This section proceeds by first examining the various adaptations of bilateral filtering on meshes (triangulated 3D surfaces) and discussing their implementation, which can depend on the surface triangulation. Finally several comparative experiments on synthetic and real meshes will be performed. Since a common notation is needed for all methods, this section starts with a small glossary and notation summary to which the reader may refer.

Glossary and Notation

- \mathcal{M} : the mesh, namely, a set of triangles
- v : current mesh vertex to be denoised
- $\mathcal{N}(v)$: neighborhood of vertex v (this neighborhood excludes v).
- n_v, n_p , etc.: normals at vertex v or point p , etc., to the underlying surface
- $w_1(||p - v||), w_2(< n_v, p - v >)$, etc.: 1D centered Gaussians with various variances, used as weighting functions applied to the distance of neighbors to the current vertex and to the distance along the normal direction at v .
- H_v, H_p , etc.: curvatures of the underlying surface at v, p , etc.
- f : triangle of a mesh
- a_f : area of triangle f
- c_f : barycenter of triangle f
- n_f : normal to triangle f
- Π_f : projection on the plane containing triangle f
- V : voxel containing points of the data set
- s', v', p', n'_v : processed versions of s, v, p, n_v , etc.
- $\|p - q\|$: Euclidean distance between points p and q

The *neighborhood filter or sigma filter* is attributed to Lee [26] in 1983 but goes back to Yaroslavsky and the Sovietic image processing theory (see the book summarizing these works [44]) in 2D image analysis. A recent variant by Tomasi and Manduchi names it bilateral filter [37]. The bilateral filter denoises a pixel by using a weighted mean of its similar neighbors gray levels. In the original article, the similarity measure was the difference of pixel gray levels, yielding for a pixel v of an image I with neighborhood $\mathcal{N}(v)$:

$$\hat{I}(v) = \frac{1}{C(v)} \sum_{p \in \mathcal{N}(v)} w_1(\|p - v\|) w_2(|I(v) - I(p)|) I(p)$$

where w_1 et w_2 are decreasing functions on \mathbb{R}^+ (e.g., Gaussian) and $C(v)$ is a normalizing coefficient: $C(v) = \sum_{p \in \mathcal{N}(v)} w_1(\|p - v\|) w_2(|I(v) - I(p)|)$. Thus $\hat{I}(v)$ is an average of pixel values for pixels that are similar in position but also in value, hence the “bilaterality.”

Bilateral Filter Definitions

Filtering without losing the sharp features is as critical for surfaces as it is for images, and a first adaptation of the bilateral filter to surface meshes was proposed by Fleishman, Drori, and Cohen-Or in [15]. Consider a meshed surface \mathcal{M} with known normals n_v at each vertex position v . Let $\mathcal{N}(v)$ be the one-ring neighborhood of v (i.e., the set of vertices sharing an edge with v). Then the filtered position of v writes $v' = v + \delta v \cdot n_v$, where

$$\delta v = \frac{1}{C(v)} \sum_{p \in \mathcal{N}(v)} w_1(\|p - v\|) w_2(\langle n_v, p - v \rangle) \langle n_v, p - v \rangle \quad (1)$$

where the weight normalization factor is $C(v) = \sum_{p \in \mathcal{N}(v)} w_1(\|p - v\|) w_2(\langle n_v, p - v \rangle)$. In a nutshell, this means that the normal component of the vertex v is moved by a weighted average of the normal components of its neighboring points which are also close to the plane tangent to the surface at v . The distance to the tangent plane plays for meshes the role that was played for images by the distance between gray levels. If v belongs to a sharp edge, then the only points close to the tangent plane at v are the points on the edge. Thus, the edge sharpness will not be smoothed away. One of the drawbacks of the above filter is clearly the use of a mesh-dependent neighborhood. In case of a mesh with fixed length edges, using the one-ring neighborhood is the same as using a fixed size neighborhood. Yet in most cases mesh edges do not have the same length. The one-ring neighborhood is then very dependent on the mesh representation and not on the shape itself. This is easily fixed by defining an intrinsic Euclidean neighborhood.

Another adaptation of the 2D bilateral filter to surface meshes is introduced by Jones, Durand, and Desbrun in [20]. This approach considers the bilateral filtering problem as a robust estimation problem for the vertex position. A set of surface predictors are linked to the mesh \mathcal{M} : for each triangle f the position estimator Π_f projects a point to the plane defined by f . Let a_f be the surface area and c_f be the center of f . Then, for each vertex v , the denoised vertex is

$$v' = \frac{1}{C(v)} \sum_{f \in \mathcal{M}} \Pi_f(v) a_f w_1(\|c_f - v\|) w_2(\|\Pi_f(v) - v\|) \quad (2)$$

where $C(v) = \sum_{f \in \mathcal{M}} a_f w_1(\|c_f - v\|) w_2(\|\Pi_f(v) - v\|)$ is the weight normalizing factor and w_1 and w_2 are two Gaussians.

Thus, the weight $w_1(\|c_f - v\|)$ is small if the triangle f is close to v . This term is the classic locality-in-space term of the bilateral. Similarly, $w_2(\|\Pi_f(v) - v\|)$ measures how far point v is from its projection onto the plane of the triangle. This weight favors the triangles f whose plane is coherent with v .

Since the projection on the tangent planes operator Π_f depends on the normals to f , these normals must be robustly estimated. Normals being first-order derivatives, they are more subject to noise than vertex positions. Hence the method starts by denoising the normal field. To do so, the mesh is first smoothed using the same formula as above without the influence weight w_2 and with $\Pi_f(v) = c_f$, namely, an updated position:

$$v' = \frac{1}{C(v)} \sum_{f \in \mathcal{M}} c_f a_f w_1(\|c_f - v\|)$$

where $C(v) = \sum_{f \in \mathcal{M}} a_f w_1(\|c_f - v\|)$. The normal for each face in the denoised mesh is then computed and assigned to the corresponding face of the original noisy mesh. It is with this robust normal field that the bilateral filter of Eq. (2) is applied in a second step.

The idea of filtering normals instead of point positions is crucial in point rendering applications, as was pointed out by Jones, Durand, and Zwicker in [21]. Indeed, when rendering a point set, removing noise from normal is more important than removing noise from point position, since normal variations are in fact what is perceived by observers. More precisely the eye perceives a dot product of the illumination and the normal, which makes it very sensitive to noisy normal orientations. The bilateral filter of [20] is seen as a deformation F of the points: $v' = F(v)$. Then, the update of normal n_v can be obtained through the transposed inverse of the Jacobian $J(v)$ of $F(v)$:

$$n'_v = J^{-T}(v)n_v, \text{ where } J_i(v) = \frac{\partial F}{\partial v_i}(v)$$

where J_i is the i th column of J and v_i is the i th component of v . n_v must then be renormalized. The rendering of the point set with smoothed normal is better than without any smoothing.

In [38], Wang introduces a related bilateral approach which denoises feature-insensitive sampled meshes. Feature insensitive means that the mesh sampling is independent of the features of the underlying surface, e.g., uniform sampling. The algorithm proceeds as follows: it detects the shape geometry (namely, sharp regions), denoises the points, and finally optimizes the mesh by removing thin triangles. The bilateral filter is defined in a manner similar to [20], with the difference that only triangles inside a given neighborhood are used on this definition. Let v be a mesh vertex, $\mathcal{N}(v)$ be the set of triangles within a given range of v , and

n_f, a_f, c_f be, respectively, the normal, area, and center of a facet f (a triangle). Denote by $\Pi_f(v)$ the projection of v onto the plane of f , and then the denoised vertex is defined by

$$v' = \frac{1}{C(v)} \sum_{f \in \mathcal{N}(v)} \Pi_f(v) a_f w_1(\|c_f - v\|) w_2(\|\Pi_f(v) - v\|)$$

where $C(v) = \sum_{f \in \mathcal{N}(v)} a_f w_1(\|c_f - v\|) w_2(\|\Pi_f(v) - v\|)$ (weight normalizing factor).

The first step is to detect sharp regions. Several steps of bilateral filtering (as defined in [20]) are applied, and then a smoothness index is computed by measuring the infimum of angles between normals of faces adjacent to v . By thresholding this measurement, the sharp vertices are selected. Triangles whose three vertices are sharp and whose size does not increase during the bilateral iterations are marked as sharp. This detection done, points are restored to their original positions. Then the bilateral filtering formula is applied to sharp vertices only, and the geometry sharpness is encoded into a data collection containing normals, centers, and areas of filtered triangles. Points are then restored to their original position. Each sharp vertex is moved using the bilateral filtering over the neighboring stored data units, and thin vertices are removed from the mesh (these last two steps are iterated a certain number of times). Finally, a post-filtering step consists in applying one step of bilateral filtering on all non-sharp edges.

