R}[q] \left(\frac{-2\mathcal{O}(\theta_n)\hat{\mathbf{x}}}{c} \right), \end{aligned}$$

where

$$\mathcal{R}[q](s, \hat{\mu}) = \int \delta(s - \hat{\mu} \cdot \mathbf{y}) q(\mathbf{y}) d\mathbf{y} \quad (37)$$

is the *Radon transform* [43, 46]. Here $\hat{\mu}$ denotes a unit vector. In other words, the Radon transform of q is defined as the integral of q over the plane $s = \hat{\mu} \cdot \mathbf{y}$.

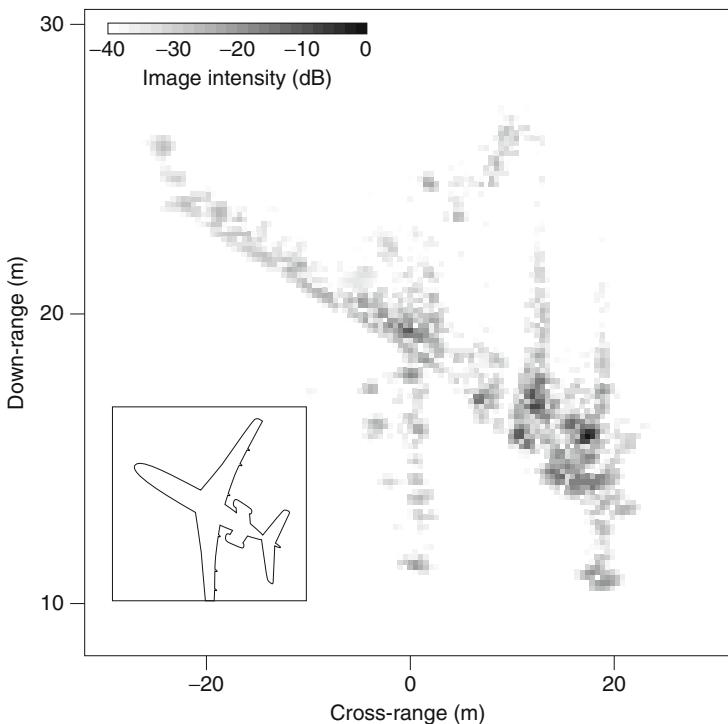

Fig. 4 An ISAR image of a Boeing 727 from a 5° aperture [70]

Fig. 5 On the *left* is an ISAR image of a ship; on the *right* is an optical image of the same ship
(Courtesy Naval Research Laboratory)

ISAR systems typically use a high-range-resolution (large-bandwidth) waveform, so that $\beta \approx \delta$ (see section “The Range Profile”). Thus ISAR imaging from time-domain data becomes a problem of inverting the Radon transform.

Synthetic Aperture Radar

In ISAR, the target rotates and the radar is stationary, whereas in synthetic aperture radar (SAR), the target is stationary and the radar moves. (In typical ISAR data-collection scenarios, both the radar and the target are actually in motion, and so this distinction is somewhat arbitrary.) For most SAR systems [9, 20, 21, 29, 35, 60], the antenna is pointed toward the earth. For an antenna viewing the earth, an antenna beam pattern must be included in the model. For highly directive antennas, often simply the antenna “footprint,” which is the illuminated area on the ground, is used.

For a receiving antenna at the same location as the transmitting antenna, the scalar Born model for the received signal is

$$S_B(\omega) = \int e^{2ik|\mathbf{x}^0 - \mathbf{y}|} A(\omega, \mathbf{x}^0, \mathbf{y}) V(\mathbf{y}) d\mathbf{y}, \quad (38)$$

where A incorporates the geometrical spreading factors $|\mathbf{x}^0 - \mathbf{y}|^{-2}$, transmitted waveform, and antenna beam pattern. More details can be found in [15].

SAR data-collection systems are usually configured to transmit a series of pulses with the n th pulse transmitted at time t_n . The antenna position at time t_n is denoted by \mathbf{y}_n . Because the time scale on which the antenna moves is much slower than the time scale on which the electromagnetic waves propagate, the time scales separate into a *slow time*, which corresponds to the n of t_n , and a *fast time* t .

In (38) the antenna position \mathbf{x}^0 is replaced by \mathbf{y}_n :

$$D(\omega, n) = F[V](\omega, s) \equiv \int e^{2ik|\mathbf{y}_n - \mathbf{y}|} A(\omega, n, \mathbf{y}) V(\mathbf{y}) d\mathbf{y}, \quad (39)$$

where with a slight abuse of notation, the \mathbf{x}^0 in the argument of A has been replaced by n . This notation also allows for the possibility that the waveform and antenna beam pattern could be different at different points along the flight path. The time-domain version of (39) is

$$d(t, n) = \int e^{-i\omega[t-2|\mathbf{y}_n - \mathbf{y}|/c]} A(\omega, n, \mathbf{y}) V(\mathbf{y}) d\mathbf{y}. \quad (40)$$

The goal of SAR is to determine V from the data d .

As in the case of ISAR, assuming that \mathbf{y} and A are known, the data depend on two variables, so it should be possible to form a two-dimensional image. For typical radar frequencies, most of the scattering takes place in a thin layer at the surface. The ground reflectivity function V is therefore assumed to be supported on

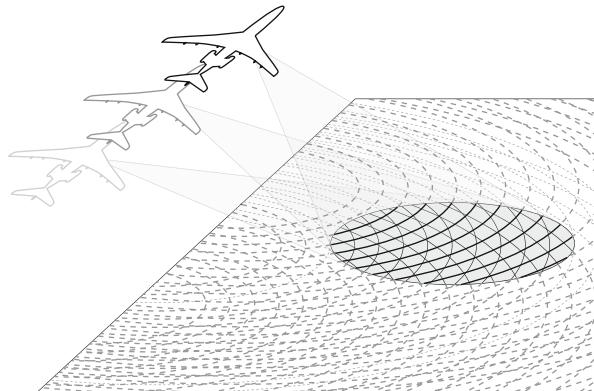

Fig. 6 In spotlight SAR, the radar is trained on a particular location as the radar moves. In this figure, the equi-range circles (dotted lines) are formed from the intersection of the radiated spherical wave front and the surface of a (flat) earth

a known surface. For simplicity this surface is assumed to be a flat plane, so that $V(\mathbf{x}) = V(\mathbf{x})\delta(x_3)$, where $\mathbf{x} = (x_1, x_2)$.

SAR imaging comes in two basic varieties: *spotlight* SAR [9, 35] and *stripmap* SAR [20, 21, 29, 60].

Spotlight SAR

Spotlight SAR is illustrated in Fig. 6. Here, the moving radar system stares at a specific location (usually on the ground), so that at each point in the flight path the same scene is illuminated from a different direction. When the ground is assumed to be a horizontal plane, the iso-range curves are large circles whose centers are directly below the antenna at \mathbf{y}_n . If the radar antenna is highly directional and the antenna footprint is sufficiently far away, then the circular arcs within the footprint can be approximated as lines. Consequently, the imaging method is mathematically the same as that used in ISAR.

In particular, the origin of coordinates is taken within the footprint, and the small-scene expansion is used, which results in an expression for the matched-filtered frequency-domain data:

$$D(\omega, n) = e^{2ik|\mathbf{y}_n|} \int e^{2ik\widehat{\mathbf{y}}_n \cdot \mathbf{y}} V(\mathbf{y}) A(\omega, n, \mathbf{y}) d\mathbf{y}. \quad (41)$$

Within the footprint, A is approximated as a product $A = A_1(\omega, n)A_2(\mathbf{y})$. The function A_1 can be taken outside the integral; the function A_2 can be divided out after inverse Fourier transforming.

As in the ISAR case, the time-domain formulation of spotlight SAR leads to a problem of inverting the Radon transform. An example of a spotlight SAR image is shown in Fig. 12.

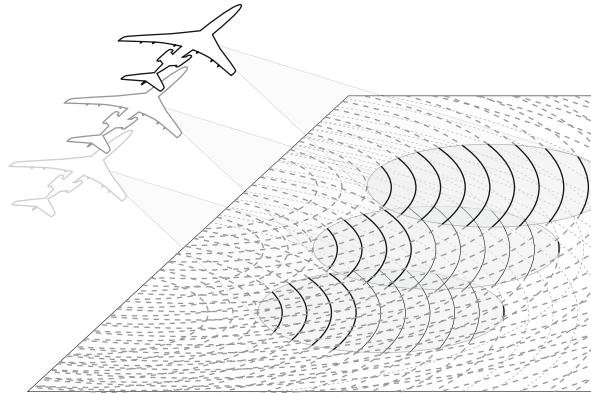

Fig. 7 Stripmap SAR acquires data without staring. The radar typically has fixed orientation with respect to the flight direction, and the data are acquired as the beam footprint sweeps over the ground

Stripmap SAR

Stripmap SAR sweeps the radar beam along with the platform without staring at a particular location on the ground (Fig. 7). The equi-range curves are still circles, but the data no longer depend only on the direction from the antenna to the scene. Moreover, because the radar does not stare at the same location, there is no natural origin of coordinates for which the small-scene expansion is valid.

To form a stripmap SAR image, the expression (39) must be inverted without the help of the small-scene approximation. One strategy is to use a filtered adjoint of the forward map F defined by Eq. (39).

The Formal Adjoint of F The adjoint F^\dagger is an operator such that

$$\langle f, Fg \rangle_{\omega,s} = \langle F^\dagger f, g \rangle_x, \quad (42)$$

where $\langle \cdot, \cdot \rangle$ denotes inner product in the appropriate variables. More specifically, (42) can be written as

$$\int f(\omega, s) (Fg)^*(\omega, s) d\omega ds = \int (F^\dagger f)(x) g^*(x) dx. \quad (43)$$

Use of (39) in (43) and an interchange of the order of integration leads to

$$F^\dagger f(x) = \iint e^{-2ik|\gamma(s)-x|} A(\omega, s, x) f(\omega, s) d\omega ds. \quad (44)$$

The Imaging Operator Thus, the imaging operator is assumed to be of the form

$$I(\mathbf{z}) = B[D](\mathbf{z}) \equiv \iint e^{-2ik|\gamma(s) - z_T|} Q(\omega, s, \mathbf{z}) D(\omega, s) d\omega ds, \quad (45)$$

where $z_T = (\mathbf{z}, 0)$ and Q is a filter to be determined below. The time-domain version is

$$I(\mathbf{z}) = \mathcal{B}[d](\mathbf{z}) \equiv \iint e^{i\omega(t - 2|\gamma(s) - z_T|/c)} Q(\omega, s, \mathbf{z}) d\omega d(t, s) ds dt. \quad (46)$$

If the filter Q were to be chosen to be identically 1, then, because of (5), the time-domain inversion would have the form

$$\begin{aligned} I(\mathbf{z}) &= \iint \delta(t - 2|\gamma(s) - z_T|/c) d(t, s) ds dt \\ &= \int d(2|\gamma(s) - z_T|/c, s) ds, \end{aligned} \quad (47)$$

which can be interpreted as follows: at each antenna position s , the data is backprojected (smeared out) to all the locations \mathbf{z} that are at the correct travel time $2|\gamma(s) - z_T|/c$ from the antenna location $\gamma(s)$. Then all the contributions are summed coherently (i.e., including the phase). Figure 8 shows the partial sums over s as the antenna (white triangle) moves along a straight flight path from bottom to top.

An alternative interpretation is that to form the image at the reconstruction point \mathbf{z} , all the contributions from the data at all points (t, s) for which $t = 2|\gamma(s) - z_T|/c$ are coherently summed.

Note the similarity between (47) and (61): (61) backprojects over lines or planes, whereas (47) backprojects over circles. The inversion (46) first applies the filter Q and then backprojects.

Other SAR Algorithms The image formation algorithm discussed here is filtered backprojection. This algorithm has many advantages, one of them being great flexibility. This algorithm can be used for any antenna beam pattern, for any flight path, and for any waveform; a straightforward extension [48] can be used in the case when the topography is not flat.

Nevertheless, there are various other algorithms that can be used in special cases, for example, if the flight path is straight, if the antenna beam is narrow, or if a chirp waveform is used. Discussions of these algorithms can be found in the many excellent radar imaging books such as [9, 20, 29, 35, 61].

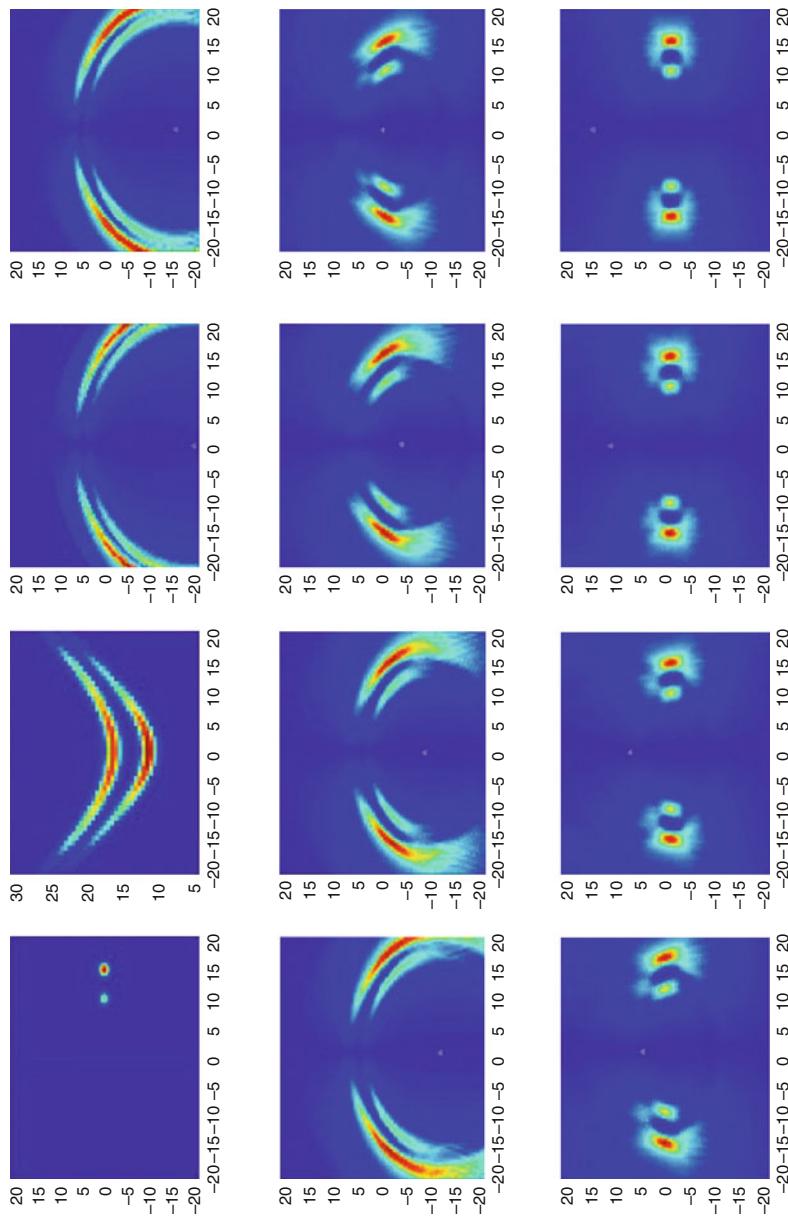

Fig. 8 This shows successive steps in the backprojection procedure for a straight flight path and an isotropic antenna. The first image is the true scene; the second is the magnitude of the data. The successive images show the image when the antenna has traveled as far as the location indicated by the small triangle

Resolution for ISAR and Spotlight SAR

To determine the resolution of an ISAR image, the relationship between the image and the target is analyzed.