In [40] (Wang, Yuan, and Chen), a two-step denoising method combines the fuzzy C-means clustering method (see Dunn's article on fuzzy means [12]) with a bilateral filtering approach. Fuzzy C-means is a clustering technique that allows a piece of data to belong to two different clusters. Each point p gets a parameter $\mu_{p,k}$ which measures the degree of membership of p to a cluster k . Let m_p be the number of points in the spherical neighborhood of a point p . If $m_p < \text{threshold}$, the point is deleted. Otherwise, a fuzzy C-means clustering center c_p is associated with p . The normal at point c_p is computed as the normal to the regression plane of the data set in a spherical neighborhood of p . Fleishman's bilateral filter [15] is used to filter c_i which yields the denoised point. This hybrid and complex method is doubly bilateral. Indeed, the previous C-means clustering selects an adapted neighborhood for each point and replaces it by an average which is by itself the result of a first bilateral filter in the wide sense of neighborhood filter. Indeed, the used neighborhood for each point depends on the point. The second part of the method therefore applies a second classical bilateral method to a cloud that has been filtered by a first bilateral filter.

The bilateral filtering idea was also used as a part of a surface reconstruction process. In [30], for example, Miropolsky and Fischer introduced a method for reducing position and sampling noise in point cloud data while reconstructing the surface. A 3D geometric bilateral filter method for edge-preserving and data reduction is introduced. Starting from a point cloud, the points are classified in an octree, whose leaf cells are called *voxels*. The voxel centers are filtered,

representative surface points are defined, and the mesh is finally reconstructed. A key point is that the denoising depends on the voxel decomposition. Indeed, the filter outputs a result for each voxel. For a voxel V , call v its centroid with normal n_v . Let w_1 and u_2 be two functions weighting, respectively, $\|p - v\|$, the distance between a point p position and the centroid location, and $\delta(p, v) = \langle n_p, n_v \rangle$, the scalar product of the normal at p and the normal at the centroid. Then the output of the filter for voxel V is

$$v' = \frac{1}{C(v)} \sum_{p \in V} w_1(\|p - v\|) u_2(\delta(p, v)) p$$

where $C(v) = \sum_{p \in V} w_1(\|p - v\|) u_2(\delta(p, v))$. Here w_1 is typically a Gaussian and u_2 is an increasing function on $[0, 1]$. But this filter proves unable to recover sharp edges, so a modification is introduced: prior to any filtering for each voxel V , points of V are projected onto a sphere centered at the centroid v . Each mapped point is given a normal \tilde{n}_p which has direction $p - v$ and is normalized. The geometric filtering is reduced to

$$v' = \frac{1}{C(v)} \sum_{p \in V} u_2(\delta(\tilde{n}_p, n_v)) p \text{ with } C(v) = \sum_{p \in V} u_2(\delta(\tilde{n}_p, n_v)).$$

Although only the similarity of normals is taken into account in the above formula, the filter is bilateral because the average is localized in the voxel.

In [27], Liu et al. interpreted the bilateral filter as the association to each vertex v of a weighted average

$$v' = \frac{1}{C(v)} \sum_{p \in \mathcal{N}(v)} w_1(\|p - v\|) w_2(\|\Pi_p(v) - v\|) \Pi_p(v)$$

where $C(v) = \sum_{p \in \mathcal{N}(v)} w_1(\|p - v\|) w_2(\|\Pi_p(v) - v\|)$ (normalizing factor) and $\Pi_p(v)$ is a *predictor* which defines a “denoised position of v due to p ,” namely, the *projection of v on the plane passing by p and having the normal n_v* . For example, the bilateral predictor used in [15] is $\Pi_p(v) = v + ((p - v) \cdot n_v) n_v$, and in [20], the used predictor is $\Pi_p(v) = v + ((p - v) \cdot n_p) n_p$ which is the projection of v on the tangent plane passing by p . With this last predictor the corners are less smoothed out, yet there is a tangential drift due to the fact that the motion is not in the normal direction n_v but in an averaged direction of the n_p for $p \in \mathcal{N}(v)$. Therefore a new predictor is introduced:

$$\Pi_p(v) = v + \frac{(p - v) \cdot n_p}{n_v \cdot n_p} n_v.$$

This predictor tends to preserve better the edges than all other bilateral filters.

The question of choosing automatically the parameters for the bilateral filter was raised by Hou, Bai, and Wang in [19]. It was proposed to choose adaptive parameters. The adaptive bilateral normal smoothing process starts by searching for the set of triangles $(T_i)_i$ whose barycenters are within a given distance of a center triangle T . (But this keeps a distance parameter anyway.) Then the influence weight parameter σ_s is computed as the standard deviation of the distance between normals $\|n(T_i) - n(T)\|$. The spatial weight parameter is estimated using a minimum length descriptor criterion (for various scales). The estimated parameters are then used to get the smoothed normal. This result is finally used for rebuilding the mesh using the smoothed normals by Ohtake, Belyaev, and Seidel's method described in [31].

The bilateral filter has proved to be very efficient to denoise a mesh while preserving sharp features. The trilateral filter is then a natural extension which takes into account still more geometric information.

Trilateral Filters

Choudhury and Tumblin [6] propose an extension of the trilateral image filter to oriented meshes. It is a 2-pass filter: a first pass filters the normals and a second pass filters the vertex positions. Starting from an oriented mesh, a first pass denoises bilaterally the vertex normals using the following update:

$$n'_v = \frac{1}{C(n_v)} \sum_{p \in \mathcal{N}(v)} n_p w_1(\|p - v\|) w_2(\|n_p - n_v\|)$$

where $C(n_v) = \sum_{p \in \mathcal{N}(v)} w_1(\|p - v\|) w_2(\|n_p - n_v\|)$. Then, an adaptive neighborhood $\mathcal{N}(v)$ is found by iteratively adding faces near v until the normals n_f of face f differ too much from n'_v . A function F measuring the similarity between normals is built using a given threshold R :

$$F(v, f) = 1 \text{ if } \|n'_v - n_f\| < R; 0 \text{ otherwise.}$$

The trilateral filter for normals filters a difference between normals. Define $n_\Delta(f) = n_f - n'_v$. Then the trilaterally filtered normal n_v is

$$n''_v = n'_v + \frac{1}{C(v)} \sum_{f \in \mathcal{N}(v)} n_\Delta(f) w_1(\|c_f - v\|) w_2(n_\Delta(f)) F(v, f)$$

where $C(v) = \sum_{f \in \mathcal{N}(v)} w_1(\|c_f - v\|) w_2(n_\Delta(f)) F(v, f)$. Finally, the same trilateral filter can be applied to vertices. Call P_v the plane passing through v and orthogonal to n'_v . Call \tilde{c}_f the projection of c_f onto P_v and $c_\Delta(f) = \|\tilde{c}_f - c_f\|$. Then the trilateral filter for vertices, using the trilaterally filtered normal n''_v , writes

$$v' = v + n_v'' \frac{1}{C(v)} \sum_{p \in \mathcal{N}(v)} c_\Delta(f) w_1(\|\tilde{c}_f - v\|) w_2(n_\Delta(f)) F(v, f)$$

where $C(v) = \sum_{p \in \mathcal{N}(v)} w_1(\|\tilde{c}_f - v\|) w_2(c_\Delta(f)) F(v, f)$.

The results are similar to [20] though slightly better. They are comparable to the results of [15] since both methods use the distance to the tangent plane as a similarity between points.

Similarity Filters

In [41] Wang et al. proposed a trilateral filter with slightly different principles. A *geometric intensity* of each sampled point is first defined as depending on the neighborhood of the point

$$\delta(p) = \frac{1}{C(p)} \sum_{q \in \mathcal{N}(p)} w_{pq} < n_p, q - p >$$

with

$$w_{pq} = w_1(\|q - p\|) w_2(\| < n_p, q - p > \|) w_h(\|H_q - H_p\|)$$

and

$$C(p) = \sum_{q \in \mathcal{N}(p)} w_{pq}.$$

This type of filter is a trilateral filter, which means that it depends on three variables: distance between the point p and its neighbors q , distance along the normal n_p between the point p and its neighbors q , and the difference of their mean curvatures H_p and H_q .

At each point, a local grid is built on the local tangent plane (obtained by local covariance analysis), and at each point of this grid, the geometry intensity is defined by interpolation. Thus, neighborhoods of the same geometry are defined for each pair of distinct points, and the similarity can be computed as a decreasing function of the L^2 distance between these neighborhoods.

Since the goal is to denoise one point with similar points, the algorithm proposes to cluster the points into various classes by the mean shift algorithm. To denoise a point, only points of the same class are used. This gives a denoised geometry intensity $\delta'(p)$ and the final denoised position $p' = p + \delta'(p)n_p$.

More recently the NL-means (Buades, Coll, Morel [3]) method which proved very powerful in image denoising was adapted to meshes and point clouds by Yoshizawa, Belyaev, and Seidel [47]. Recall that for an image I , the NL-means filter computes a filtered value $J(x)$ of pixel x as

$$J(x) = \frac{1}{C(x)} \int_{\Omega} w(x, y) I(y) dy,$$

an adaptive average with weights

$$w(x, y) = \exp - \frac{1}{h^2} \int G_a(|t|) |I(x - t) - I(y - t)|^2 dt$$

and $C(x) = \int_{\Omega} w(x, y) dy$.

Here G_a is a Gaussian or a compactly supported function, so that it defines a patch. Thus, the denoised point is a mean of pixel values with weights measuring the local image similarity of patches around other pixels with the patch around the current pixel.

Consider now the adaptation to a mesh \mathcal{M} . Let $\Omega_\sigma(v) = \{y \in \mathcal{M} \mid |v - y| \leq 2\sigma\}$. The smoothing is done by changing v at each step: $v^{n+1} = v^n + k(v^n)n_v^n$ with n_v the normal to \mathcal{M} at v . Let S_y be the surface associated to vertex y . The following definitions are directly adapted from the image case (a continuous formalism is adopted here for clarity):

$$k(v) = \frac{1}{C(v)} \int_{\Omega_{\sigma_2}} w(v, y) I(y) dS_y$$

$$C(v) = \int_{\Omega_{\sigma_2}} w(v, y) dS_y$$

$$I(y) = \langle n_v, y - v \rangle$$

$$w(v, y) = \exp - \frac{D(v, y)}{h^2}.$$

The problem is to define the similarity kernel D . Let σ_3 be the half radius of the neighborhood used to define the geometric similarity between two points, and σ_2 be the half radius of the domain where similar points are looked for, with $\sigma_3 < \sigma_2$. The local tangent plane at y is parameterized by t_1 and t_2 . For all z of $\Omega_{\sigma_2}(y)$, the translation t is defined as $t = -(\langle t_1, z - y \rangle, \langle t_2, z - y \rangle) = -(u_z, v_z)$, where (u_z, v_z, w_z) are the coordinates of vertex z in the local coordinate system (y, t_1, t_2, n_y) .

A local approximation $F_v(u, v)$ by radial basis functions (RBF) is built around each vertex v , and the similarity kernel finally yields

$$D(v, y) = \int_{\Omega_{\sigma_3}(y)} G_{\sigma_3}(|t|) |F_v(u_z, v_z) - I(y - t)|^2 dt$$

with $I(y - t) = \langle n_v, z - v \rangle$ and G_{σ_3} a Gaussian kernel with variance σ_3 .

Thus each vertex is compared with vertices in a limited domain around it, and the weighted mean over all these nodes yields the denoised position. This results in

a better feature preserving mesh denoising method, but at the cost of a considerably higher computation time.

To improve the computation time when denoising data using neighborhood filters, bilateral approximations were introduced by Paris and Durand, among others, in [32], where a signal processing interpretation of the 2D bilateral filter is given, yielding an efficient approximation. Another efficient method is the Gaussian k-d trees introduced by Adams et al. in [1]. The proposed method was designed to compute efficiently a class of n -dimensional filters which replace a pixel value by a linear combination of other pixel values. The basic idea is to consider those filters as nearest neighbors search in a higher-dimensional space, for example, (r, g, b, x, y) in case of a 2D color image and a bilateral filter. To accelerate this neighbor search, a Gaussian k-d tree is introduced. Consider the nonlocal means filter which has, in its naive implementation, a $O(n^2 f^2)$ complexity for n pixels and $f \times f$ patches. To apply Gaussian k-d tree, the position of a pixel is set to be the patch, and the value is set to be the color value of the pixel. A simple Principle Component Analysis (PCA) on patches helps to capture the dimensions that best describe the patches. The Gaussian k-d tree is also used to perform 3D NL-means on meshes or point clouds. To produce a meaningful value to describe geometry, the idea of spin images is used. At each point sample p , a regression plane is estimated, and the coordinates of the neighboring points in the local coordinate system are used to build a histogram of cylindrical coordinates around (p, n_p) (the spin image). This gives the position vector. The value of p is then set to be the difference $d = p' - p$ between p and the Laplacian filtered position p' expressed in the local coordinate system. This gives the input for building the Gaussian k-d tree yielding good results for mesh denoising.

Summary of 3D Mesh Bilateral Filter Definitions

The filters reviewed in this section are almost all defined for meshes. Yet, with very little effort almost all of them can be adapted to unstructured point clouds by simply redefining the neighborhoods as the set of points within a given distance from the center point (spherical neighborhood). Several classic variants of bilateral filters were examined, but their main principle is to perform an average of neighboring vertices pondered by the distance of these vertices to an estimated tangent plane of the current vertex. This distance takes the role played by the gray level in image bilateral filters. It can be implemented in several ways either by projecting the current vertex to the neighboring triangles or by projecting the neighboring vertices on the current triangle or by using an estimate of the normal at the current vertex which has been itself previously filtered. An interesting and simple possibility is to directly combine distance of vertices and of their normals or even distances of vertices, normals, and curvatures (but this requires a previous smoothing to get denoised normals and curvatures). Notice that position, normal, and curvature characterize the cloud shape in a larger neighborhood. Thus, at this point, the obvious generalization of bilateral filters is NL-means, which directly compares

point-wise the shape of the neighborhood of a vertex with the overall shape of the neighborhoods of others before performing an average of the most similar neighborhoods to deliver a filtered neighborhood.

Sticking to the simplicity of comparisons and to the essentials of bilateral filter, we shall be contented in the comparative section to illustrate the gains of the bilateral filter with respect to a (good) implementation of its unilateral counterpart, the mean curvature motion, performed by the projection of each vertex on a local regression plane. The remainder of this section is divided as follows: section “Comparison of Bilateral Filter and Mean Curvature Motion Filter on Artificial Shapes” presents experiments and comparisons on artificial shapes, and section “Comparison of the Bilateral Filter and the Mean Curvature Motion Filter on Real Shapes” presents results on some real shapes.

Comparison of Bilateral Filter and Mean Curvature Motion Filter on Artificial Shapes

In the following experiments, the denoising of the bilateral filter as introduced in [15] will be compared with the mean curvature motion (MCM). Recall that [15] defined the update of a point as

$$\delta v = \frac{1}{C(v)} \sum_{p \in \mathcal{N}(v)} w_1(\|p - v\|) w_2(\langle n_v, p - v \rangle) \langle n_v, p - v \rangle$$

with

$$C(v) = \sum_{p \in \mathcal{N}(v)} w_1(\|p - v\|) w_2(\langle n_v, p - v \rangle)$$

(see first section, Eq. (1) for notations).

The mean curvature motion used here is the projection on the regression plane: a vertex v with normal n_v and spherical neighborhood $\mathcal{N}(v)$ is projected on the regression plane of $\mathcal{N}(v)$. In [9], Digne et al. showed that this operator was an approximation of the mean curvature motion:

$$\frac{\partial v}{\partial t} = Hn_v.$$

The effects of bilateral denoising are first shown on some artificial shapes. A cube with sidelength 5 is created with added Gaussian noise with standard deviation 0.02 (Fig. 1). Figures 1 and 2 show all points of the 3D cloud seen from one side of the cube. Obviously, the edges seem to have some width due to the noise.

The experiments of Fig. 2a–c show the denoising power of the bilateral filter in terms of preserving edges and should be compared with the standard mean curvature motion filter (Fig. 2d–f). The comparison is particularly interesting in the

Fig. 1 A noisy cube with Gaussian noise

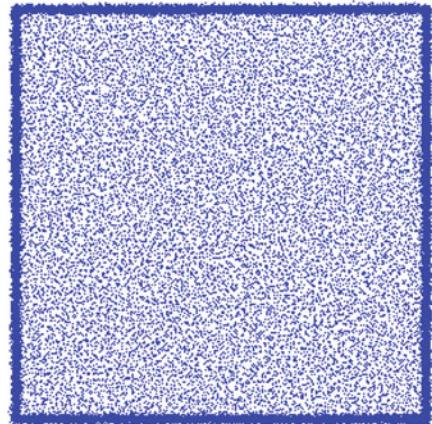

Table 1 Noise estimation for the sharp edge denoising

| | Input | Iteration 1 | Iteration 2 | Iteration 5 |
|------------------|-------|-------------|-------------|-------------|
| RMSE (bilateral) | 0.01 | 0.0031 | 0.0019 | 0.0035 |
| RMSE (mcm) | 0.01 | 0.0051 | 0.0085 | 0.0164 |

corner areas. The bilateral filter implies an anisotropic curvature motion leading to a diffusion only in smooth parts while preserving the sharp areas. Let us now see how those filters perform in case of a sharp edge. An estimation of the noise for each of the denoising methods is shown on Table 1. This estimation was obtained as follows: an edge was created by sampling two intersecting half-planes and adding Gaussian noise, the obtained edge was then denoised by bilaterally filtering an mean curvature motion. Finally, the root-mean-square error (RMSE) to the underlying model is computed. Table 1 tends to prove that mean curvature motion, although it smoothes well the noisy flat parts and also smoothes away the sharpness, whereas the bilateral filter tends to preserve the sharp edges better. With few iterations, the noisy parts are smoothed out decreasing the root-mean-square error. Then, when iterating the operator, the sharpness tends to be smoothed, increasing the RMSE again. This phenomenon is of course far quicker with the mean curvature motion since this filter does not preserve edges at all.