For turntable geometry, (30) is used. The viewing direction is taken to be $\mathbf{x}^0 = (1, 0, 0)$, with $\hat{\mathbf{e}}_\theta = \mathcal{O}(\theta)\mathbf{x}^0$ and $\tilde{k} = 2k$. Then (32) is proportional to

$$\begin{aligned}\widetilde{D}(\tilde{k}, \theta) &= \int e^{-i\tilde{k}\hat{\mathbf{e}}_\theta \cdot \mathbf{y}} q(\mathbf{y}) d\mathbf{y} \\ &= \iint e^{-i\tilde{k}(y_1 \cos \theta + y_2 \sin \theta)} \underbrace{\int q(y_1, y_2, y_3) dy_3}_{\tilde{q}(y_1, y_2)} dy_1 dy_2.\end{aligned}\quad (48)$$

The data depend only on the quantity $\tilde{q}(y_1, y_2) = \int q(y_1, y_2, y_3) dy_3$, which is a projection of the target onto the plane orthogonal to the axis of rotation. In other words, in the turntable geometry, the radar imaging projection is the projection onto the horizontal plane. With the notation $\mathbf{y} = (y_1, y_2)$, so that $\mathbf{y} = (\mathbf{y}, y_3)$, it is clear that $\hat{\mathbf{e}}_\theta \cdot \mathbf{y} = (\mathcal{P}\hat{\mathbf{e}}_\theta) \cdot \mathbf{y}$, where $\mathcal{P} : \mathbb{R}^3 \rightarrow \mathbb{R}^2$ denotes the projection onto the first two components of a three-dimensional vector.

The data-collection manifold $\Omega = \{\tilde{k}\hat{\mathbf{e}}_\theta : \omega_1 < \omega < \omega_2 \text{ and } |\theta| < \Phi\}$ is shown in Fig. 2. Then (48) can be written as

$$\widetilde{D}(\tilde{k}, \theta) = \chi_\Omega(\tilde{k}\hat{\mathbf{e}}_\theta) \mathcal{F}[\tilde{q}](\tilde{k}\hat{\mathbf{e}}_\theta), \quad (49)$$

where $\chi_\Omega(\tilde{k}\hat{\mathbf{e}}_\theta)$ denotes the function that is 1 if $\tilde{k}\hat{\mathbf{e}}_\theta \in \Omega$ and 0 otherwise.

The image is formed by taking the two-dimensional inverse Fourier transform of (49):

$$\begin{aligned}I(\mathbf{x}) &= \iint e^{i\mathbf{x} \cdot \tilde{k}(\mathcal{P}\hat{\mathbf{e}}_\theta)} \widetilde{D}(\tilde{k}, \theta) \tilde{k} d\tilde{k} d\theta \propto \int_{\Omega} e^{i\mathbf{x} \cdot \tilde{k}(\mathcal{P}\hat{\mathbf{e}}_\theta)} \iint e^{-i\mathbf{y} \cdot \tilde{k}(\mathcal{P}\hat{\mathbf{e}}_\theta)} \tilde{q}(\mathbf{y}) d\mathbf{y} \tilde{k} d\tilde{k} d\theta \\ &= \int \underbrace{\iint_{\Omega} e^{i(\mathbf{x}-\mathbf{y}) \cdot \tilde{k}(\mathcal{P}\hat{\mathbf{e}}_\theta)} \tilde{k} d\tilde{k} d\theta}_{K(\mathbf{x} - \mathbf{y})} \tilde{q}(\mathbf{y}) d\mathbf{y}.\end{aligned}\quad (50)$$

The function K is the *point-spread function* (PSF); it is also called the *imaging kernel*, *impulse response*, or sometimes *ambiguity function*. The PSF can be written as

$$K(\mathbf{x}) \propto \iint_{\Omega} e^{i\mathbf{x} \cdot \tilde{k}(\mathcal{P}\hat{\mathbf{e}}_\theta)} \tilde{k} d\tilde{k} d\theta = \int_{|\xi|=\tilde{k}_1}^{\tilde{k}_2} \int_{-\Phi}^{\Phi} e^{i\mathbf{x} \cdot \tilde{k}(\mathcal{P}\hat{\mathbf{e}}_\theta)} \tilde{k} d\tilde{k} d\theta. \quad (51)$$

It can be calculated by writing

$$\mathbf{x} = r(\cos \psi, \sin \psi) \quad \text{and} \quad (\mathcal{P}\hat{\mathbf{e}}_\theta) = (\cos \phi, \sin \phi), \quad (52)$$

so that $\mathbf{x} \cdot (\mathcal{P}\hat{\mathbf{e}}_\theta) = r \cos(\phi - \psi)$. The “down-range” direction corresponds to $\psi = 0$ and “cross-range” corresponds to $\psi = \pi/2$.

Down-Range Resolution in the Small-Angle Case

For many radar applications, the target is viewed from only a small range of aspects $\hat{\mathbf{e}}_\theta$; in this case, the small-angle approximations $\cos \phi \approx 1$ and $\sin \phi \approx \phi$ can be used.

In the down-range direction ($\psi = 0$), under the small-angle approximation, (51) becomes

$$\begin{aligned} K(r, 0) &\approx \int_{\tilde{k}_1}^{\tilde{k}_2} \tilde{k} \int_{-\Phi}^{\Phi} e^{i\tilde{k}r} d\phi d\tilde{k} \\ &= 2\Phi \int_{\tilde{k}_1}^{\tilde{k}_2} \tilde{k} e^{i\tilde{k}r} d\tilde{k} = \frac{2\Phi}{i} \frac{d}{dr} \int_{\tilde{k}_1}^{\tilde{k}_2} e^{i\tilde{k}r} d\tilde{k} \\ &= \frac{2\Phi}{i} \frac{d}{dr} \left[e^{i\tilde{k}_0 r} \frac{b}{2} \operatorname{sinc} \frac{br}{2} \right], \end{aligned} \quad (53)$$

where $b = \tilde{k}_2 - \tilde{k}_1 = 4\pi B/c$, B is the bandwidth in hertz, and $\tilde{k}_0 = (\tilde{k}_1 + \tilde{k}_2)/2 = 2\pi(v_1 + v_2) = 2\pi v_0$, where v_0 is the center frequency in hertz.

Since $\tilde{k}_0 \gg b$, the leading order term of (53) is obtained by differentiating the exponential:

$$K(r, 0) \approx b\tilde{k}_0 \Phi e^{i\tilde{k}_0 r} \operatorname{sinc} \frac{1}{2} br, \quad (54)$$

yielding peak-to-null down-range resolution $2\pi/b = c/(2B)$. Here, it is the sinc function that governs the resolution.

Cross-Range Resolution in the Small-Angle Case

In the cross-range direction ($\psi = \pi/2$), the approximation $\cos(\phi - \psi) = \sin \phi \approx \phi$ holds under the small-angle assumption. With this approximation, the computation of (51) is

$$\begin{aligned} K(0, r) &\approx \int_{\tilde{k}_1}^{\tilde{k}_2} \tilde{k} \int_{-\Phi}^{\Phi} e^{i\tilde{k}r\phi} d\phi d\tilde{k} \\ &= \int_{\tilde{k}_1}^{\tilde{k}_2} \tilde{k} \frac{e^{i\tilde{k}r\Phi} - e^{-i\tilde{k}r\Phi}}{i\tilde{k}r} d\tilde{k} \\ &= \frac{1}{ir} \left[e^{i\tilde{k}_0 r\Phi} b \operatorname{sinc} \left(\frac{1}{2} br\Phi \right) - e^{-i\tilde{k}_0 r\Phi} b \operatorname{sinc} \left(\frac{1}{2} br\Phi \right) \right] \\ &= 2b\tilde{k}_0 \Phi \operatorname{sinc} \left(\frac{1}{2} br\Phi \right) \operatorname{sinc}(\tilde{k}_0 r\Phi). \end{aligned} \quad (55)$$

Since $\tilde{k}_0 \gg b$,

$$K(0, r) \approx 2b\tilde{k}_0\Phi \operatorname{sinc}(\tilde{k}_0 r \Phi). \quad (56)$$

Thus the peak-to-null cross-range resolution is $\pi/(\tilde{k}_0\Phi) = c/(4v_0\Phi) = \lambda_0/(4\Phi)$. Since the angular aperture is 2Φ , the cross-range resolution is λ_0 divided by twice the angular aperture.

Example Figure 9 shows a numerical calculation of K for $\phi = 12^\circ$ and two different frequency bands: $[\tilde{k}_1, \tilde{k}_2] = [0, 300]$ (i.e., $b = 300$ and $\tilde{k}_0 = 150$, and $[\tilde{k}_1, \tilde{k}_2] = [200, 300]$) (i.e., $b = 100$ and $\tilde{k}_0 = 250$). The first case is not relevant for most radar systems, which do not transmit frequencies near zero, but is relevant for other imaging systems such as X-ray tomography. These results are plotted in Fig. 9.

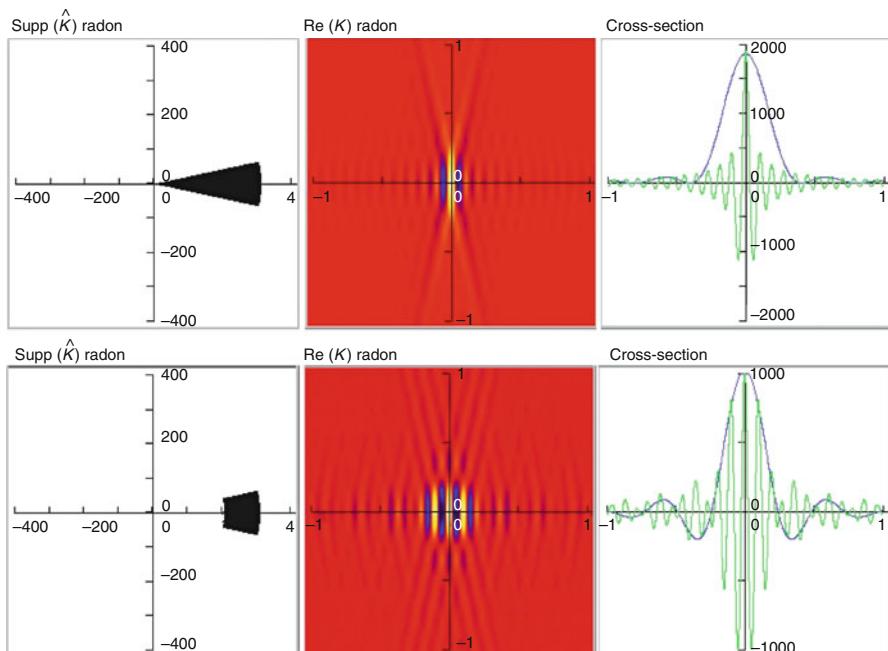

Fig. 9 From left to right: the data-collection manifold, the real part of K , cross sections (horizontal is rapidly oscillating; vertical is slowly oscillating) through the real part of K for the two cases. Down range is horizontal (Reprinted with permission from [45])

5 Numerical Methods

ISAR and Spotlight SAR Algorithms

The Polar Format Algorithm (PFA) For narrow-aperture, turntable-geometry data, such as shown in Fig. 2, the polar format algorithm (PFA) is commonly used. The PFA consists of the following steps, applied to frequency-domain data:

1. Interpolate from a polar grid to a rectangular grid (see Fig. 10.)
2. Use the two-dimensional discrete (inverse) Fourier transform to form an image of q .

Alternatively, algorithms for computing the Fourier transform directly from a nonuniform grid can be used [33, 46, 57].

Inversion by Filtered Backprojection For the n -dimensional Radon transform, one of the many inversion formulas [43, 44] is

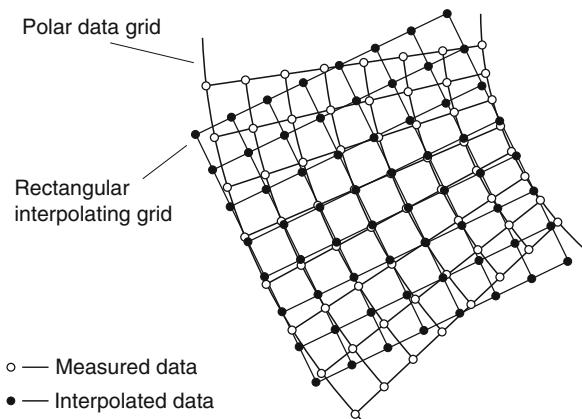

$$f = \frac{1}{2(2\pi)^{n-1}} \mathcal{R}^\dagger \mathcal{I}^{1-n} (\mathcal{R}[f]), \quad (57)$$

where \mathcal{I}^{1-n} is the Riesz operator (filter)

$$\mathcal{I}^\alpha f = \mathcal{F}^{-1} [|v|^{-\alpha} \mathcal{F} f] \quad (58)$$

operating on the s variable, and the operator \mathcal{R}^\dagger is the formal adjoint of \mathcal{R} . (Here the term “formal” means that the convergence of the integrals is not considered; the

Fig. 10 This illustrates the process of interpolating from a polar grid to a rectangular grid

identities are applied only to functions that decay sufficiently rapidly, so that the integrals converge.) The adjoint is defined by the relation

$$\langle \mathcal{R}f, h \rangle_{s,\hat{\mu}} = \langle f, \mathcal{R}^\dagger h \rangle_x, \quad (59)$$

where

$$\langle \mathcal{R}f, h \rangle_{s,\hat{\mu}} = \iint \mathcal{R}(s, \hat{\mu}) h^*(s, \hat{u}) ds d\hat{\mu} \quad (60)$$

and

$$\langle f, \mathcal{R}^\dagger h \rangle_x = \int f(x) [\mathcal{R}^\dagger h]^*(x) dx.$$

Using (37) in (60) and interchanging the order of integration show that the adjoint \mathcal{R}^\dagger operates on $h(s, \mu)$ via

$$(R^\dagger h)(x) = \int_{S^{n-1}} h(x \cdot \hat{\mu}, \hat{\mu}) d\hat{\mu}. \quad (61)$$

Here \mathcal{R}^\dagger integrates over the part of h corresponding to all planes ($n = 3$) or lines ($n = 2$) through x . When \mathcal{R}^\dagger operates on Radon data, it has the physical interpretation of *backprojection*. For example, in the case where h represents Radon data from a point-like target, for a fixed direction $\hat{\mu}$, the quantity $h(x \cdot \hat{\mu}, \hat{\mu})$, as a function of x , is constant along each plane (or line if $n = 2$) $x \cdot \hat{\mu} = \text{constant}$. Thus, at each $\hat{\mu}$, the function $h(x \cdot \hat{\mu}, \hat{\mu})$ can be thought of as an image in which the data h for direction \hat{u} is backprojected (smeared) onto all points x that could have produced the data for that direction. The integral in (61) then sums the contributions from all the possible directions. (See Fig. 11.) The inversion formula (57) is thus a *filtered backprojection* formula. Fast backprojection algorithms have been developed by a number of authors (e.g., [24, 76]).