Comparison of the Bilateral Filter and the Mean Curvature Motion Filter on Real Shapes

This section starts with running some experiments on the Michelangelo's David point cloud. At each step an interpolating mesh was built for visualization.

On Fig. 3, denoising artifacts created by the bilateral filter can be seen. They appear as oscillations, for example, on David's cheek. These artifacts can be explained by the fact that the bilateral filter enhances structures. Added noise

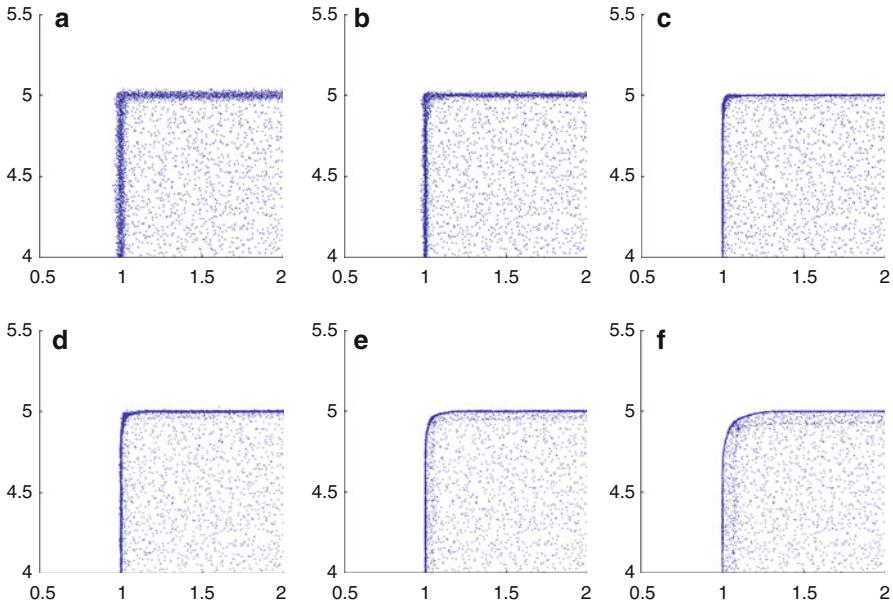

Fig. 2 Bilateral and MCM iterations on the cube corner. Notice how the sharpness is much better preserved by the bilateral filter than by the mean curvature equation. (a) 1 bilateral iteration. (b) 2 bilateral iterations. (c) 5 bilateral iterations. (d) 1 MCM iteration. (e) 2 MCM iterations. (f) 5 MCM iterations

structures can thus be randomly enhanced by the bilateral filter. Figure 4 shows that some noise remains after one iteration of bilateral denoising. The bilateral filter is therefore iterated with the same parameters. Then, obviously, the remaining noise disappears at the cost of some sharpness loss (see Fig. 5). Still, the bilateral filter preserves sharp features much better than the mean curvature motion (Fig. 6). This can also be seen on a noisy simple scan of a screw nut driver (Fig. 7) and on a fragment of the Stanford Digital Forma Urbis Romae Project (Fig. 8).

3 Depth-Oriented Applications

This section focuses on the applications of the bilateral filter and its generalized version to depth-oriented image processing tasks. The common idea to all these applications is to constrain the diffusion of depth information to the intensity similarity between pixels. The underlying assumption is that pixels with similar intensity around a region are likely to have similar depths. Therefore, when diffusing depth information based on intensity similarity, the discontinuities in depth are assured to be consistent with the color discontinuities. This is often a desirable property, as it was noticed by Gamble and Poggio [16] and Kellman and Shipley [22].

Images” describes an application to the resolution enhancement of range images. Section “Bilateral Filter for the Global Integration of Local Depth Information” reviews applications to the estimation of depth in single images.

Bilateral Filter for Improving the Depth Map Provided by Stereo Matching Algorithms

Stereo matching algorithms address the problem of recovering the depth map of a 3D scene from two images captured from different viewpoints. This is achieved by finding a set of points in one image which can be identified in the other one. In fact, the point-to-point correspondences allow to compute the relative disparities, which are directly related to the distance of the scene point to the image plane.

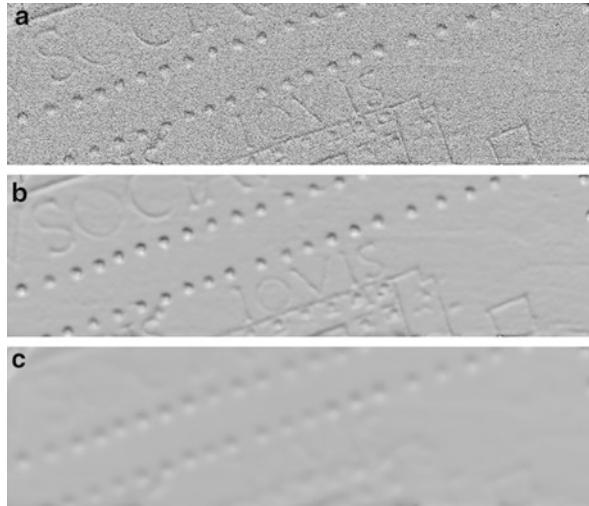

Fig. 8 Denoising of fragment “31u” of Stanford Digital Forma Urbis Romae; see Koller et al. [23] for an explanation of the data. (a) Initial fragment with added Gaussian noise. (b) Bilateral denoising. (c) MCM

The matching process is based on a similarity measure between pixels of both images. Due to the presence of noise and repetitive texture, these correspondences are extremely difficult to find without global reasoning. In addition, occluded and textureless regions are ambiguous. Indeed, local image matching is not enough to find reliable disparities in the whole image. Because of all these reasons, the matching process yields either low-accuracy dense disparity maps or high-accuracy sparse ones.

Improvements can be obtained through filtering or interpolation, by using median or morphological filters, for instance. However, their ability to do so is limited. Yin and Cooperstock have proposed [45] a post-processing step to improve dense depth maps produced by any stereo matching algorithm. The proposed method consists in applying an iterated bilateral filter, which diffuses the depth values. This diffusion relies on the original image gradient instead of the one of the depth images. This allows to incorporate edge information into the depth map, assuring discontinuities in depth to be consistent with intensity discontinuities.

The color-weighted correlation idea underlying the bilateral filter has been exploited by Yoon and Kweon [46] to reduce the ambiguity of the correspondence search problem. Classically, this problem has been addressed by area-based methods relying on the use of local support windows. In this approach, all pixels in a window are assumed to have similar depth in the scene and, therefore, similar disparities. Accordingly, pixels in homogeneous regions get assigned the disparities inferred from the disparities of neighboring pixels.

However, when the windows are located on depth discontinuities, the same disparity is assigned to pixels having different depths, resulting in a foreground-

fattening phenomenon. This phenomenon was studied by Delon and Rougé [8]. To obtain accurate results, an appropriate window should be selected for each pixel adaptively. This problem is addressed by Yoon and Kweon [46] by weighting the pixels in a given window taking into account their color similarity and geometric proximity to the reference pixel.

The similarity between two pixels is then measured using the support weights in both windows, taking into account the edge information into the disparity map. Experimental results show that the use of adaptive support weights produces accurate piecewise smooth disparity maps while preserving depth discontinuities.

The idea of exploiting the color-weighted correlation to reduce the ambiguity of the correspondence problem has been implemented in a parallel architecture, allowing its use in real-time applications and more complex stereo systems. See Yang et al. [42] and Wang et al. [39] papers which achieved a good rank in the Middlebury benchmark (Evaluation of the Middlebury stereo website <http://vision.middlebury.edu/stereo/>) proposed by Scharstein and Szeliski [36].

The bilateral filter averages the pixel colors, based on both their geometric closeness and their photometric similarity, preferring near values in space and color to distant ones. Ansar, Castano, and Matthies [2], Yoon and Kweon [46], and, more recently, Mattoccia, Giardino, and Gambin [28] have used the bilateral filter to weight the correlation windows before the stereo correspondence search. On the other hand, Gehrig and Franke [17] have applied the bilateral filter to obtain an improved and smoother disparity map.

The interpolation of disparity maps and in particular of digital elevation models (DEMs) has been considered in several recent works. Facciolo and Caselles [14] propose to interpolate unknown areas by constraining a diffusion anisotropic process to the geometry imposed by a reference image and coupling the process with a data fitting term which tries to adjust the reconstructed surface to the known data. More recently, Facciolo et al. [13] have proposed a new interpolation method which defines a geodesic neighborhood and fits an affine model at each point. The geodesic distance is used to find the set of points that are used to interpolate a piecewise affine model in the current sample. This interpolation is refined by merging the obtained affine patches with a Mumford-Shah-like algorithm. The a contrario methodology has been used in this merging procedure. In the urban context, Lafarge et al. [25] use a dictionary of complex building models to fit the disparity map. However, the applicability of such a method is less evident because of the initial delineation of buildings by a rectangle fitting.

We shall illustrate the bilateral interpolation process with experiments from Sabater's Ph.D. thesis [35] where the bilateral filter is used to interpolate a sparse disparity map. Let q be a point in the image I . Consider $L_q \subset I$ the subimage where the weight is learned. For each $p \in L_q$ the weight due to color similarity and proximity is computed.

Color similarity: the following color distance is considered

$$d_c(u_q, u_p) = ((R_u(q) - R_u(p))^2 + (G_u(q) - G_u(p))^2 + (B_u(q) - B_u(p))^2)^{1/2},$$

where R_u , G_u , and B_u are the red, green, and blue channels of u . Then the weight corresponding to the color similarity between p and q is

$$w_c(p, q) = \exp\left(-\frac{d_c(u_q, u_p)^2}{h_1^2}\right).$$

Proximity: The Euclidean distance between the point positions in the image plane is used

$$d(q, p) = ((q_1 - p_1)^2 + (q_2 - p_2)^2)^{1/2},$$

where $p = (p_1, p_2)$ and $q = (q_1, q_2)$. Then the weight corresponding to proximity is

$$w_d(p, q) = \exp\left(-\frac{d(q, p)^2}{h_2^2}\right).$$

Therefore, the total associated weight between the two points q and p is

$$W(p, q) = \frac{1}{Z_q} w_c(p, q) w_d(p, q) = \frac{1}{Z_q} \exp\left(-\left(\frac{d_c(u_q, u_p)^2}{h_1^2} + \frac{d(q, p)^2}{h_2^2}\right)\right),$$

where Z_q is the normalizing factor $Z_q = \sum_{p \in L_q} w_c(p, q) w_d(p, q)$. The interpolated disparity map μ_I is computed via an iterative scheme

$$\mu_I(q, k) = \sum_{p \in L_q} W(p, q) \mu_I(p, k-1),$$

where k is the current iteration and the initialization $\mu_I(\cdot, 0) = \mu(\cdot)$ is the sparse disparity to be interpolated.

Figures 9 and 10 show the interpolated Middlebury results (100 % density). The experiments demonstrate that, starting from a disparity map which is very sparse near image boundaries, the bilateral diffusion process can recover a reasonable depth map.

Bilateral Filter for Enhancing the Resolution of Low-Quality Range Images

Contrary to intensity images, each pixel of a range image expresses the distance between a known reference frame and a visible point in the scene. Range images are acquired by range sensors that, when acquired at video rate, are either very expensive or very limited in terms of resolution. To increase the resolution of

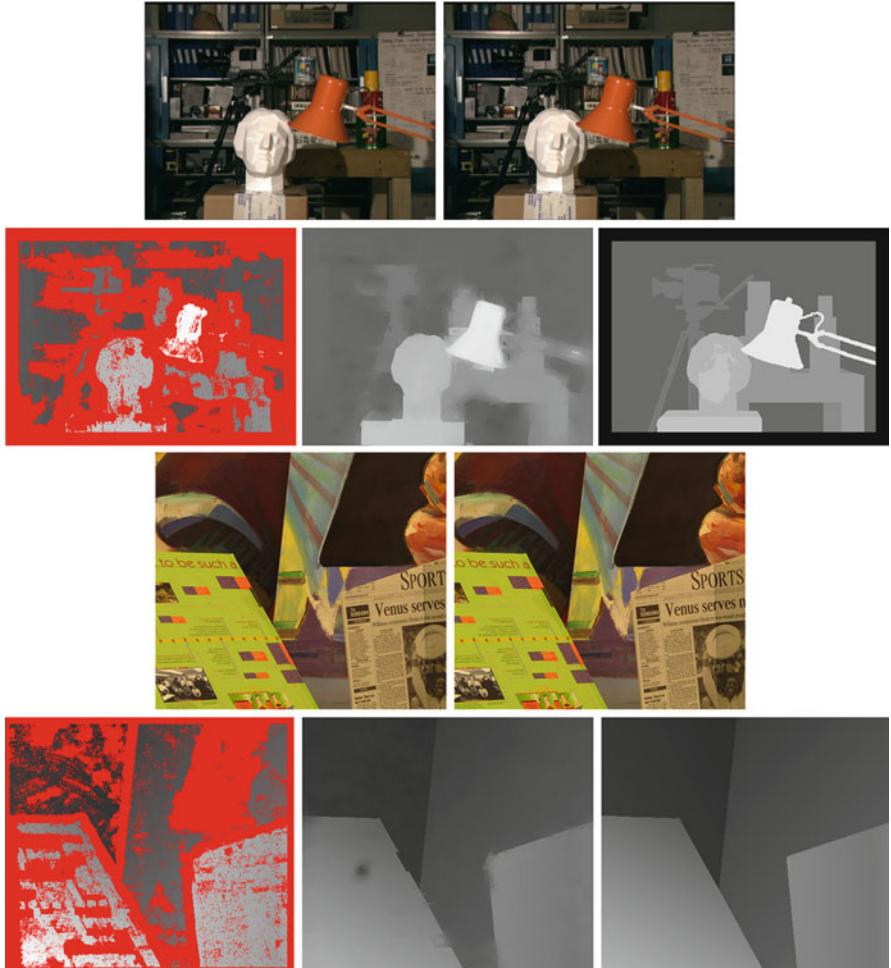

Fig. 9 Tsukuba and Venus results. For each couple of images: stereo pair of images, output of a sparse algorithm retaining only sure points, points (in red) are the rejected correspondences, interpolated version of these results and ground truth

low-quality range images acquired at video rate, Yang et al. [43] have proposed a post-processing step relying on an iterated bilateral filter. The filter diffuses the depth values of the low-quality range image, steering the diffusion by the color information provided by a registered high-quality camera image.

The input low-resolution range image is up-sampled to the camera image resolution. Then an iterative refinement process is applied. The up-sampled range image D_0 is used as the initial depth map to build an initial 3D cost volume c_0 . The 3D cost volume $c_i(\mathbf{x}, \mathbf{y}, d)$ associated to the current depth map D_i at the i th iteration is given by

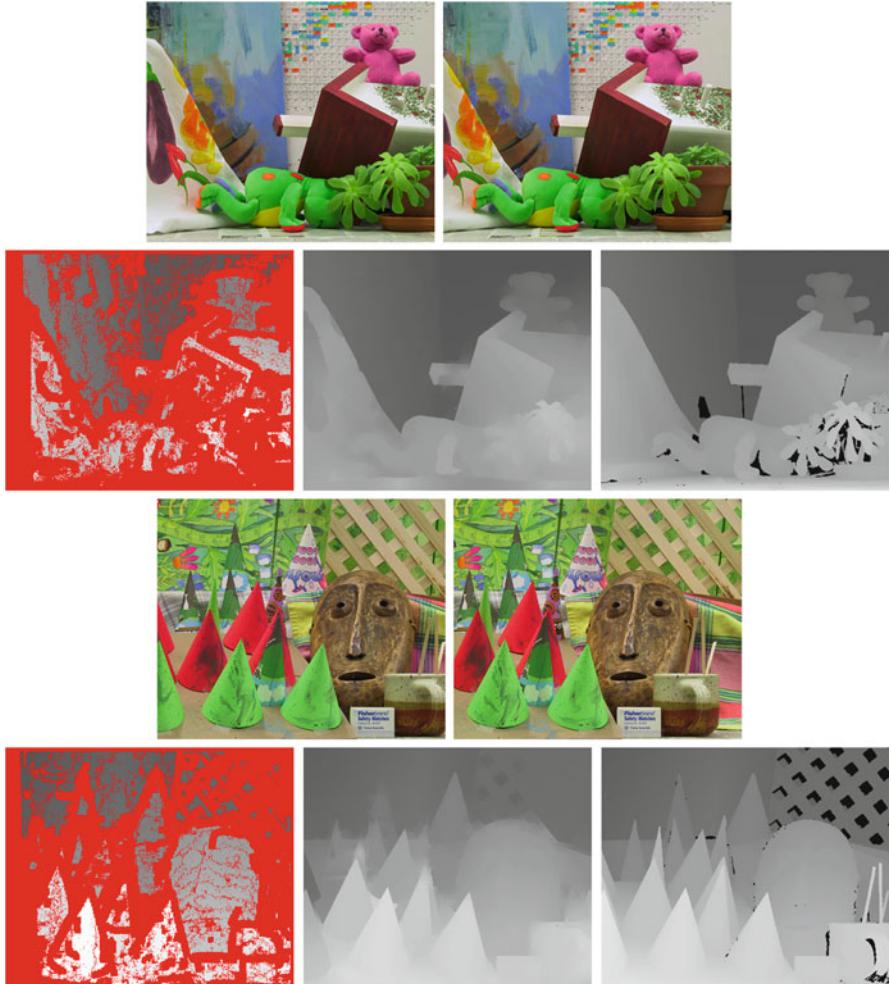

Fig. 10 Teddy and Cones results. For each couple of images: stereo pair of images, output of a sparse algorithm retaining only sure points, points (in red) are the rejected correspondences, interpolated version of these results and ground truth