Range Alignment

ISAR imaging relies on target/radar relative motion. An assumption made throughout is that the target moves as a rigid body – an assumption that ignores the flexing of aircraft lift and control surfaces or the motion of vehicle treads. Moreover, arbitrary rigid-body motion can always be separated into a rotation about the body's center of mass and a translation of that center of mass. Backprojection shows how the rotation part of the relative radar/target motion can be used to reconstruct a two-dimensional image of the target in ISAR and spotlight SAR. But, usually while the target is rotating and the radar system is collecting data, *the target will also be translating*,

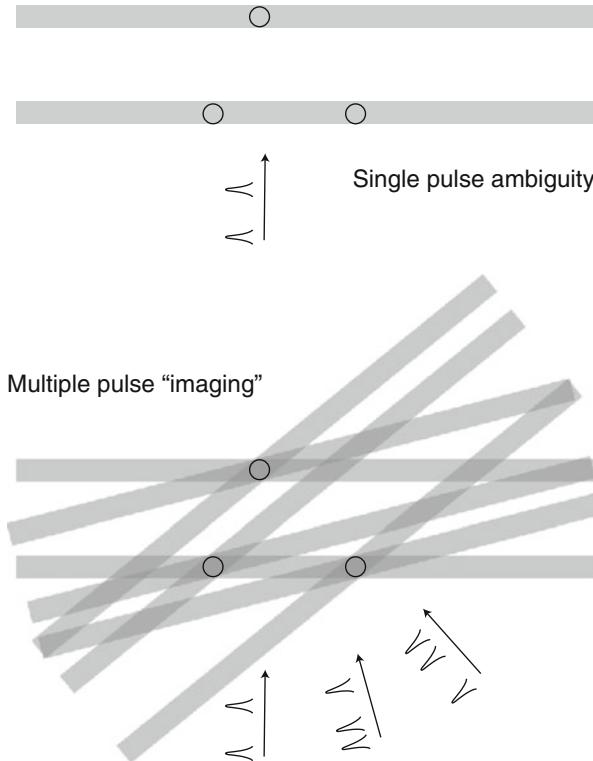

Fig. 11 This figure illustrates the process of backprojection. The range profiles (inset) suggest the time delays that would result from an interrogating radar pulse incident from the indicated direction. Note that scatterers that lie at the same range from one view do *not* lie at the same range from other views

and this has not been accounted for in the imaging algorithm. In Eqs. (27) and (28), for example, $R = |x_0|$ was implicitly set to a constant (Fig. 12).

Typically, the radar data are preprocessed to subtract out the effects of target translation before the imaging step is performed. Under the start-stop approximation, the range profile data $\eta_B(t, \theta_n)$ is approximately a shifted version of the range profile (see section “The Range Profile”) at the previous pulse. Thus $\eta_B(t, \theta_{n+1}) \approx \eta_B(t + \Delta t_n, \theta_n)$, where Δt_n is a range offset that is determined by target motion between pulses.

The collected range profiles can be shifted to a common origin if Δt_n can be determined for each θ_n . One method to accomplish this is to assume that one of the peaks in each of the range profiles (e.g., the strongest peak) is always due to the *same* target feature and so provides a convenient origin. This correction method is known as “range alignment” and must be very accurate in order to correct the offset error within a fraction of a wavelength. (Note that the wavelength in question is that of the signal output by the correlation receiver and not the wavelength of the

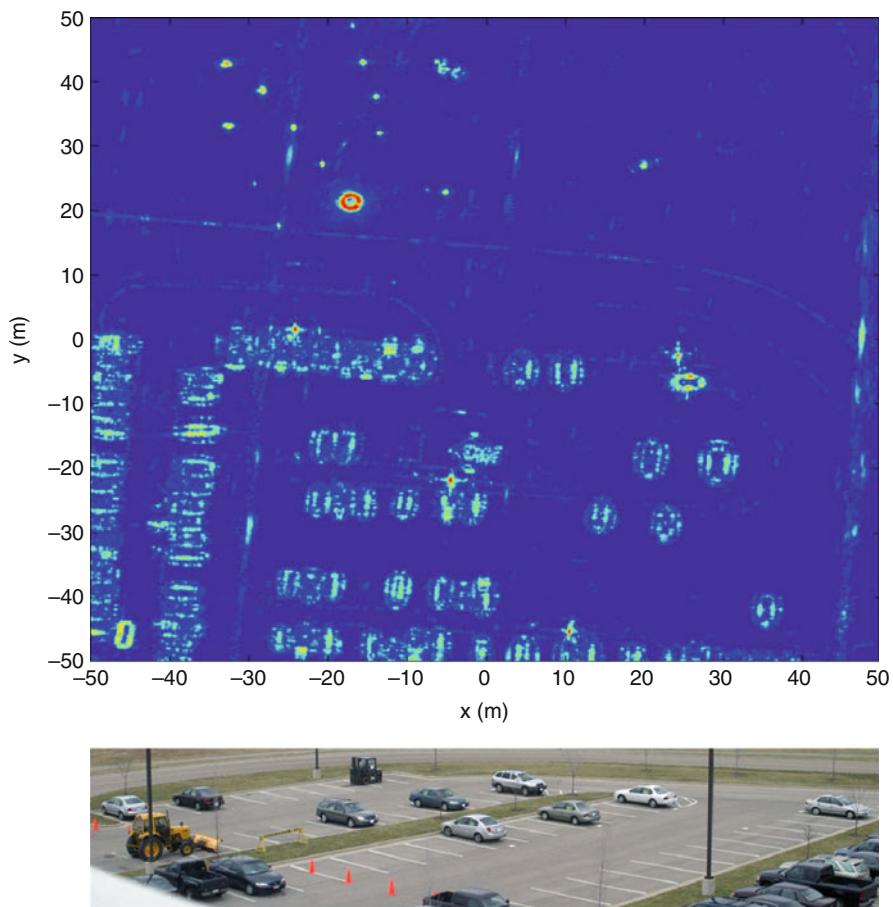

Fig. 12 A radar image from a circular flight path, together with an optical image of the same scene. The bright ring in the top half of the radar image is a “top-hat” calibration target used to focus the image (Courtesy US Air Force Sensors Directorate)

transmitted waveform. In HRR systems, however, this wavelength can still be quite small.) Typically, $\eta_B(t + \Delta t_n, \theta_n)$ is correlated with $\eta_B(t, \theta_{n+1})$, and the correlation maximum is taken to indicate the size of the shift Δt_n . This idea is illustrated in Fig. 13 which displays a collection of properly aligned range profiles.

When the scattering center used for range alignment is not a single point but, rather, several closely spaced and *unresolved* scattering centers, then additional constructive and destructive interference effects can cause the range profile alignment feature – assumed to be due to a single well-localized scatterer – to vary rapidly across the synthetic aperture (i.e., such scattering centers are said to “scintillate”). For very complex and scintillating targets, other alignment methods are used: for example, if the target is assumed to move along a “smooth” path, then estimates

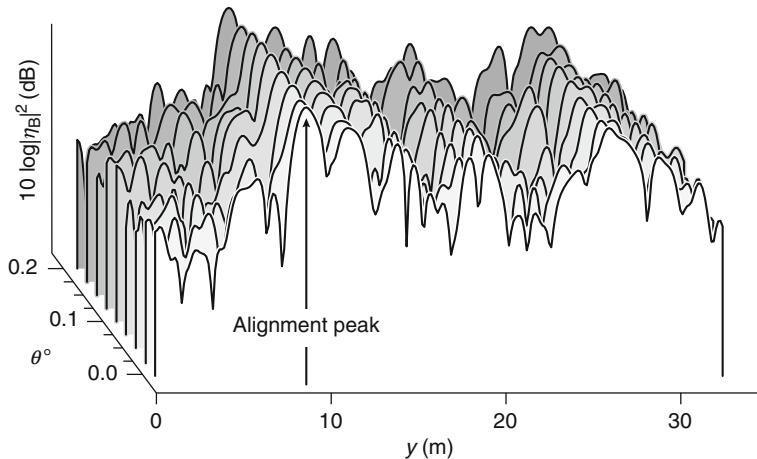

Fig. 13 Range alignment preprocessing in synthetic aperture imaging. The effects of target translation must be removed before backprojection can be applied

of its range, range rate, range acceleration, and range jerk (time derivative of acceleration) can be used to express target range as a polynomial in time

$$R(\theta_n) = R(0) + \dot{R}\theta_n + \frac{1}{2}\ddot{R}\theta_n^2 + \frac{1}{6}\dddot{R}\theta_n^3. \quad (62)$$

In terms of this polynomial,

$$\Delta t_n = 2 \frac{R(\theta_n) - R(0)}{c} = 2 \frac{\dot{R}\theta_n + \frac{1}{2}\ddot{R}\theta_n^2 + \frac{1}{6}\dddot{R}\theta_n^3}{c}, \quad (63)$$

where \dot{R} , \ddot{R} , and \dddot{R} are radar measurables.

Of course, the need for range alignment preprocessing is not limited to ISAR imaging; similar *motion compensation* techniques are needed in SAR as well (Fig. 14).

6 Open Problems

In the decades since the invention of synthetic aperture radar imaging, there has been much progress, but many open problems still remain. And most of these open problems are mathematical in nature.

As outlined at the beginning of Sect. 3, SAR imaging is based on specific assumptions, which in practice may not be satisfied. When they are not satisfied, artifacts appear in the image.

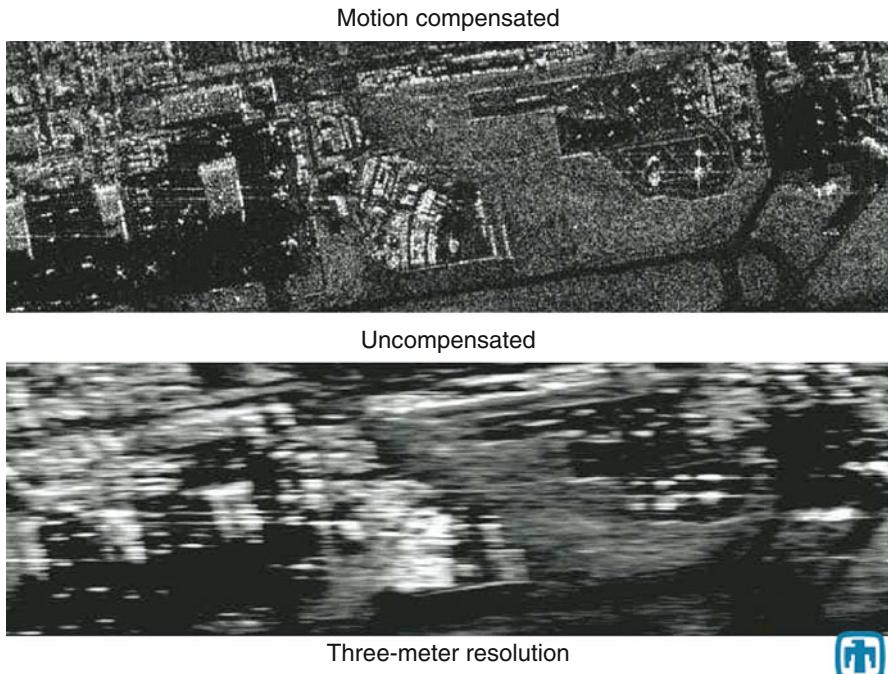

Fig. 14 The effect of motion compensation in a Ku-band image (Courtesy Sandia National Laboratories)

Problems Related to Unmodeled Motion

SAR image formation algorithms assume the scene to be stationary. Motion in the scene gives rise to mispositioning or streaking (see Figs. 15 and 16). This effect is analyzed in [28].

However, it is of great interest to use radar to identify moving objects; systems that can do this are called *moving target indicator* (MTI) systems or *ground moving target indicator* (GMTI) systems.

1. How can artifacts associated with targets that move during data collection [54] be mitigated? Moving targets cause Doppler shifts and also present different aspects to the radar [14]. An approach for exploiting unknown motion is given in [65].
2. Both SAR and ISAR are based on known relative motion between the target and sensor, for example, the assumption that the target behaves as a rigid body. When this is not the case, the images are blurred or uninterpretable. Better methods for finding the relative motion between the target and sensor are also needed [6, 65]. Better algorithms are needed for determining the antenna position from the radar

Fig. 15 A Ku-band image showing streaking due to objects moving in the scene (Courtesy Sandia National Laboratories and SPIE)

data itself. Such methods include *autofocus* algorithms [35, 40], some of which use a criterion such as image contrast to focus the image.

3. When the target motion is complex (pitching, rolling, and yawing), it may be possible to form a three-dimensional image; fast, accurate methods for doing this are needed [65]. How can moving objects be simultaneously tracked [58] and imaged?

Problems Related to Unmodeled Scattering Physics

1. How can images be formed without the Born approximation? The Born approximation leaves out many physical effects, including not only multiple scattering and creeping waves but also shadowing, obscuration, and polarization changes. But without the Born approximation (or the Kirchhoff approximation, which is similar), the imaging problem is nonlinear. In particular, how can images be formed in the presence of multiple scattering? (See [6, 13, 31, 49, 73].) Artifacts due to the Born approximation can be seen in Fig. 4, where the vertical streaks near the tail are due to multiple scattering in the engine inlets. Can multiple scattering be exploited [13, 39] to improve resolution?

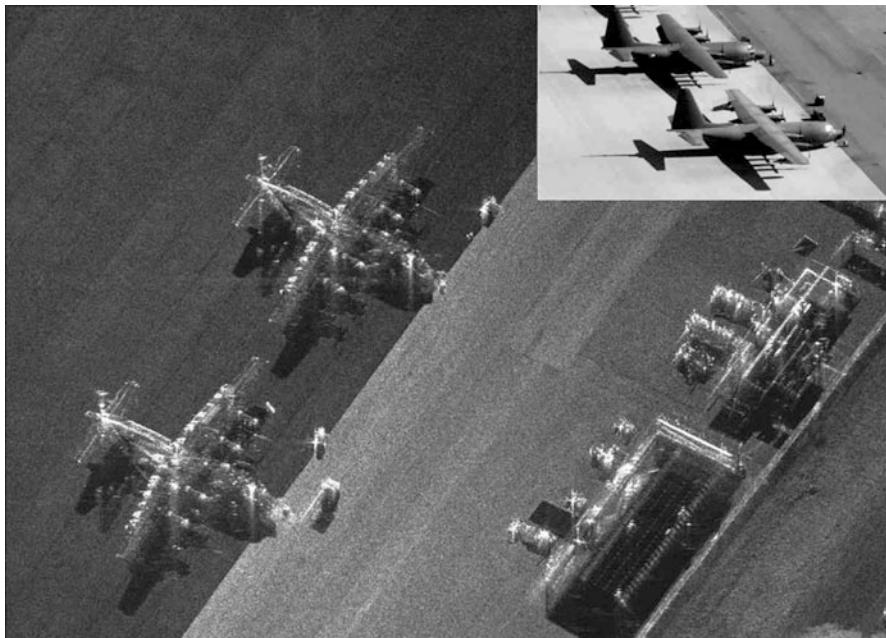

Fig. 16 A 4-in. resolution of SAR image from Sandia National Laboratories. Only certain parts of the airplanes reflect radar energy. The *inset* is an optical image of the airplanes (Courtesy Sandia National Laboratories)

2. Scattering models need to be developed that include as much of the physics as possible but are still simple enough for use in the inverse problem. An example of a simple model that includes relevant physics is [56].
3. How can polarization information [4, 17, 18, 55, 71] be exploited? This problem is closely connected to the issue of multiple scattering: the usual linear models predict no change in the polarization of the backscattered electric field. Consequently linear imaging methods cannot provide information about how scatterers change the polarization of the interrogating field. A paper that may be useful here is [68].
4. How can prior knowledge about the scene be incorporated in order to improve resolution? There is interest in going beyond simple aperture/bandwidth-defined resolution [45,66]. One approach that has been suggested is to apply compressive sensing ideas [1, 10, 42] to SAR.
5. How can information in the radar shadow be exploited? In many cases it is easier to identify an object from its shadow than from its direct-scattering image. (See Fig. 17.) A backprojection method for reconstructing an object's three-dimensional shape from its shadows obtained at different viewing angles is proposed in [23]. What determines the resolution of this reconstruction?