$$c_i(\mathbf{x}, \mathbf{y}, d) = \min (\mu L, (d - D_i(\mathbf{x}, \mathbf{y}))^2) \quad (3)$$

where d is the depth candidate, L is the search range controlled by constant μ , and $D_i(\mathbf{x}, \mathbf{y})$ is the current depth estimate. To each depth candidate, d in the search range corresponds a single slice (disparity image) of the current cost volume. At each iteration, a bilateral filter is applied on each slice of the current cost volume c_i . This allows to smooth each slice image while preserving the edges. A new cost volume c_i^{BF} is therefore generated. Based on this new cost volume, a refined depth map D_{i+1} is obtained by selecting for each (\mathbf{x}, \mathbf{y}) the lowest cost candidate d .

(4). **(a)** Gray-level image, where BSPs and FSPs are marked in *white* and *black*, respectively. **(b)** Depth image, where points corresponding to FSPs are initialized with a positive value (marked in *white*) and the rest of the image with value zero. **(c)** and **(d)** Depth images after an increasing number of iterations of the DDF

Bilateral Filter for the Global Integration of Local Depth Information

Following the phenomenological approach of gestaltists [29], the perception of depth in single images results from the global integration of a set of monocular depth cues. However, all methods proposed in the computer vision literature to estimate depth in single *real* images rely on the use of prior experience about objects and their relationships to the environment. As a consequence, these methods generally rely on strong assumptions on the image structure [7, 18], for instance, that the world is made of ground/horizontal planes and vertical walls, or assumptions on the image content [34] such as the prior knowledge of the class of objects being involved.

In contrast to the state of the art, Dimiccoli, Morel, and Salembier [11] proposed a general low-level approach for estimating depth in single real images. In this approach the global depth interpretation is directly inferred from a set of monocular depth cues, without relying on any previously learned contextual information nor on any strong assumption on the image structure. In particular the set of initial local depth hypothesis derived from different monocular depth cues is used to initialize and constrain a diffusion process. This diffusion is based on an iterated neighborhood filter.

With this strategy, the occlusion boundaries and the relative distances from the viewpoint of depicted objects are simultaneously recovered from local depth information, without the need of any explicit segmentation. Possible conflicting depth relationships are automatically solved by the diffusion process itself.

Once monocular depth cues are detected, each region involved in a depth relationship is marked by one or few points, called *source points* (see Fig. 11a). Source points marking the regions closer to the viewpoint are called Foreground Source Points (FSPs), whereas source points marking the regions more distant to the viewpoint are called Background Source Points (BSPs). In case of occlusion, three source points are marked (see white circle in Fig. 11a). A single FSP marks the region representing the occluding object, and two corresponding BSPs mark the partially occluded object and the background. In case of convexity, there is a single FSP and its corresponding BSP (see black circle in Fig. 11a). The depth image z is initialized by assigning a positive value Δ to FSPs and value 0 to BSPs. The rest of the image is initialized with value 0 (see Fig. 11b). The diffusion process is applied to the depth image z by using the gradient of the original image u rather than the one of the depth image. Doing so, the edge information is incorporated into the depth map, ensuring that depth discontinuities are consistent with gray-level (color) discontinuities.

The depth diffusion filter (DDF) proposed in [11] by Dimiccoli, Morel, and Salembier is

$$\text{DDF}_{h,r} z(x) = \frac{1}{C(x)} \int_{S_r(x)} z(y) e^{\frac{-|u(x)-u(y)|^2}{h^2}} dy, \quad (4)$$

where $S_r(x)$ is a square of center x and side r , h is the filtering parameter which controls the decay of the exponential function, and

$$C(x) = \int_{S_r(x)} e^{\frac{-|u(x)-u(y)|^2}{h^2}} dy \quad (5)$$

is the normalization factor. In practice, the parameters are $r = 3$ and $h = 10$.

Equation (4) is applied iteratively until the stability is attained. In the discrete case, after each iteration, the values of FSPs and BSPs are updated. More precisely, if the difference between the values of an FSP and the corresponding BSP becomes smaller than Δ , then Δ is added to the value of the FSP. In the continuous case, the neighborhood filter can be seen as a partial differential equation (Buades, Coll, Morel [4]). With this interpretation, the depth difference constraints in the discrete case can be understood as the Dirichlet boundary conditions. Furthermore they allow to handle multiple depth layers.

Figure 11 is an example of the diffusion through the DDF. Using Eq. (4) a very large number of iterations are needed to attain the stability. To make the diffusion faster, the following equation is used as initialization:

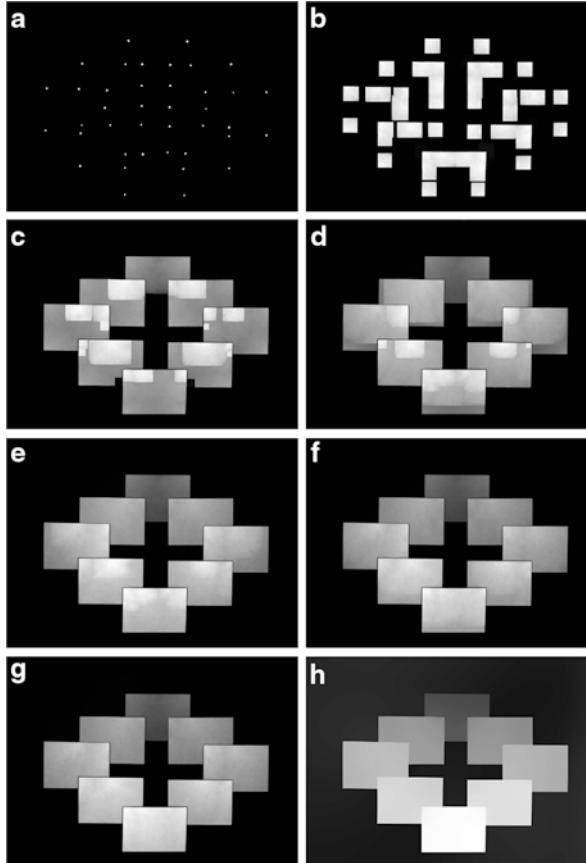

Fig. 12 Example of depth diffusion using Eq. (6) to speed up the diffusion. (a) Depth image, where FSPs have been initialized with a positive value (marked in gray) and the rest of the image with value zero. From (b) to (g) depth images corresponding to an increasing number of iterations. After each iteration, the depth difference between corresponding FSPs and BSPs is forced to be at least equal to the initial depth difference Δ , by adding Δ to FSPs when the difference between corresponding FSPs and BSPs becomes less than Δ . (h) Final depth image obtained using Eq. (4) on image (g)

$$\text{DDF}_{h,r} z(x) = \sup_{y \in S_r(x)} z(y) e^{\frac{-|u(x)-u(y)|^2}{h^2}}, \quad (6)$$

while Eq. (4) is used only in the last iterations (see Fig. 12).

Experimental results on real images (see [10]) proved that this simple formulation turns out to be very effective for the integration of several monocular depth cues. In particular, contradictory information given by conflicting depth cues is dealt with the bilateral diffusion mechanism, which allows two regions to invert harmoniously their depths, in full agreement with the phenomenology.

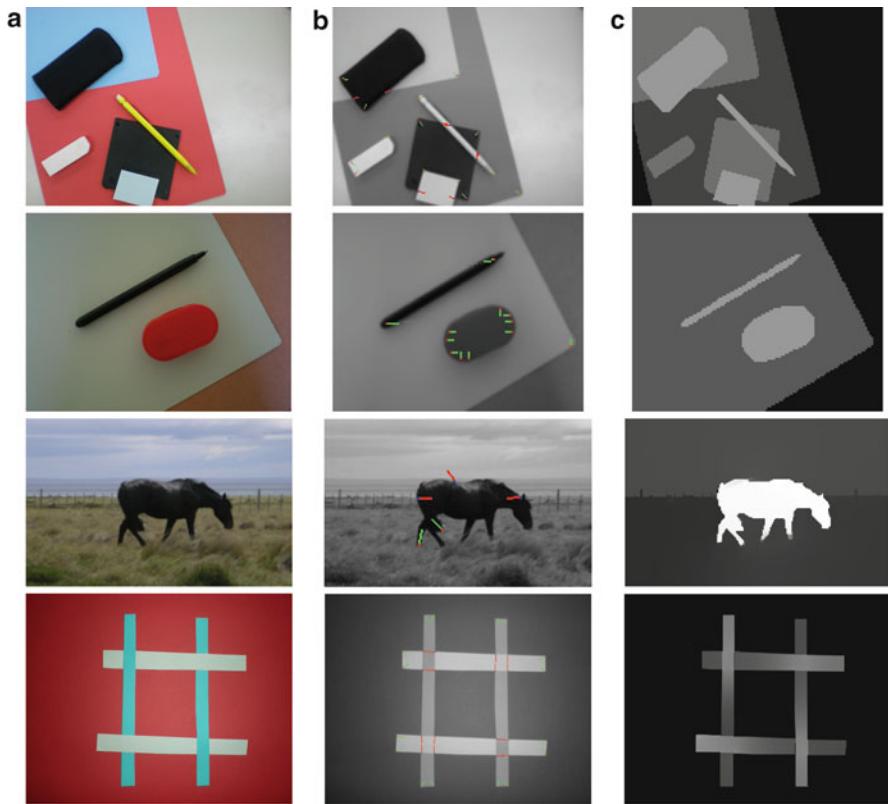

Fig. 13 (a) Original image. (b) Local depth cues are represented through vectors that point to the region closer to the viewpoint. (c) Depth image

In Fig. 13, some experimental result involving occlusion and convexity is shown. For each experiment three images are shown.

First, the original image (Fig. 13a) is shown. Then, on the second image, the initial depth gradient at depth cue points is represented by vectors pointing to the region closer to the viewpoint (red vectors arise from T-junctions, green vectors arise from local convexity) (Fig. 13b). Finally, the third image is the final result of the bilateral diffusion method (Fig. 13c). In this depth map high values indicate regions that are close to the camera. First and second rows of Fig. 13 show examples of indoor scenes, for which a proper solution is obtained. On the third row, there is an example of an outdoor scene involving a conflict. The T-junction detected on the back of the horse is due to a reflectance discontinuity, and its local depth interpretation is incorrect. However, on the depth map, the shape of the horse appears clearly on the foreground since the diffusion process allowed to overcome the local inconsistency. On the last row there is an example involving self-occlusion: occluding contours have different depth relationships at different points along its

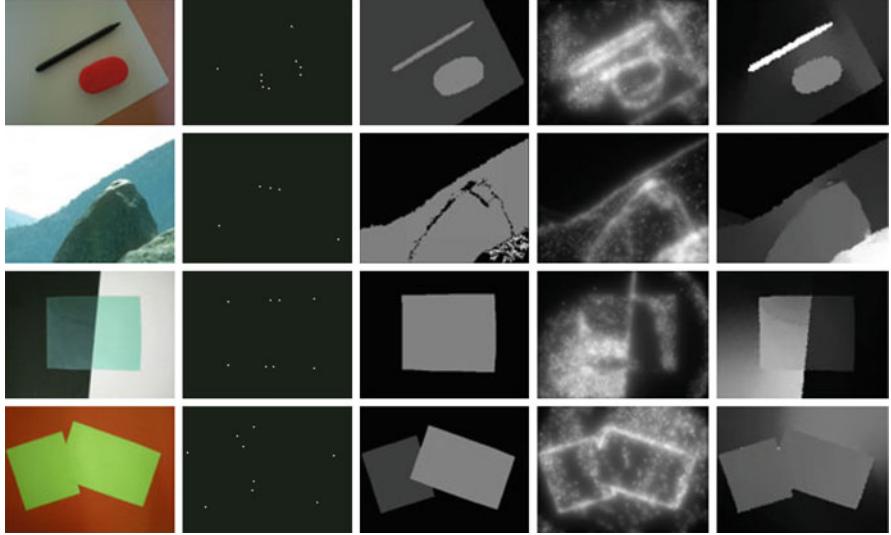

Fig. 14 (1st column) Original image. (2nd column) Depth cues computed by Dimiccoli, Morel, and Salembier [11]: FSPs are initialized with a positive value (marked in white), and BSP and the rest of the images are initialized with value zero. (3rd column) Depth image computed by Dimiccoli, Morel, and Salembier [11]. (4th column) Local depth cues computed by Calderero and Caselles [5]: they are encoded through gray-level values. High values indicate pixels closer to the viewpoint. (5th column) Depth image computed by Calderero and Caselles [5]

continuum. However, the bilateral diffusion method performs also well in this ambiguous situation.

More recently, the idea of using a neighborhood filter to globally integrate local depth information in single images has been re-proposed by Calderero and Caselles [5]. With the aim of achieving more accurate diffusion results on real images, they relied on color image information to determine the adaptive neighborhood by using the bilateral filter of Tomasi and Manduchi [37]. In other words, they averaged depth information on a pixel neighborhood using color-based weights in the same spirit as Yang et al. [42] and Kopf et al. [24].

Contrary to Dimiccoli, Morel, and Salembier [11], the local depth information extracted by Calderero and Caselles [5] is not sparse but behaves in a continuous manner. More precisely, the depth value at each pixel encodes the likelihood that an occlusion process is taking place at that pixel (see the fourth column of Fig. 14). This information is computed in a multi-scale fashion and therefore has the advantage of being more robust with respect to the depth information extracted by Dimiccoli, Morel, and Salembier [11]. However, due to its local nature, their method has the inconvenient of not being able to handle special cases of occlusions that involve more global processes, such as transparency and amodal completion, as illustrated in Fig. 14.

Due to the fact that depth information is initially estimated for each image pixel, Calderero and Caselles [5] use the neighborhood filter solely for assuring depth homogeneity of neighbor regions having similar color. Their diffusion filter is simpler and more robust with respect to errors coming from the estimation of local depth cues, but contrary to the filter of Dimiccoli, Morel, and Salembier [11], it does not allow to handle the case of multiple depth layers.

In conclusion, the method of Calderero and Caselles [5] gives better results on real images, whereas the method of Dimiccoli, Morel, and Salembier [11] gives results that better accord to phenomenology.

4 Conclusion

This chapter has reviewed the use of neighborhood filters for the recovery of 3D information. The first part of the chapter has reviewed bilateral filters applied to 3D data point sets, often organized in a triangulation, and has compared them to the simplest possible isotropic filter, the mean curvature motion, illustrating the advantage of bilateral filters on isotropic filtering. The second part of the chapter has reviewed bilateral filter applied to a data composed of a coarse, often sparse, depth map (or of depth cues) obtained through stereoscopy, or monocular depth cues estimation techniques. When diffusing depth information with a bilateral filter based on locality and color similarity, the discontinuities in depth are assured to be consistent with the color discontinuities, which is generally a desirable property. Experimental results have shown that the bilateral filter used as a diffusion tool performs well in restoring a dense depth map.

Abstract

Splines and multiresolution are two independent concepts, which – considered together – yield a vast variety of bases for image processing and image analysis. The idea of a multiresolution analysis is to construct a ladder of nested spaces that operate as some sort of mathematical looking glass. It allows to separate coarse parts in a signal or in an image from the details of various sizes. Spline functions are piecewise or domainwise polynomials in one dimension (1D) resp. n D. There is a variety of spline functions that generate multiresolution analyses. The viewpoint in this chapter is the modeling of such spline functions in frequency

domain via Fourier decay to generate functions with specified smoothness in time domain resp. space domain. The mathematical foundations are presented and illustrated at the example of cardinal B-splines as generators of multiresolution analyses. Other spline models such as complex B-splines, polyharmonic splines, hexagonal splines, and others are considered. For all these spline families exist fast and stable multiresolution algorithms which can be elegantly implemented in frequency domain. The chapter closes with a look on open problems in the field.

AMS Subject Classification (2010): 41A15 Spline approximation 65D07 Numerical analysis – Splines 68U10 computing methodologies and applications – Image processing 65T99 numerical methods in Fourier analysis

1 Introduction

This chapter deals with two originally independent concepts, which were recently combined and since together have a strong impact on signal and image analysis: the concept of splines, i.e., of piecewise polynomials, and the concept of multiresolution analysis, i.e., splitting functions – or more general data – into coarse approximations and details of various sizes. Ever since the combination of the two concepts, they have led to a load of new applications in, e.g., signal and image analysis, as well as in signal and image reconstruction, computer vision, numerics of partial differential equations, and other numerical fields. An impression of the vast area of applications can be gained in, e.g., [1, 17, 20, 64].