Fig. 17 A 4-in. resolution image from Sandia National Laboratories. Note the shadows of the historical airplane, helicopter, and trees (Courtesy of Sandia National Laboratories)

New Applications of Radar Imaging

1. Can radar systems be used to identify individuals by their gestures or gait? Time-frequency analysis of radar signals gives rise to *micro-Doppler* time-frequency images [11], in which the motion of arms and legs can be identified.
2. How can radar be used to form images of urban areas? It is difficult to form SAR images of urban areas, because in cities the waves undergo complicated multipath scattering. Areas behind buildings lie in the radar shadows, and images of tall buildings can obscure other features of interest. In addition, urban areas tend to be sources of electromagnetic radiation that can interfere with the radiation used for imaging.

One approach that is being explored is to use a *persistent* or *staring* radar system [27] that would fly in circles [61] around a city of interest (see, e.g., Fig. 12). Thus, the radar would eventually illuminate most of the areas that would be shadowed when viewed from a single direction. However, this approach has the added difficulty that the same object will look different when viewed from different directions. How can the data from a staring radar system be used to obtain the maximum amount of information about the (potentially changing) scene?

3. If sensors are flown on unoccupied aerial vehicles (UAVs), where should these UAVs fly? The notion of swarms of UAVs [2] gives rise not only to challenging problems in control theory but also to challenging imaging problems.
 4. Many of these problems motivate a variety of more theoretical open problems such as the question of whether backscattered data uniquely determines a penetrable object or a non-convex surface [63, 72]. There is a close connection between radar imaging and the theory of Fourier integral operators [48]. How can this theory be extended to the case of dispersive media and to nonlinear operators? Is it possible to develop a theory of the information content [37, 52] of an imaging system?
-

7 Conclusion

Radar imaging is a mathematically rich field with many interesting open problems.

Abstract

We define *tomography* as the process of producing an image of a distribution (of some physical property) from estimates of its line integrals along a finite number of lines of known locations. We touch upon the computational and mathematical procedures underlying the data collection, image reconstruction, and image display in the practice of tomography. The emphasis is on reconstruction methods, especially the so-called series expansion reconstruction algorithms.

We illustrate the use of tomography (including three-dimensional displays based on reconstructions) both in electron microscopy and in X-ray computerized tomography (CT), but concentrate on the latter. This is followed by a classification and discussion of reconstruction algorithms. In particular, we discuss how to evaluate and compare the practical efficacy of such algorithms.

1 Introduction

To get the flavor of tomography in general, we first discuss a special case: X-ray computerized tomography (CT) for reconstructing the distribution within a transverse section of the human body of a physical parameter (the “relative linear attenuation at energy \bar{e} ” whose value at the point (x, y) in the section is denoted by $\mu_{\bar{e}}(x, y)$) from multiple X-ray projections. A typical method by which data are collected for transverse section imaging in CT is indicated in Fig. 1. A large number of measurements are taken. Each of these measurements is related to an X-ray source position combined with an X-ray detector position, and from the measurements we can (based on physical principles) estimate the line integral of $\mu_{\bar{e}}$ along the line between the source and the detector. The mathematical problem is: given a large number of such projections, reconstruct the image $\mu_{\bar{e}}(x, y)$.

A chapter such as this can only cover a small part of what is known about tomography. A much extended treatment in the same spirit as this chapter is given in [23]. For additional information on mathematical matters related to CT, the reader may consult the books [7, 17, 24, 29, 50]. In particular, because of the mathematical orientation of this handbook, we will not get into the details of how the line integrals are estimated from the measurements. (Such details can be found in [23]. They are quite complicated: in addition to the *actual measurement* with the patient in the scanner a *calibration measurement* needs to be taken, both of these need to be normalized by the *reference detector* indicated in Fig. 1, correction has to be made for the *beam hardening* that occurs due to the X-ray beam being polychromatic rather than consisting of photons at the desired energy \bar{e} , etc.)

2 Background

The problem of image reconstruction from projections has arisen independently in a large number of scientific fields. A most-important version of the problem in medicine is CT; it has revolutionized diagnostic radiology over the past four decades. The 1979 Nobel prize in physiology and medicine was awarded to Allan M. Cormack and Godfrey N. Hounsfield for the development of X-ray computerized tomography [9, 31]. The 1982 Nobel prize in chemistry was awarded to Aaron Klug, one of the pioneers in the use of reconstruction from electron microscopic projections for the purpose of elucidation of biologically important molecular complexes [11, 13]. The 2003 Nobel prize in physiology and medicine was awarded to Paul C. Lauterbur and Peter Mansfield for their discoveries concerning magnetic resonance imaging, which also included the use of image reconstruction from projections methods [38].

In some sense this problem was solved in 1917 by Johann Radon [52]. Let ℓ denote the distance of the line L from the origin, let θ denote the angle made with the x axis by the perpendicular drawn from the origin to L (see Fig. 1), and let $m(\ell, \theta)$ denote the integral of $\mu_{\bar{e}}$ along the line L . Radon proved that

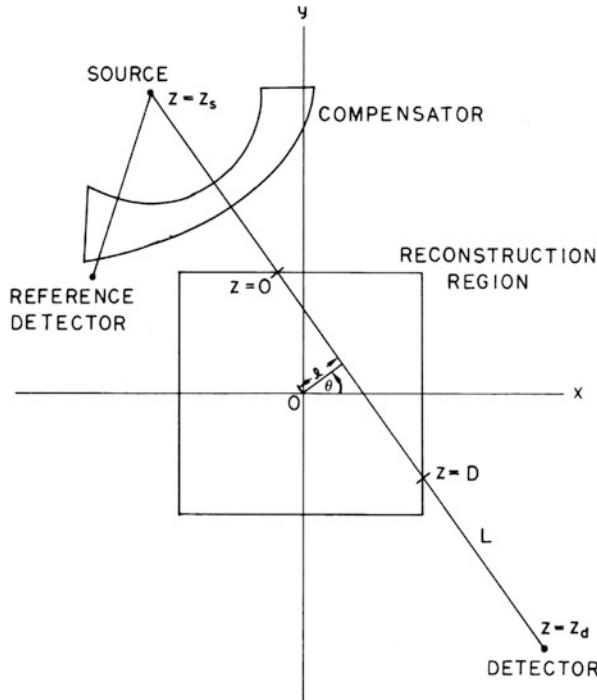

Fig. 1 Data collection for CT (reproduced from [23])

$$\mu_{\ell}(x, y) = -\frac{1}{2\pi^2} \lim_{\varepsilon \rightarrow 0} \int_{\varepsilon}^{\infty} \frac{1}{q} \int_0^{2\pi} m_1(x \cos \theta + y \sin \theta + q, \theta) d\theta dq, \quad (1)$$

where $m_1(\ell, \theta)$ denotes the partial derivative of $m(\ell, \theta)$ with respect to ℓ . The implication of this formula is clear: the distribution of the relative linear attenuation in an infinitely thin slice is uniquely determined by the set of *all* its line integrals. However:

- (a) Radon's formula determines an image from all its line integrals. In CT we have only a finite set of measurements; even if they were *exactly* integrals along lines, a finite number of them would not be enough to determine the image uniquely, or even accurately. Based on the finiteness of the data one can produce objects for which the reconstructions will be very inaccurate (Section 15.4 of [23]).
- (b) The measurements in computed tomography can only be used to estimate the line integrals. Inaccuracies in these estimates are due to the width of the X-ray beam, scatter, hardening of the beam, photon statistics, detector inaccuracies, etc. Radon's inversion formula is sensitive to these inaccuracies.
- (c) Radon gave a mathematical formula; we need an *efficient* algorithm to evaluate it. This is not necessarily trivial to obtain. There has been a very great deal of

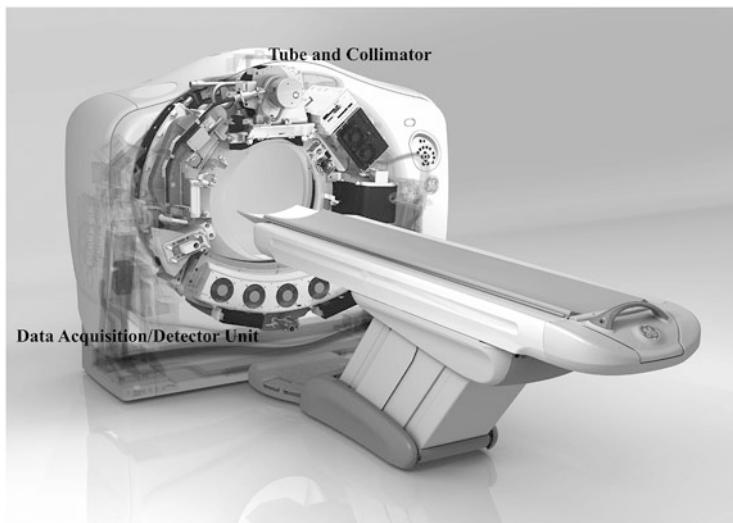

Fig. 2 Engineering rendering of a 2008 CT scanner (provided by GE Healthcare)

activity to find algorithms that are fast when implemented on a computer and yet produce acceptable reconstructions in spite of the finite and inaccurate nature of the data. This chapter concentrates on this topic.

3 Mathematical Modeling and Analysis

The mathematical model for CT is illustrated in Fig. 1. An engineering realization of this model is shown in Fig. 2. The tube contains a single X-ray source, the detector unit contains an array of X-ray detectors. Suppose for the moment that the X-ray Tube and Collimator on the one side and the Data Acquisition/Detector Unit on the other side are stationary, and the patient on the table is moved between them at a steady rate. By shooting a fan beam of X-rays through the patient at frequent regular intervals and detecting them on the other side, we can build up a two-dimensional X-ray projection of the patient that is very similar in appearance to the image that is traditionally captured on an X-ray film. Such a projection is shown in Fig. 3a. The brightness at a point is indicative of the total attenuation of the X-rays from the source to the detector. This mode of operation is *not* CT, it is just an alternative way of taking X-ray images. In the CT mode, the patient is kept stationary, but the tube and the detector unit rotate (together) around the patient. The fan beam of X-rays from the source to the detector determines a slice in the patient's body. The location of such a slice is shown by the horizontal line in Fig. 3a.

Data are collected for a number of fixed positions of the source and detector; these are referred to as *views*. For each view, we have a reading by each of

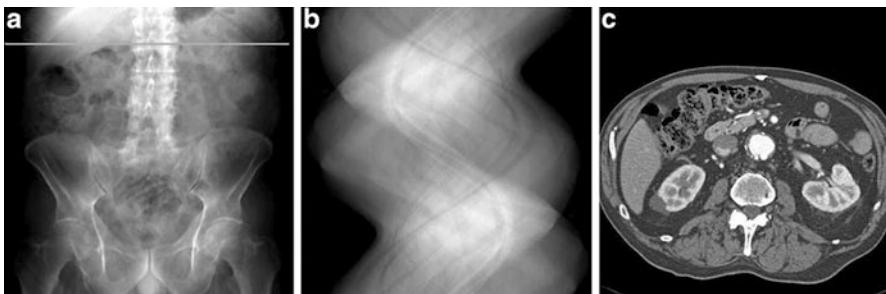

Fig. 3 (a) Digitally radiograph with *line* marking the location of the cross section for which the following images were obtained. (b) Sinogram of the projection data. (c) Reconstruction from the projection data (images were obtained using a Siemens Sensation CT scanner by R. Fahrig and J. Starman at Stanford University)

the detectors. All the detector readings for all the views can be represented as a *sinogram*, shown in Fig. 3b. The intensities in the sinogram are proportional to the line integrals of the X-ray attenuation coefficient between the corresponding source and detector positions. From these line integrals, a two-dimensional image of the X-ray attenuation coefficient distribution in the slice of the body can be produced by the techniques of image reconstruction. Such an image is shown in Fig. 3c. Inasmuch as different tissues have different X-ray attenuation coefficients, boundaries of organs can be delineated and healthy tissue can be distinguished from tumors. In this way CT produces cross-sectional slices of the human body without surgical intervention.

We can use the reconstructions of a series of parallel transverse sections to discover and display the precise shape of selected organs; see Fig. 4. Such displays are obtained by further computer processing of the reconstructed cross sections [59].

As a second illustration of the many applications of tomography (for a more complete coverage see Section 1.1 of [23]), we note that three-dimensional reconstruction of nano-scale objects (such as biological macromolecules) can be accomplished using data recorded with a transmission *electron microscope* (see Fig. 5) that produces *electron micrographs*, such as the one illustrated in Fig. 6, in which the grayness at each point is indicative of a line integral of a physical property of the object being imaged. From multiple electron micrographs one can recover the structure of the object that is being imaged; see Fig. 7.

What we have just illustrated in our electron microscopy example is a reconstruction of a three-dimensional object from two-dimensional projections; as opposed to what is shown in Fig. 1, which describes the collection of data for the reconstruction of a two-dimensional object. In fact, recently developed CT scanners are not like that, they collect a series of two-dimensional projections of the three-dimensional object to be reconstructed.

Helical CT (also referred to as *spiral CT*) first started around 1990 [10, 34] and has become standard for medical diagnostic X-ray CT. Typical state-of-the-

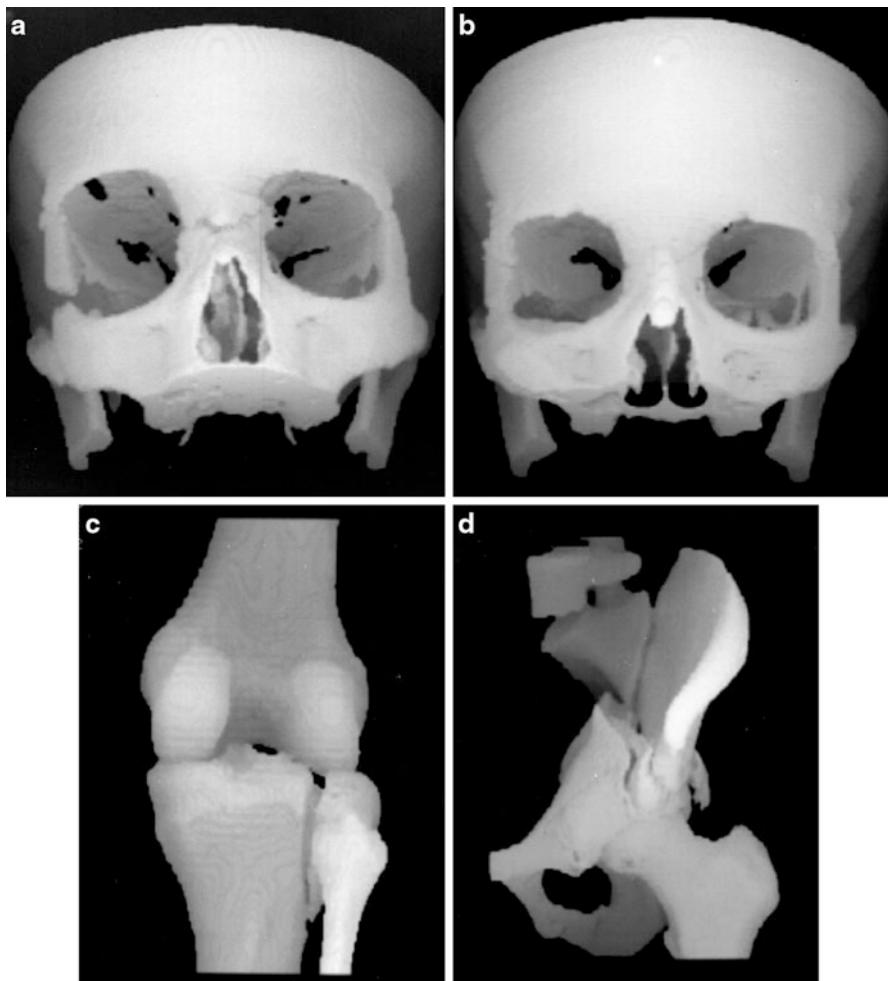

Fig. 4 Three-dimensional displays of bone structures of patients produced during 1986–1988 by software developed in the author's research group at the University of Pennsylvania for the General Electric Company. (a) Facial bones of an accident victim prior to operation. (b) The same patient at the time of a 1-year postoperative follow-up. (c) A tibial fracture. (d) A pelvic fracture (reproduced from [23])

art versions of such systems have a single X-ray source and multiple detectors in a two-dimensional array. The main innovation over previously used technologies is the presence of two independent motions: while the source and detectors rotate around the patient, the table on which the patient lies is continuously moved between them (typically orthogonally to the plane of rotation), see Fig. 8. Thus, the trajectory of the source relative to the patient is a helix (hence the name “helical CT”). Helical CT allows rapid imaging as compared with the previous commercially viable approaches, which has potentially many advantages. One example is when

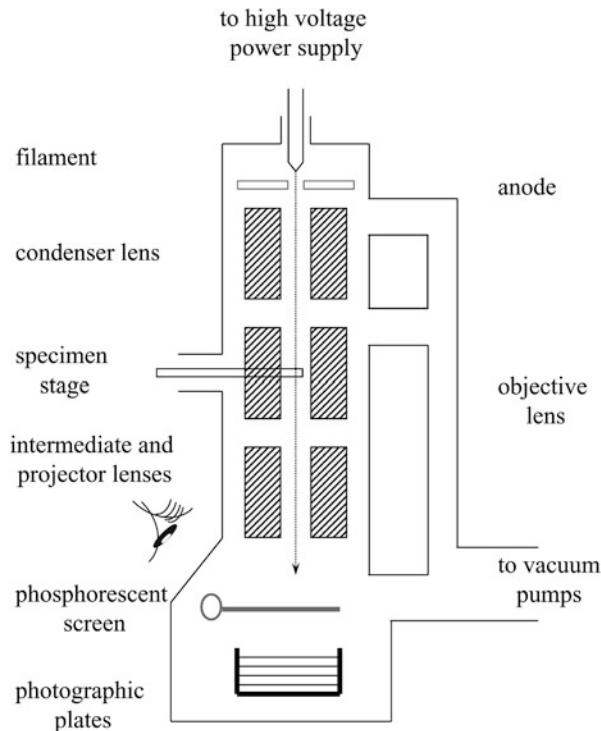

Fig. 5 Schematic drawing of a transmission electron microscope (illustration provided by C. San Martín of the Centro Nacional de Biotecnología, Spain)

we wish to image a long blood vessel that is made visible to X-rays by the injection of some contrast material: helical CT may very well allow us to image the whole vessel before the contrast from a single injection washes out and this may not be possible by the slower scanning modes. We point out that the CT scanner illustrated in Fig. 2 is in fact modern helical CT scanner.

For the sake of not over-complicating our discussion, in this chapter we restrict our attention (except where it is explicitly stated otherwise) to the problem of reconstructing two-dimensional objects from one-dimensional projections, rather than to what is done by modern helical cone-beam scanning (as in Fig. 8) and volumetric reconstruction. Schematically, the method of our data collection is shown in Fig. 9. The source and the detector strip are on either side of the object to be reconstructed and they move in unison around a common center of rotation denoted by O in Fig. 9. The data collection takes place in M distinct steps. The source and detector strip are rotated between two steps of the data collection by a small angle, but are assumed to be stationary while the measurement is taken. The M distinct positions of the source during the M steps of the data collection are indicated by the points S_0, \dots, S_{M-1} in Fig. 9. In simulating this geometry of data collection,

San Martín of the Centro Nacional de Biotecnología, Spain)

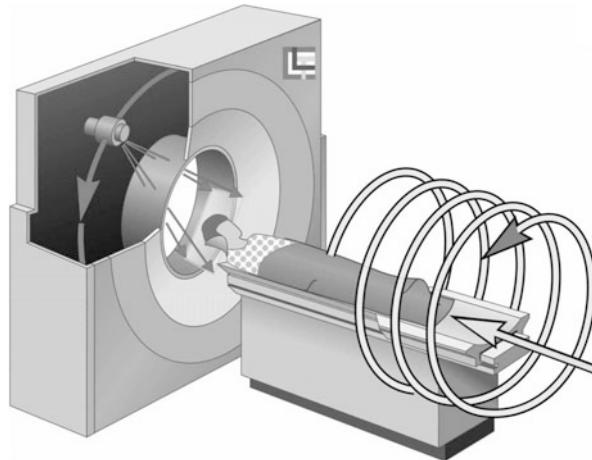

Fig. 8 Helical (also known as spiral) CT (illustration provided by G. Wang of the Virginia Polytechnic Institute & State University)

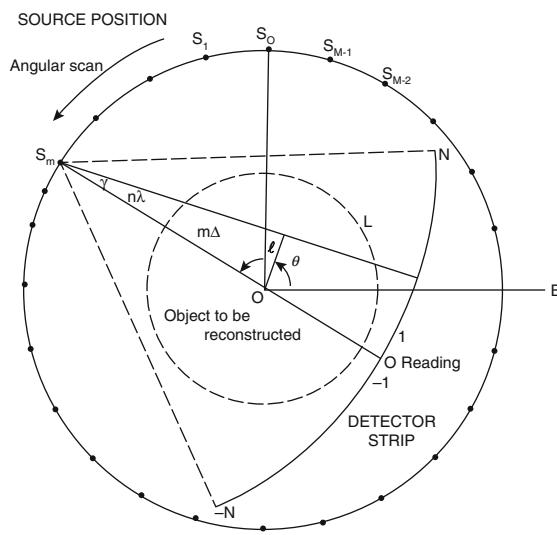

Fig. 9 Schematic of a standard method of data collection (divergent beam). This is consistent with the data collection mode for CT that is shown in Fig. 1 (reproduced from [23])

we assume that the source is a point source. The detector strip consists of $2N + 1$ detectors, spaced equally on an arc whose center is the source position. The line from the source to the center of rotation goes through the center of the central detector. (This description is that of the geometry that is assumed in much of what follows and it does not exactly match the data collection by any actual CT scanner. In particular, in real CT scanners the central ray usually does not go through the

middle of the central detector, as a 1/4 detector offset is quite common.) The object to be reconstructed is a picture such that its picture region (i.e., a region outside of which the values assigned to the picture are zero) is enclosed by the broken circle shown in Fig. 9. We assume that the origin of the coordinate system (with respect to which the picture values $\mu_{\bar{e}}(x, y)$ are defined) is the center of rotation, O, of the apparatus.

Until now we have used $\mu_{\bar{e}}(x, y)$ to denote the relative linear attenuation at the point (x, y) , where (x, y) was in reference to a rectangular coordinate system, see Fig. 1. However, it is often more convenient to use polar coordinates. We use the phrase a *function of two polar variables* to describe a function f whose values $f(r, \phi)$ represent the value of some physical parameter (such as the relative linear attenuation) at the geometrical point whose polar coordinates are (r, ϕ) .

We define the *Radon transform* $\mathcal{R}f$ of a function f of two polar variables as follows: for any real number pairs (ℓ, θ) ,

$$\begin{aligned} [\mathcal{R}f](\ell, \theta) &= \int_{-\infty}^{\infty} f\left(\sqrt{\ell^2 + z^2}, \theta + \tan^{-1}(z/\ell)\right) dz, \quad \text{if } \ell \neq 0, \\ [\mathcal{R}f](0, \theta) &= \int_{-\infty}^{\infty} f(z, \theta + \pi/2) dz. \end{aligned} \tag{2}$$

Observing Fig. 1, we see that $[\mathcal{R}f](\ell, \theta)$ is the line integral of f along the line L . (Note that the dummy variable z in (2) does not exactly match the variable z as indicated in Fig. 1. In (2) $z = 0$ corresponds to the point where the perpendicular dropped on L from the origin meets L .)

In tomography we may assume that a *picture function* has bounded support; i.e., that there exists a real number E , such that $f(r, \phi) = 0$ if $r > E$. (E can be chosen as the radius of the broken circle in Fig. 9, which should enclose the square-shaped reconstruction region in Fig. 1.) For such a function, $[\mathcal{R}f](\ell, \theta) = 0$ if $\ell > E$.

The input data to a reconstruction algorithm are estimates (based on physical measurements) of the values of $[\mathcal{R}f](\ell, \theta)$ for a finite number of pairs (ℓ, θ) ; its output is an estimate, in some sense, of f . Suppose that estimates of $[\mathcal{R}f](\ell, \theta)$ are known for I pairs: $(\ell_1, \theta_1), \dots, (\ell_I, \theta_I)$. For $1 \leq i \leq I$, we define $\mathcal{R}_i f$ by

$$\mathcal{R}_i f = [\mathcal{R}f](\ell_i, \theta_i). \tag{3}$$

In what follows we use y_i to denote the available estimate of $\mathcal{R}_i f$ and we use y to denote the I -dimensional vector whose i th component is y_i . We refer to the vector y as the *measurement vector*. When designing a reconstruction algorithm we assume that the method of data collection, and hence the set $\{(\ell_1, \theta_1), \dots, (\ell_I, \theta_I)\}$, is fixed and known. The reconstruction problem is

given the data y , **estimate** the picture f .

We shall usually use f^* to denote the estimate of the picture f .

In the mathematical idealization of the reconstruction problem, what we are looking for is an operator \mathcal{R}^{-1} , which is an *inverse* of \mathcal{R} in the sense that, for any picture function f , $\mathcal{R}^{-1}\mathcal{R}f$ is f (i.e., \mathcal{R}^{-1} associates with the function $\mathcal{R}f$ the function f). Just as (2) describes how the value of $\mathcal{R}f$ is defined at any real number pair (ℓ, θ) based on the values f assumes at points in its domain, we need a formula that for functions p of two real variables defines $\mathcal{R}^{-1}p$ at points (r, ϕ) . Such a formula is

$$[\mathcal{R}^{-1}p](r, \phi) = \frac{1}{2\pi^2} \int_0^\pi \int_{-E}^E \frac{1}{r \cos(\theta - \phi) - \ell} p_1(\ell, \theta) d\ell d\theta, \quad (4)$$

where $p_1(\ell, \theta)$ denotes the partial derivative of $p(\ell, \theta)$ with respect to ℓ ; it is of interest to compare this formula with (1). That the \mathcal{R}^{-1} defined in this fashion is indeed the inverse of \mathcal{R} is proven, for example, in Section 15.3 of [23].

A major category of algorithms for image reconstruction calculate f^* based on (4), or on alternative expressions for the inverse Radon transform \mathcal{R}^{-1} . We refer to this category as *transform methods*. While (4) provides an exact mathematical inverse, in practice it needs to be evaluated based on finite and imperfect data using the not unlimited capabilities of computers. The essence of any transform method is a *numerical procedure* (i.e., one that can be implemented on a digital computer), which estimates the value of a double integral, such as the one that appears on the right-hand side of (4), from given values of $y_i = p(\ell_i, \theta_i)$, $1 \leq i \leq I$. A very widely used example of transform methods is the so-called *filtered backprojection* (FBP) algorithm. The reason for this name can be understood by looking at the right-hand side of (4): the inner integral is essentially a filtering of the projection data for a fixed θ and the outer integral backprojects the filtered data into the reconstruction region. However, the implementational details for the divergent beam data collection specified in Fig. 9 are less than obvious, the solution outlined below is based on [28].

The data collection geometry we deal with is also described in Fig. 10. The X-ray source is always on a circle of radius D around the origin. The detector strip is an arc centered at the source. Each line can be considered as one of a set of divergent lines (σ, β) , where β determines the source position and σ determines which of the lines diverging from this source position we are considering. This is an alternative way of specifying lines to the (ℓ, θ) notation used previously (in particular in Fig. 1). Of course, each (σ, β) line is also an (ℓ, θ) line, for some values of ℓ and θ that depend on σ and β . We use $g(\sigma, \beta)$ to denote the line integral of f along the line (σ, β) . Clearly,

$$g(\sigma, \beta) = [\mathcal{R}f](D \sin \sigma, \beta + \sigma). \quad (5)$$

As shown in Fig. 9, we assume that projections are taken for M equally spaced values of β with angular spacing Δ , and that for each view the projected values are sampled at $2N + 1$ equally spaced angles with angular spacing λ . Thus g is known at points $(n\lambda, m\Delta)$, $-N \leq n \leq N$, $0 \leq m \leq M - 1$, and $M\Delta = 2\pi$.

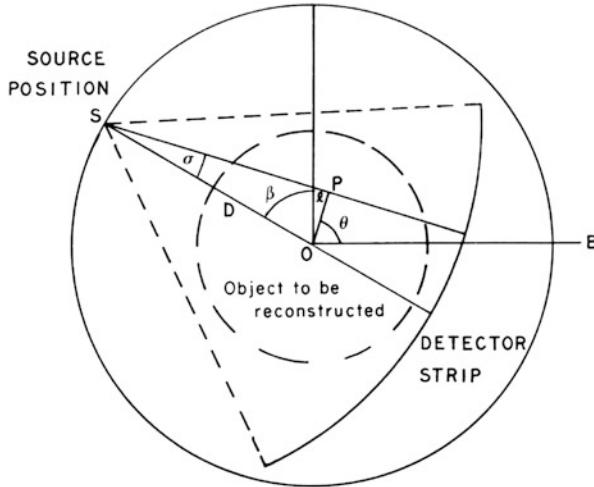

Fig. 10 Geometry of divergent beam data collection. Every one of the diverging lines is determined by two parameters β and σ . Let O be the origin and S be the position of the source, which always lies on a circle of radius D around O . Then $\beta + \pi/2$ is the angle the line OS makes with the baseline B and σ is the angle the divergent line makes with SO . The divergent line is also one of a set of parallel lines. As such it is determined by the parameters ℓ and θ . Let P be the point at which the divergent line meets the line through O that is perpendicular to it. Then ℓ is the distance from O to P and θ is the angle that OP makes with the baseline (reproduced from [22], Copyright 1981)

Even though the projection data consist of estimates (based on measurements) of $g(n\lambda, m\Delta)$, we use the same notation $g(n\lambda, m\Delta)$ for these estimates. The numerical implementation of the FBP method for divergent beams is carried out in two stages.

First we define, for $-N \leq n' \leq N$,

$$\begin{aligned} g_c(n'\lambda, m\Delta) = & \lambda \sum_{n=-N}^N \cos(n\lambda) g(n\lambda, m\Delta) q^{(1)}((n' - n)\lambda) \\ & + \lambda \cos(n'\lambda) \sum_{n=-N}^N g(n\lambda, m\Delta) q^{(2)}((n' - n)\lambda). \end{aligned} \quad (6)$$

The functions $q^{(1)}$ and $q^{(2)}$ determine the nature of the “filtering” in the filtered backprojection method. They are not arbitrary, but there are many possible choices for them, for a detailed discussion see Chapter 10 of [23]. Note that the first sum in (6) is a discrete convolution of $q^{(1)}$ and the projection data weighted by a cosine function, and the second sum is a discrete convolution of $q^{(2)}$ and the projection data.

Second we specify our reconstruction by

$$f^*(r, \phi) = \frac{D\Delta}{4\pi^2} \sum_{m=0}^{M-1} \frac{1}{W^2} g_c(\sigma', m\Delta), \quad (7)$$

where

$$\sigma' = \tan^{-1} \frac{r \cos(m\Delta - \phi)}{D + r \sin(m\Delta - \phi)}, \quad -\frac{\pi}{2} \leq \sigma' \leq \frac{\pi}{2}, \quad (8)$$

and

$$W = \left((r \cos(m\Delta - \phi))^2 + (D + r \sin(m\Delta - \phi))^2 \right)^{1/2}, \quad W > 0. \quad (9)$$

The meanings of σ' and W are that when the source is at angle $m\Delta$, the line that goes through (r, ϕ) is $(\sigma', m\Delta)$ and the distance between the source and (r, ϕ) is W . Implementation of (7) involves interpolation for approximating $g_c(\sigma', m\Delta)$ from values of $g_c(n'\lambda, m\Delta)$. The nature of such an interpolation is discussed in some detail in Section 8.5 of [23]. Note that (7) can be described as a “weighted backprojection.” Given a point (r, ϕ) and a source position $m\Delta$, the line $(\sigma', m\Delta)$ is exactly the line from the source position $m\Delta$ through the point (r, ϕ) . The contribution of the convolved ray sum $g_c(\sigma', m\Delta)$ to the value of f^* at points (r, ϕ) that the line goes through is inversely proportional to the square of the distance of the point (r, ϕ) from the source position $m\Delta$.

In this chapter we concentrate on the other major category of reconstruction algorithms, the so-called *series expansion methods*. In transform methods the techniques of mathematical analysis are used to find an inverse of the Radon transform. The inverse transform is described in terms of operators on functions defined over the whole continuum of real numbers. For implementation of the inverse Radon transform on a computer we have to replace these continuous operators by discrete ones that operate on functions whose values are known only for finitely many values of their arguments. This is done at the very end of the derivation of the reconstruction method. The series expansion approach is basically different. The problem itself is discretized at the very beginning: estimating the function is translated into finding a finite set of numbers. This is done as follows.

For any specified picture region, we fix a set of J basis functions $\{b_1, \dots, b_J\}$. These ought to be chosen so that, for any picture f with the specified picture region that we may wish to reconstruct, there exists a linear combination of the basis functions that we consider an adequate approximation to f .

An example of such an approach is the $n \times n$ digitization in which we cover the picture region by an $n \times n$ array of identical small squares, called *pixels*. In this case $J = n^2$. We number the pixels from 1 to J , and define

$$b_j(r, \phi) = \begin{cases} 1, & \text{if } (r, \phi) \text{ is inside the } j\text{th pixel,} \\ 0, & \text{otherwise.} \end{cases} \quad (10)$$

Then the $n \times n$ *digitization* of the picture f is the picture \hat{f} defined by

$$\hat{f}(r, \phi) = \sum_{j=1}^J x_j b_j(r, \phi), \quad (11)$$

where x_j is the average value of f inside the j th pixel. A shorthand notation we use for equations of this type is $\hat{f} = \sum_{j=1}^J x_j b_j$.

Another (and usually preferable) way of choosing the basis functions is the following. *Generalized Kaiser–Bessel window functions*, which are also known by the simpler name *blobs*, form a large family of functions that can be defined in a Euclidean space of any dimension [40]. Here we restrict ourselves to a subfamily in the two-dimensional plane, whose elements have the form

$$b_{a,\alpha,\delta}(r, \phi) = \begin{cases} C_{a,\alpha,\delta} \left(1 - \left(\frac{r}{a}\right)^2\right) I_2 \left(\alpha \sqrt{1 - \left(\frac{r}{a}\right)^2}\right), & \text{if } 0 \leq r \leq a, \\ 0, & \text{otherwise,} \end{cases} \quad (12)$$

where I_k denotes the modified Bessel function of the first kind of order k , a stands for the nonnegative radius of the blob, and α is a nonnegative real number that controls the shape of the blob. The multiplying constant $C_{a,\alpha,\delta}$ is defined below. Note that such a blob is circularly symmetric, since its value does not depend on ϕ . It has the value zero for all $r \geq a$ and its first derivatives are continuous everywhere. The “smoothness” of blobs can be controlled by the choice of the parameters a , α and δ , they can be made very smooth indeed as shown in Fig. 11.

For now let us consider the parameters a , α and δ , and hence the function $b_{a,\alpha,\delta}$, to be fixed. This fixed function gives rise to a set of J basis functions $\{b_1, \dots, b_J\}$ as follows. We define a set $G = \{g_1, \dots, g_J\}$ of *grid points* in the picture region. Then, for $1 \leq j \leq J$, b_j is obtained from $b_{a,\alpha,\delta}$ by shifting it in the plane so that its center is moved from the origin to g_j . This definition leaves a great deal of freedom in the selection of G , but it was found in practice advisable that it should consist of those points of a set (in rectangular coordinates)

$$G_\delta = \left\{ \left(\frac{m\delta}{2}, \frac{\sqrt{3}n\delta}{2} \right) \middle| m \text{ and } n \text{ are integers and } m + n \text{ is even} \right\} \quad (13)$$

that are also in the picture region. Here δ has to be a positive real number and G_δ is referred to as the *hexagonal grid with sampling distance* δ . Having fixed δ , we complete the definition in (12) by

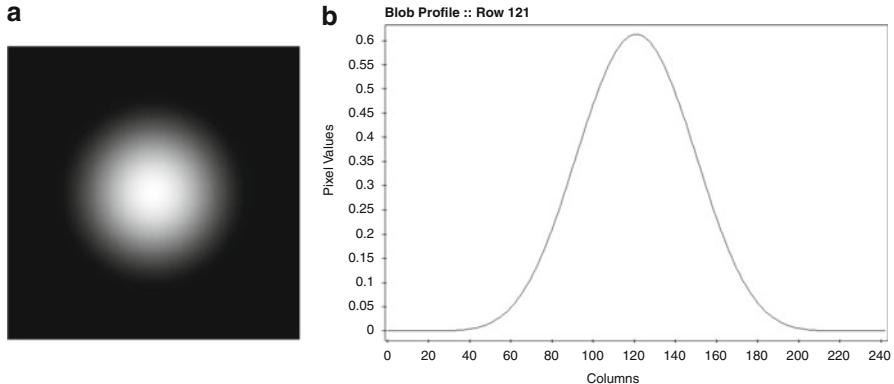

Fig. 11 (a) A 243×243 digitization of a blob. (b) Its values on the central row (reproduced from [23])

$$C_{a,\alpha,\delta} = \frac{\sqrt{3}\delta^2\alpha}{4\pi a^2 I_3(\alpha)}. \quad (14)$$

Pixel-based basis functions (10) have a unit value inside the pixels and zero outside. Blobs, on the other hand, have a bell-shaped profile that tapers smoothly in the radial direction from a high value at the center to the value 0 at the edge of their supports (i.e., at $r = a$ in (12)); see Fig. 11. The smoothness of blobs suggests that reconstructions of the form (11) are likely to be resistant to noise in the data. This has been shown to be particularly useful in fields in which the projection data are noisy, such as positron emission tomography and electron microscopy.

For blobs to achieve their full potential, the selection of the parameters a , α , and δ is important. When they are properly chosen [46], one can approximate homogeneous regions very well, in spite of the bell-shaped profile of the individual blobs. This is illustrated in Fig. 12b, in which a bone cross section shown in Fig. 12a is approximated by a linear combination of blob basis functions with the parameters $a = 0.1551$, $\alpha = 11.2829$, and $\delta = 0.0868$. There are some inaccuracies very near the sharp edges, but the interior of the bone is approximated with great accuracy. However, if we change the parameters ever so slightly to $a = 0.16$, $\alpha = 11.28$, and $\delta = 0.09$, then the best approximation that can be obtained by a linear combination of blob basis functions is shown in Fig. 12c, which is clearly inferior.

Irrespective of how the basis functions have been chosen, any picture \hat{f} that can be represented as a linear combination of the basis functions b_j is uniquely determined by the choice of the coefficients x_j , $1 \leq j \leq J$, in the formula (11). We use x to denote the vector whose j th component is x_j and refer to x as the *image vector*.

It is easy to see that, under some mild mathematical assumptions,

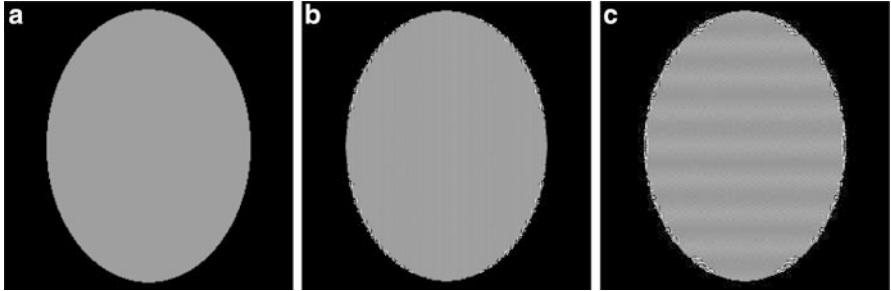

Fig. 12 (a) A 243×243 digitization of a bone cross section. (b) Its approximation with default blob parameters and (c) with slightly different parameters. The display window is very narrow for better indication of errors (reproduced from [23])

$$\mathcal{R}_i f \simeq \mathcal{R}_i \hat{f} = \sum_{j=1}^J x_j \mathcal{R}_i b_j, \quad (15)$$

for $1 \leq i \leq I$. Since the b_j are user-defined, usually the $\mathcal{R}_i b_j$ can be easily calculated by analytical means. For example, in the case when the b_j are defined by (10), $\mathcal{R}_i b_j$ is just the length of intersection with the j th pixel of the line of the i th position of the source-detector pair. We use $r_{i,j}$ to denote our calculated value of $\mathcal{R}_i b_j$. Hence,

$$r_{i,j} \simeq \mathcal{R}_i b_j. \quad (16)$$

Recall that y_i denotes the physically obtained estimate of $\mathcal{R}_i f$. Combining this with (15) and (16), we get that, for $1 \leq i \leq I$,

$$y_i \simeq \sum_{j=1}^J r_{i,j} x_j. \quad (17)$$

Let R denote the matrix whose (i, j) th element is $r_{i,j}$. We refer to this matrix as the *projection matrix*. Let e be the I -dimensional column vector whose i th component, e_i , is the difference between the left- and right-hand sides of (17). We refer to this as the *error vector*. Then (17) can be rewritten as

$$y = Rx + e. \quad (18)$$

The series expansion approach leads us to the following *discrete reconstruction problem*: based on (18),

given the data y , **estimate** the image vector x .

If the estimate that we find as our solution to the discrete reconstruction problem is the vector x^* , then the estimate f^* to the picture to be reconstructed is given by

$$f^* = \sum_{j=1}^J x_j^* b_j. \quad (19)$$

In (18), the vector e is unknown. The simple approach of trying to solve (18) by first assuming that e is the zero vector is dangerous: $y = Rx$ may have no solutions, or it may have many solutions, possibly none of which is any good for the practical problem at hand. Some criteria have to be developed, indicating which x ought to be chosen as a solution of (18). One way of doing this is by considering both the image vector x and the error vector e to be samples of random variables, denoted by X and E , respectively.

As an example of such an approach, let μ denote a J -dimensional vector of real numbers and let V denote a $J \times J$ positive definite symmetric matrix of real numbers. We can define a function p_X over the set of all J -dimensional vectors of real numbers by

$$p_X(x) = \frac{1}{(2\pi)^{J/2}(\det V)^{1/2}} \exp\left(-\frac{1}{2}(x - \mu)^T V^{-1} (x - \mu)\right). \quad (20)$$

This p_X is a probability density function of a random variable X on the set of all J -dimensional vectors of real numbers whose mean vector is $\mu_x = \mu$ and whose covariance matrix is $V_X = V$. A random variable X defined in such a fashion is called a *multivariate Gaussian random variable*.

Let us now consider the random variables X and E associated with x and e of (18) without assuming any special form for them. In any case, p_X is referred to as the *prior probability density function*, since $p_X(x)$ indicates the likelihood of coming across an image vector similar to x . In CT it makes sense to adjust p_X to the area of the body we are imaging; the probabilities of the same picture representing a cross section of the head or of the thorax should be different. Based on p_X and p_E , a reasonable approach to solving the discrete reconstruction problem is: given the data y , choose the image vector x for which the value of

$$p_E(y - Rx)p_X(x) \quad (21)$$

is as large as possible. Note that the second term in the product is large for vectors x that have large prior probabilities, while the first term is large for vectors x that are consistent with the data (at least if p_E peaks at the zero vector). The relative importance of the two terms depends on the nature of p_X and p_E . If p_X is flat (many image vectors are equally likely) and p_E is highly peaked near the zero vector, then our criterion will produce an image vector x^* that fits the measured data y in the sense that Rx^* will be nearly the same as y . On the other hand, if p_E is flat (large errors are nearly as likely as small ones) but p_X is highly peaked, our having

made our measurements will have only a small effect on our preconceived idea as to how the image vector should be chosen. The x^* that maximizes (21) is called the *Bayesian estimate*. The discussion in this paragraph is quite general, since we have not assumed anything regarding the form of the random variables X and E .

If we assume that both X and E are multivariate Gaussian, then maximizing (21) becomes relatively simple. In that case it is easy to see from (20) that, assuming that μ_E is the zero vector, the x that maximizes (21) is the same x that minimizes

$$(y - Rx)^T V_E^{-1} (y - Rx) + (x - \mu_X)^T V_X^{-1} (x - \mu_X). \quad (22)$$

When more precise information regarding the mean vector μ_X is not available, one can use for it a uniform picture, with an estimated (based on the projection data) average value assigned to every pixel; how well this works out in practice is illustrated below in the section on Numerical Methods and Case Examples. We also illustrate there an alternative choice that is appropriate for cardiac imaging in which μ_X is a time-averaged reconstruction. The noise model expressed by the first term of (22) is only approximate, but it is a reasonable accurate approximation of the effect of photon statistics in CT (see Section 3.1 of [23]).

As representative examples of the series expansion methods for image reconstruction we now discuss the *algebraic reconstruction techniques* (ART). All ART methods of image reconstruction are iterative procedures: they produce a sequence of vectors $x^{(0)}, x^{(1)}, \dots$ that is supposed to *converge* to x^* . The process of producing $x^{(k+1)}$ from $x^{(k)}$ is referred to as an *iterative step*.

In ART, $x^{(k+1)}$ is obtained from $x^{(k)}$ by considering a single one of the I approximate equations, see (17). In fact, the equations are used in a *cyclic order*. We use i_k to denote $k(\text{mod } I) + 1$; i.e., $i_0 = 1, i_1 = 2, \dots, i_{I-1} = I, i_I = 1, i_{I+1} = 2, \dots$, and we use r_i to denote the J -dimensional column vector whose j th component is $r_{i,j}$. In other words, r_i is the transpose of the i th row of R . (In what follows we assume that, for $1 \leq i \leq I$, $\|r_i\|^2 = \langle r_i, r_i \rangle \neq 0$, where, as usual, $\|\bullet\|$ denotes the norm and $\langle \bullet, \bullet \rangle$ denotes the inner product.) An important point here is that this specification is incomplete because it depends on how we index the lines for which the integrals are estimated. As stated above, we assume that estimates of $[\mathcal{R}f](\ell, \theta)$ are known for I pairs: $(\ell_1, \theta_1), \dots, (\ell_I, \theta_I)$. However, we have not specified the geometrical locations of the lines that are parametrized by these pairs. Since the order in which we do things in ART depends on the indexing i for the set of lines for which data are collected, the specification of ART as a reconstruction algorithm is complete only if it includes the indexing method for the lines, which we refer to as the *data access ordering*. We return to this point later on in this chapter.

A particularly simple variant of ART is the following.

$$\begin{aligned} x^{(0)} &\text{ is arbitrary,} \\ x^{(k+1)} &= x^{(k)} + c^{(k)} r_{i_k}, \end{aligned} \quad (23)$$

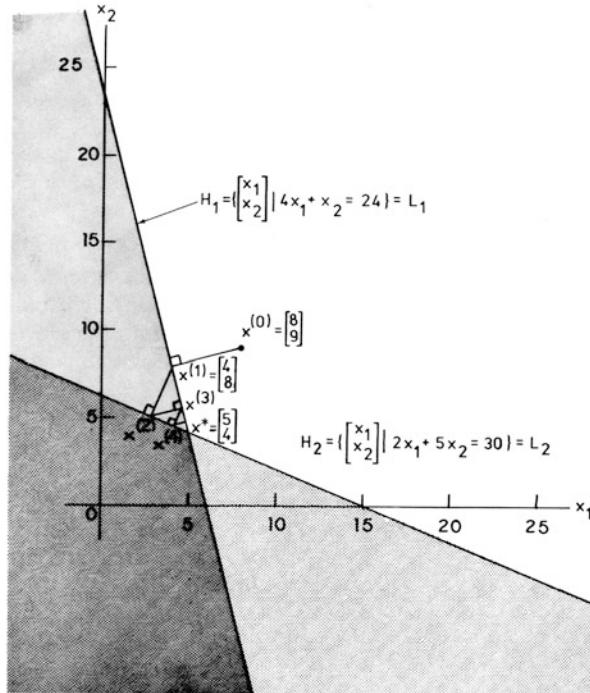

Fig. 13 Demonstration of the method of (23) and (24) (with $\lambda^{(k)} = 1$, for all k) for the simple case when $I = J = 2$ (illustration based on [25], Copyright 1976, with permission from Elsevier)

where

$$c^{(k)} = \lambda^{(k)} \frac{y_{i_k} - \langle r_{i_k} x^{(k)} \rangle}{\|r_{i_k}\|^2}, \quad (24)$$

with each $\lambda^{(k)}$ a real number, referred to as a *relaxation parameter*. It is easy to check that, for $k \geq 0$, if $\lambda^{(k)} = 1$, then

$$y_{i_k} = \sum_{j=1}^J r_{i_k, j} x_j^{(k+1)}, \quad (25)$$

i.e., the i_k th approximate equality is exactly satisfied after the k th step. This behavior is illustrated in Fig. 13 for a two-dimensional case with two equalities.

This method has an interesting, although by itself not particularly useful, mathematical property. Let

$$L = \{x | Rx = y\}. \quad (26)$$

A sequence $x^{(0)}, x^{(1)}, x^{(2)}, \dots$ generated by (23) and (24) converges to a vector x^* in L , provided that L is not empty and that, for some ε_1 and ε_2 and for all k ,

$$0 < \varepsilon_1 \leq \lambda^{(k)} \leq \varepsilon_2 < 2. \quad (27)$$

Furthermore, if x^0 is chosen to be the vector with zero components, then

$$\|x^*\| < \|x\|, \quad (28)$$

for all x in L other than x^* . A proof of this can be found in Section 11.2 of [23].

The reason why this result is not useful by itself is that the condition that L is not empty is unlikely to be satisfied in a real tomographic situation. However, as it is shown in Section 11.3 of [23], it can be used to derive an alternative ART algorithm that is useful in real applications, as we now explain.

Let us make the simplifying assumptions in (22) that V_X and V_E are both multiples of identity matrices of appropriate sizes. In other words, we assume that components of a sample of $X - \mu_X$ are uncorrelated, and that each component is a sample from the same Gaussian random variable; and we also assume that components of a sample of E are uncorrelated and that each component is a sample from the same zero mean Gaussian random variable. We use s^2 to denote the diagonal entries of V_X and n^2 to denote the diagonal entries of V_E and let $t = s/n$. According to (22), the Bayesian estimate is the vector x that minimizes

$$t^2 \|y - Rx\|^2 + \|x - \mu_X\|^2. \quad (29)$$

Note that a small value of t indicates that prior knowledge of the expected value of the image vector is important relative to the measured data, while a large value of t indicates the opposite. The following variant of ART converges to this Bayesian estimate, provided only that the condition expressed in (27) holds:

$$\begin{aligned} u^{(0)} &\text{ is the } I\text{-dimensional zero vector,} \\ x^{(0)} &= \mu_X, \\ u^{(k+1)} &= u^{(k)} + c^{(k)} e_{i_k}, \\ x^{(k+1)} &= x^{(k)} + t c^{(k)} r_{i_k}, \end{aligned} \quad (30)$$

where

$$c^{(k)} = \lambda^{(k)} \frac{t (y_{i_k} - \langle r_{i_k}, x^{(k)} \rangle) - u_{i_k}^{(k)}}{1 + t^2 \|r_{i_k}\|^2}. \quad (31)$$

Note that both in (23) and in (30) the updating of $x^{(k)}$ is very simple: we just add to $x^{(k)}$ a multiple of the vector r_{i_k} . In practice, this updating of $x^{(k)}$ can be computationally very inexpensive. Consider, for example, the basis functions associated with a digitization into pixels (10). Then $r_{i,j}$ is just the length of

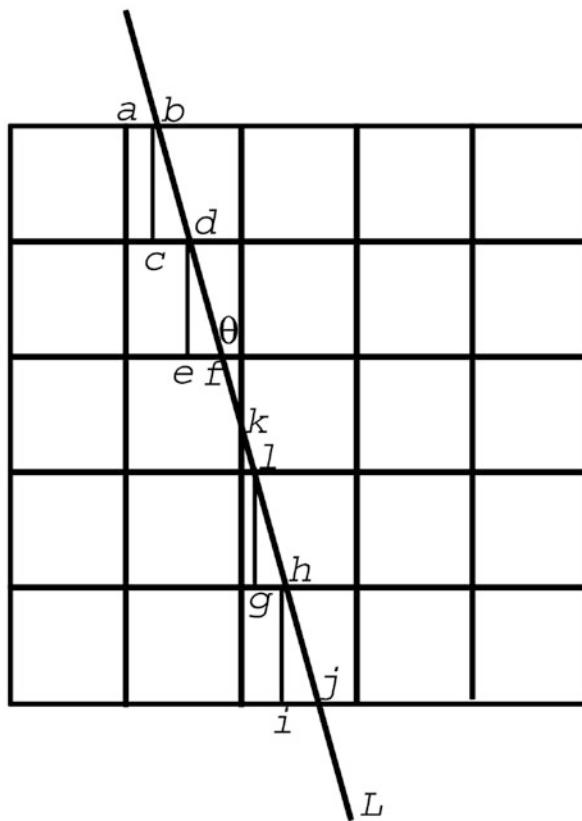

Fig. 14 A digital difference analyzer (DDA) for lines (reproduced from [23])

intersection of the i th line with the j th pixel. This has two consequences. First, most of the components of the vector r_{i_k} are zero. At most $2n - 1$ pixels can be intersected by a straight line in an $n \times n$ digitization of a picture. Thus, of the n^2 components of r_{i_k} , at most $2n - 1$ (and typically only about n) are nonzero. Second, the location and size of the nonzero components of r_{i_k} can be rapidly calculated from the geometrical location of the i_k th line relative to the $n \times n$ grid using a *digital difference analyzer* (DDA) methodology demonstrated in Fig. 14 (for details, see Section 4.6 of [23]). Thus, the projection matrix R does not need to be stored in the computer. Only one row of the matrix is needed at a time, and all information about this row is easily calculable. For this reason such methods are also referred to as *row-action methods*.

We investigate this point further, since it is basic to the understanding of the computational efficacy of ART. Suppose that we have obtained, using a DDA, the list j_1, \dots, j_U of indices such that $r_{i_k, j} = 0$ unless j is one of the j_1, \dots, j_U . Then evaluation of $\langle r_{i_k}, x^{(k)} \rangle$ or of $\|r_{i_k}\|^2$ requires only U multiplications, which in our application is much smaller than J . The updating of x can be achieved by a further

U multiplications. This is because only those x_j need to be altered for which $j = j_u$ for some u , $1 \leq u \leq U$, and the alteration requires adding to $x_j^{(k)}$ a fixed multiple of $r_{i_k,j}$. This shows that a single step of either of the ART algorithms described above is very simple to implement in a computationally efficient way.

The ART are, in fact, a subclass of the class of *projection methods*, which have been demonstrated to be very effective in practice for solving convex feasibility problems with linear inequality constraints [6]. A recent advance in this direction is the development of the *superiorization methodology* [30] whose underlying idea is the following. There are many efficient iterative algorithms that produce feasible solutions for given constraints. Often the algorithm is perturbation resilient in the sense that, even if certain kinds of changes are made at the end of each iterative step, the algorithm still produces a feasible solution. This property is exploited in superiorization by using the perturbations to steer the algorithm to a solution that is not only constraints-compatible, but is also desirable according to an optimization criterion. This approach is applicable to many iterative procedures and optimization criteria.

4 Numerical Methods and Case Examples

Having seen that there is a variety of reconstruction algorithms, it is natural to ask for guidance as to when it is better to apply one rather than the others. Unfortunately, any general answer is likely to be misleading since the relative efficacy of algorithms depends on many things: the underlying task at hand, the method of data collection, the hardware/software available for implementing the algorithms, etc. The practical appropriateness of an algorithm under some specific circumstances needs experimental evaluation.

We are now going to illustrate this by comparing, from certain points of view, the various reconstruction algorithms mentioned in the previous section. Except where otherwise stated, the generation of images and their projection data, the reconstructions from such data, the evaluation of the results, and the graphical presentation of both the images and the evaluation results were done within the software package SNARK09 [12, 37].

We studied a cross section of a human head that was reconstructed by CT (see Fig. 15). Based on this cross section we described a skull enclosing the brain with ventricles, two tumors, and a hematoma (blood clot) using five ellipses, eight segments of circles, and two triangles. The tumors were placed so that they are vertically above the blood clot in the display. We used SNARK09 to obtain the density in each of 243×243 pixels of size 0.0752 cm. The resulting array of numbers is represented in Fig. 16. The nature of this display deserves careful discussion. The displayed values are linear attenuation coefficients $\mu_{\bar{e}}(x, y)$ at energy $\bar{e} = 60$ keV of the appropriate tissue types measured in cm^{-1} . Thus the values range between 0 (background, can be thought of as air) and 0.416 (bone of the skull). However, the interesting part of the picture is inside the skull. The values there range from

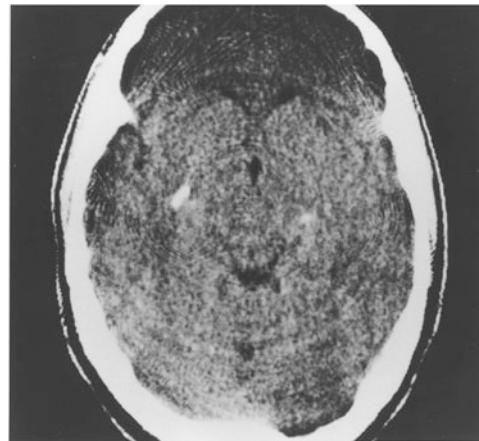

Fig. 15 Central part of an X-ray CT reconstruction of a cross section of the head of a patient. This served as the basis for our piecewise-homogeneous head phantom (reproduced from [23])

0.207 (cerebrospinal fluid) to 0.216 (metastatic breast tumor). The small differences between these tissues would not be noticeable if we used black to display zero, white to display 0.5, and corresponding grayness for values in between. To see clearly the features in the interior of the skull, we use zero (black) to represent the value 0.204 (or anything less) and 255 (white) to represent the value 0.21675 (or anything more). This way the small change in density by 0.001 corresponds to a change of 20 in display grayness, which is visible. We did this to produce Fig. 16 and the displays of all the reconstructions of the head phantoms used as illustrations in this chapter.

In Fig. 17a we show an actual brain cross section. The left half of the image shows a malignant tumor that has a highly textured appearance. In order to simulate the occurrence of a similarly textured object in our phantom we produced the phantom shown in Fig. 17b. Because of the medical relevance of imaging brains with such tumors, for the rest of this chapter we use the head phantom with this tumor added to it. (Due to our display method, it seems that there is a large range of values in the tumor. However, this is an illusion: the range of values in the tumor is less than 7 % of the range of values in the picture that is displayed in Fig. 16.)

One problem with the phantoms as defined so far is that a brain is far from being homogeneous: it has gray matter, white matter, blood vessels and capillaries carrying oxygenated blood to and deoxygenated blood from the brain, etc. This is even more so for bone, whose strength to a large extent is derived from its structural properties. There are methods that can obtain remarkably accurate reconstruction of piecewise homogeneous objects, but their performance may not be medically efficacious when applied to CT data from real objects with local inhomogeneities. So as not to fall into the trap of drawing too optimistic conclusions from experiments using piecewise homogeneous objects, we superimposed on our head phantom a random local variation that is obtained by picking, for each pixel, a sample

Fig. 16 A piecewise-homogeneous head phantom (reproduced from [23])

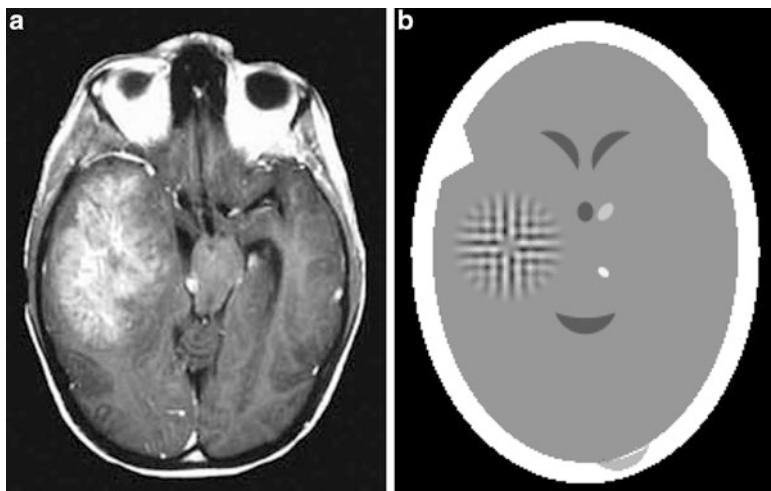

Fig. 17 (a) An actual brain cross section with a tumor (image is reproduced, with permission, from the Roswell Park Cancer Institute website). (b) The head phantom of Fig. 16 with a “large tumor” added to it (reproduced from [23])

from a Gaussian random variable X with mean $\mu_X = 1$ and standard deviation $\sigma_X = 0.0025$ and then multiplying the previously estimated linear attenuation coefficient at that energy level with that sample. In Fig. 18 we show the result of this.

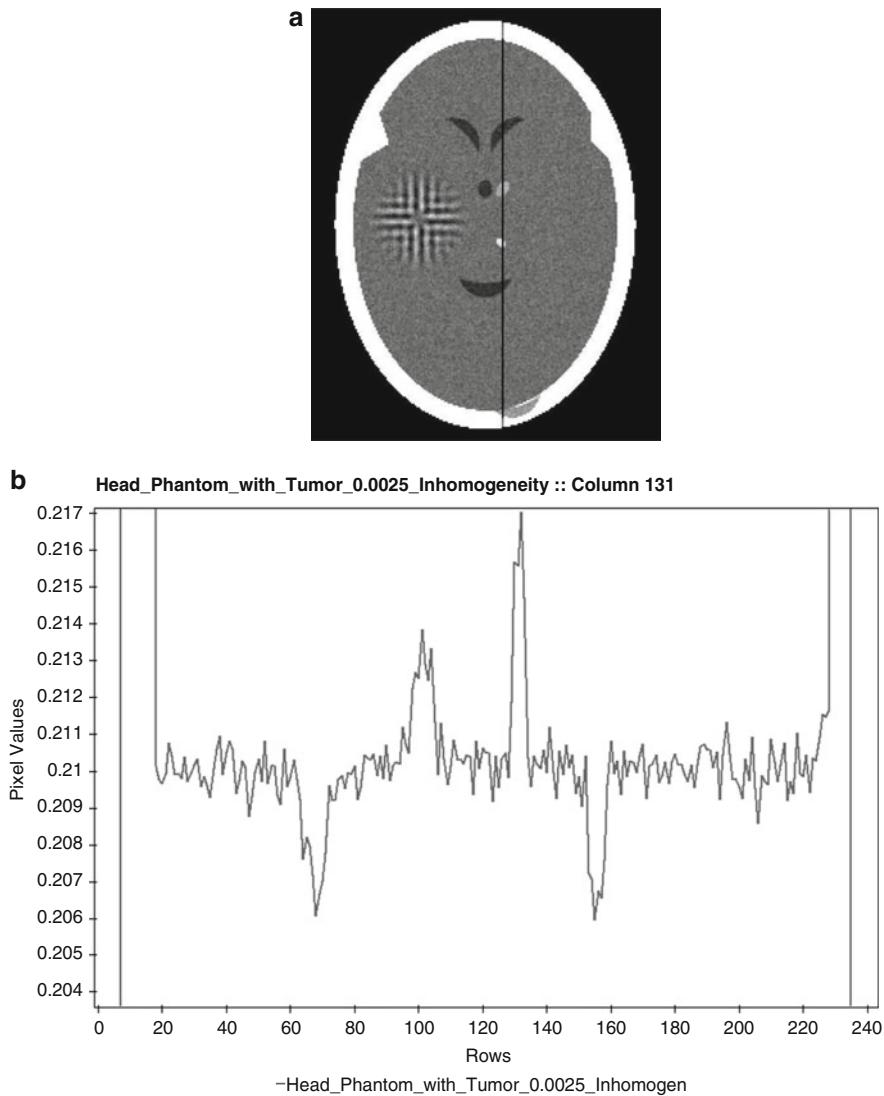

Fig. 18 (a) A head phantom with local inhomogeneities with the 131st of the 243 columns indicated by a vertical line. (b) The densities along this column in the phantom (reproduced from [23])

A reconstruction is a digitized picture. If it is a reconstruction from simulated projection data of a test phantom, we can judge its quality by comparing it with the digitization of the phantom. Naturally, both the picture region and the grid must be the same size for the reconstruction and the digitized phantom. We now discuss how to illustrate and measure the resemblance between a reconstruction and a phantom.

Visual evaluation is of course the most straightforward way. One may display both the phantom and the reconstruction and observe whether all features in which one is interested in the phantom are reproduced in the reconstruction and whether any spurious features have been introduced by the reconstruction process. A difficulty with such a qualitative evaluation is its subjectivity, people often disagree on which of two pictures resembles a third one more closely.

A more quantitative way of evaluating pictures is the following. Select a column of pixels that goes through a number of interesting features. For example, in our digitized head phantom the 131st of the 243 columns goes through the ventricles, both tumors, and the hematoma. In Fig. 18a we indicate this column. A way to evaluate the quality of a reconstruction is to compare the graphs of the 243 pixel densities for this column in the phantom (shown in Fig. 18b) and the reconstruction.

It also appears desirable to use a single value that provides a rough measure of the closeness of the reconstruction to the phantom. We now describe two different methods of doing this. In our definition of these two *picture distance measures* we use $t_{u,v}$ and $r_{u,v}$ to denote the densities of the v th pixel of the u th row of the digitized test phantom and the reconstruction, respectively, and \bar{t} to denote the average of the densities in the digitized test phantom. We assume that both pictures are $n \times n$. Let

$$d = \left(\sum_{u=1}^n \sum_{v=1}^n (t_{u,v} - r_{u,v})^2 / \sum_{u=1}^n \sum_{v=1}^n (t_{u,v} - \bar{t})^2 \right)^{1/2}. \quad (32)$$

$$r = \sum_{u=1}^n \sum_{v=1}^n |t_{u,v} - r_{u,v}| / \sum_{u=1}^n \sum_{v=1}^n |t_{u,v}|. \quad (33)$$

($|x|$ denotes the absolute value of x .) These are often-used measures in the literature.

These measures emphasize different aspects of picture quality. The first one, d , is a *normalized root mean squared distance measure*. A large difference in a few places causes the value of d to be large. Note that the value of d is 1 if the reconstruction is a uniformly dense picture with the correct average density. The second one, r , is a *normalized mean absolute distance measure*. As opposed to d , it emphasizes the importance of a lot of small errors rather than of a few large errors. Note that the value of r is 1 if the reconstruction is a uniformly dense picture with zero density.

However, a collection of a few numbers cannot possibly take care of all the ways in which two pictures may differ from each other. Rank ordering reconstructions based on a few measures of closeness to the phantom can be misleading. We recommend instead a *statistical hypothesis testing* based methodology that allows us to evaluate the relative efficacy of reconstruction methods for a given task.

This evaluation methodology considers the following to be the relevant basic question: given a specific medical problem, what is the relative merit of two (or more) image reconstruction algorithms in presenting images that are helpful for solving the problem? (Compare this with the alternative essentially unanswerable question: which is the best reconstruction algorithm?) Ideally, the evaluation should

be based on the performance of human observers. However, that is costly and complex, since a number of observers have to be used, each has to read many images, conditions have to be carefully controlled, etc. Such reasons lead us to use *numerical observers* instead of humans. The evaluation methodology consists of four steps:

- (i) Generation of random samples from a statistically described ensemble of images (phantoms) representative of the medical problem and computer simulation of the data collection by the device under investigation.
- (ii) Reconstruction from the data so generated by each of the algorithms.
- (iii) Assignment of a *figure of merit* (FOM) to each reconstruction. The FOM should measure the usefulness of the reconstruction for solving the medical problem.
- (iv) Calculation of *statistical significance* (based on the FOMs of all the reconstructions) by which the null hypothesis that the reconstructions are equally helpful for solving the problem at hand can be rejected.

We now discuss details. For relevance to a particular medical task, the steps must be adjusted to that task. The task for which comparative evaluations of various pairs of reconstruction algorithms are reported below is that of detecting small low-contrast tumors in the brain based on reconstructions from CT data.

The ensemble of images generated for this task is based on the head phantom with a large tumor and local inhomogeneities. Note that this by itself provides us a statistical ensemble because the local inhomogeneities are introduced using a Gaussian random variable. However there is an additional (for the task more relevant) variability within the ensemble that is achieved as follows. We specify a large number of pairs of potential tumor sites, the locations of the sites in a pair are symmetrically placed in the left and right halves of the brain. In any sample from the ensemble, exactly one of each pair of the sites will actually have a tumor placed there, with equal probability for either site. The tumors are circular in shape of radius 0.1 cm and with linear attenuation as for the meningioma in the original phantom. In Fig. 19a we illustrate one sample from this ensemble. Once a sample has been picked, we generate projection data for it by simulating a CT scanner, with all its physical inaccuracies as compared to the idealized Radon transform. (Such inaccuracies include: the finite number of measurements, statistical noise due to the finite number of X-ray photons used during the measurements, the hardening of the polychromatic X-ray beam as it passes through the body, the width of the detector, and the scattering of X-ray photons.) Further variability is introduced at this stage, since the data are generated by simulating noise due to photon statistics. In Fig. 19b we show a reconstruction from one such projection data set. The tumors are hard to see in this reconstruction, but that is exactly the point: we are trying to evaluate which of two reconstruction algorithms provides images in which the tumors are easier to identify. If we make the task too easy (by having large and/or high-contrast tumors), then all reasonable reconstruction algorithms would perform perfectly from the point of view of the task. On the other hand, if the task is too difficult (very small and very low-contrast tumors), then correct detection would become essentially a

matter of luck, rather than of algorithm performance. Our ensemble was chosen to be in-between these extremes. The FOM that we chose to use is specific to the type of ensemble of phantoms that we have just specified.

Given a phantom and one of its reconstructions, as in Fig. 19, we define the *image-wise region of interest FOM* (IROI) as

$$\text{IROI} = \frac{\sum_{b=1}^B (\alpha_t^r(b) - \alpha_n^r(b))}{\sqrt{\sum_{b=1}^B \left(\alpha_n^r(b) - \frac{1}{B} \sum_{b'=1}^B \alpha_n^r(b') \right)^2}} / \frac{\sum_{b=1}^B (\alpha_t^p(b) - \alpha_n^p(b))}{\sqrt{\sum_{b=1}^B \left(\alpha_n^p(b) - \frac{1}{B} \sum_{b'=1}^B \alpha_n^p(b') \right)^2}}. \quad (34)$$

The specification of the terms in this formula is as follows. For any digitized picture and for any potential tumor site, let the *average density* in that picture for that site be the sum over all pixels whose center falls within the site of the pixel densities divided by the number of such pixels. Let us number the pairs of potential tumor sites from 1 to B , and let (for $1 \leq b \leq B$) $\alpha_t^p(b)$ (respectively, $\alpha_n^p(b)$) denote the average density in the phantom for site of the b th pair that has (respectively, has not) the tumor in it. We specify similarly $\alpha_t^r(b)$ (respectively, $\alpha_n^r(b)$), for the reconstruction. The first thing to note about the resulting formula (34) is that the numerator and the denominator in the big fraction are exactly the same except that the numerator refers to the reconstruction and the denominator refers to the phantom. Thus, if the reconstruction is perfect (in the sense of being identical to the phantom) then

$\text{IROI} = 1$. Analyzing the contents of the numerator and the denominator, we see that they are (except for constants that cancel out) the mean difference between the average values at the sites with tumors and the sites without tumors, divided by the standard deviation of the average values at the non-tumor sites. It has been found by experiments with human observers that this FOM correlates well with the performance of people [49].

In order to obtain statistically significant results we need to sample the ensemble of phantoms and generate projection data a number (say C) of times. (For the experiments reported below we used $C = 30$.) Suppose that we wish to compare the task-oriented performance of two reconstruction algorithms. For $1 \leq c \leq C$, let $\text{IROI}^1(c)$ and $\text{IROI}^2(c)$ denote the values of IROI, as defined by (34), for the reconstructions by the two algorithms from projection data of the c th phantom. The *null hypothesis* that the two reconstruction methods are equally good for the task at hand translates into the statistical statement that each value of $\text{IROI}^1(c) - \text{IROI}^2(c)$ is a sample of a continuous random variable D whose mean is 0. We have no idea of the shape of the probability density function p_D of this random variable, but by the central limit theorem (see, e.g., Section 1.2 of [23]), for a sufficiently large C ,

$$s = \sum_{c=1}^C (\text{IROI}^1(c) - \text{IROI}^2(c)) \quad (35)$$

can be assumed to be a sample from a Gaussian random variable S with mean 0. This fact allows us to say (for details see Section 5.2 of [23]) that, at least approximately, S is a Gaussian random variable whose mean is 0 and whose variance is

$$V_S = \sum_{c=1}^C (\text{IROI}^1(c) - \text{IROI}^2(c))^2. \quad (36)$$

It is a consequence of the null hypothesis that s is a sample from a zero-mean random variable. However, even if that were true, we would not expect our particular sample s to be exactly 0. Suppose for now that $s > 0$. This makes us suspect that in fact the first algorithm is better than the second one (for our task) and so the null hypothesis may be false. The question is: how significant is the observed value s for rejecting the null hypothesis? To answer this question we consider the *P-value*, which is the probability of a sample of S being as large or larger than s . If the null hypothesis were correct, we would not expect to come across an s defined by (35) for which the *P-value* is very small. Thus, the smallness of the *P-value* is a measure of *significance* for rejecting the null hypothesis that the two reconstruction algorithms are equally good for our task in favor of the *alternative hypothesis* that the first one is better than the second one. This is for the case when $s > 0$. If $s < 0$, then the *P-value* is the probability of a sample of S being as small or smaller than s and the alternative hypothesis is that the second algorithm is better than the first one.

Having specified various methodologies for reconstruction algorithm evaluation, we now apply them to specific algorithms. Whenever we report on the performance

of an algorithm for the reconstruction of a single two-dimensional phantom, the phantom is the one shown in Fig. 18. For experiments involving statistical hypothesis testing, we use the ensemble illustrated by Fig. 19. In either case, the data collection geometry is the one described in Fig. 9 with the number of source positions $M = 720$. Consequently, the angle $m\Delta$ shown in Fig. 9 is $0.5m$ degrees. The source positions are equally spaced around a circle of radius 78 cm. The distance of the source from the detector strip is 110.735 cm. There are 345 detectors, and the distance between two detectors along the arc of the detector strip is 0.10668 cm. We refer to this geometry of data collection as the *standard geometry*.

The reconstruction algorithm estimates a digitization of the phantom from the projection data. Figure 20 shows the 243×243 digitization of the head phantom, a reconstruction by FBP from perfect projections (line integrals) for the geometry just described, and the values of the digitized phantom and the reconstruction along the 131st column. The picture distance measures for this reconstruction are $d = 0.0531$ and $r = 0.0185$. Even though the data are perfect, the reconstruction is not. This is because a picture is not uniquely determined by its integrals along a finite number of lines. The best that a reconstruction algorithm can do is to *estimate* the picture.