Already, the spline functions alone proved to be very useful for mathematical analysis as well as for signal and image processing, analysis and representation, computer graphics, and many more; see, e.g., [3, 15, 22, 24, 35, 50, 58]. An example for a family of spline functions are I. J. Schoenberg's polynomial splines with uniform knots [59, 60]:

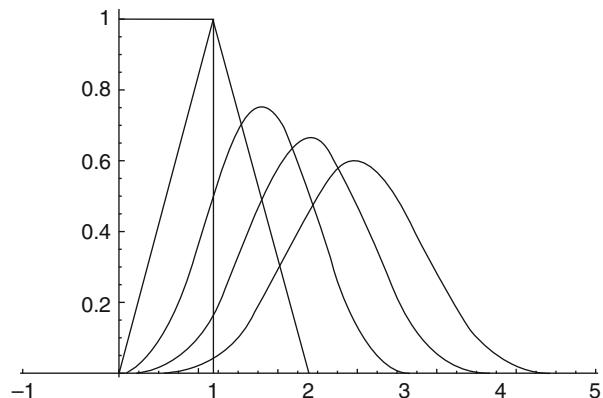

$$\beta^m(t) = \frac{1}{m!} \sum_{k=0}^{m+1} (-1)^k \binom{m+1}{k} (t-k)_+^m, \quad m \in \mathbb{N}. \quad (1)$$

Here, t_+^m denotes the one-sided power function, i.e., $t_+^m = 0$ for $t < 0$ and $t_+^m = t^m$ for $t \geq 0$. The B-splines β^m can be easily generated by an iterative process. Let $\beta^0(t) = \chi_{[0,1]}(t)$ be the characteristic function of the interval $[0, 1]$. Then the B-spline of degree m is derived by the convolution product

$$\beta^m = \beta^0 * \beta^{m-1} = \underbrace{\beta^0 * \dots * \beta^0}_{m+1\text{-times}} \quad \text{for } m \in \mathbb{N}, \quad (2)$$

where

Fig. 1 Cardinal B-splines of degree $m = 0, \dots, 4$

$$\beta^0 * \beta^{m-1}(x) = \int_{\mathbb{R}} \beta^0(y) \beta^{m-1}(x-y) dy = \int_0^1 \beta^{m-1}(x-y) dy.$$

For an illustration of the cardinal B-splines, see Fig. 1.

Splines had their second breakthrough as Battle [4] and Lemarié [38] discovered that B-splines generate multiresolution analyses. The simple form of the B-splines and their compact support, in particular, were convenient for designing multiresolution algorithms and fast implementations.

Definition 1. Let $A : \mathbb{R}^n \rightarrow \mathbb{R}^n$ be a linear mapping that leaves \mathbb{Z}^n invariant, i.e., $A(\mathbb{Z}^n) \subset \mathbb{Z}^n$ and that has (real or complex) eigenvalues with absolute values greater than 1.

A multiresolution analysis associated with the dilation matrix A is a sequence of nested subspaces $(V_j)_{j \in \mathbb{Z}}$ of $L^2(\mathbb{R}^n)$ such that the following conditions hold:

- (i) $\dots \subset V_{-1} \subset V_0 \subset V_1 \subset \dots$,
- (ii) $\cap_{j \in \mathbb{Z}} V_j = \{0\}$,
- (iii) Span $\cup_{j \in \mathbb{Z}} V_j$ is dense in $L^2(\mathbb{R}^n)$,
- (iv) $f \in V_j \Leftrightarrow f(A^{-j} \cdot) \in V_0$,
- (v) $f \in V_0 \Leftrightarrow f(\cdot - k) \in V_0$ for all $k \in \mathbb{Z}^n$.
- (vi) There exists a so-called scaling function $\phi \in V_0$ such that the family $\{\phi(\bullet - k)\}_{k \in \mathbb{Z}^n}$ of translates of ϕ forms a Riesz basis of V_0 .

Here, $L^2(\mathbb{R}^n)$ denotes the vector space of square-integrable functions $f : \mathbb{R}^n \rightarrow \mathbb{C}$ with norm

$$\|f\|_2 = \left(\int_{\mathbb{R}^n} |f(x)|^2 dx \right)^{\frac{1}{2}}$$

and corresponding inner product

$$\langle f, g \rangle = \int_{\mathbb{R}^n} f(x) \overline{g(x)} \, dx,$$

where \bar{g} denotes the complex conjugate of g . The elements in $L^2(\mathbb{R}^n)$ are also called functions of finite energy.

Riesz bases are a slightly more general concept than orthonormal bases. In fact, Riesz bases are equivalent to orthonormal bases and therefore can be generated by applying a topological isomorphism on some orthonormal basis.

Definition 2. A sequence of functions $\{f_n\}_{n \in \mathbb{Z}}$ in a Hilbert space V is called a Riesz sequence if there exist positive constants A and B , the Riesz bounds, such that

$$A \|c\|_{l^2} \leq \left\| \sum_{k \in \mathbb{Z}^n} c_k f_k \right\|_V \leq B \|c\|_{l^2}$$

for all scalar sequences $C = (c_k)_{k \in \mathbb{Z}^n} \subset l^2(\mathbb{Z}^n)$.

A Riesz sequence is called a Riesz basis if it additionally spans the space V .

A good introduction to Riesz bases, their properties, and their relation to orthonormal bases is given in the monography by Young [75]. Multiresolution constructions with splines are treated in numerous sources. As a starting point, there are, e.g., the books by Christensen [13, 14] and Wojtaszczyk [74].

The mathematical properties in Definition 1 have intuitive interpretations. A function $f \in L^2(\mathbb{R}^n)$, which is projected orthogonally on V_j , is approximated with the so-called resolution A^j . In fact, let

$$P_j : L^2(\mathbb{R}^n) \rightarrow V_j$$

denote the orthogonal projection operator. Then (ii) yields that by going to lower resolutions, all details are lost:

$$\lim_{j \rightarrow -\infty} \|P_j f\| = 0.$$

In contrast, when the resolution is increased, $j \rightarrow \infty$, more and more details are added. By (iii), the projection then converges to the original function f :

$$\lim_{j \rightarrow \infty} \|f - P_j f\| = 0.$$

Hereby, the rate of convergence depends on the regularity of f .

The approximation spaces V_j are nested, which allows for computing coarser approximations in V_k for $k < j$ for functions $f \in V_j$. The scaling A^k enlarges details. Property (iv) shows that the approximation spaces have a similar structure over the scales and emanate from one another. The translation invariance (v) ensures that the analysis of a function in V_j is independent of the starting time or location.

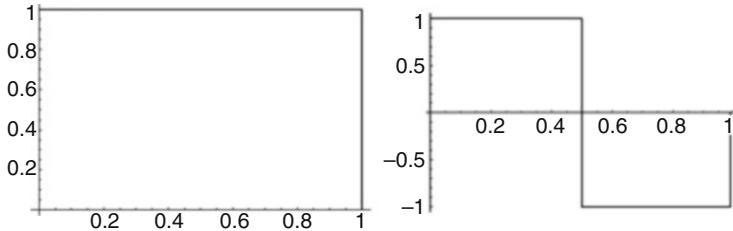

Fig. 2 *Left:* The B-spline β^0 is a scaling function and operates as mean value. *Right:* The corresponding wavelet, the Haar wavelet, operates as a local difference operator

And property (vi) finally ensures the beautiful and mighty property that the whole sequence of nested approximation spaces can be generated by translates and scalings of one single function – the scaling function. In fact, (vi) together with (iv) yields that

$$\{\phi(A^j \bullet -k), k \in \mathbb{Z}^n\}$$

is a Riesz basis for V_j .

While moving from the coarser approximation space V_j to the finer, larger space V_{j+1} , information has to be added. In fact, there is an orthogonal complement W_j , $j \in \mathbb{Z}$, such that

$$V_{j+1} = V_j \oplus W_j.$$

These spaces are called detail spaces or wavelet spaces. It is well known that these spaces also possess a Riesz basis spanned by shifts of $|\det A| - 1$ generators, the wavelets $\psi_1, \dots, \psi_{|\det A|-1}$. Here, A is the dilation matrix in Definition 1. The wavelets can be constructed from the scaling function. As a consequence, the knowledge of just the single function ϕ allows for the construction of the approximation spaces V_j and for the wavelet spaces W_j . Detailed information on the generation of wavelets and their properties can be found in various books, e.g., [16, 21, 41, 44, 74].

Example 1. A simple example for a multiresolution analysis on $L^2(\mathbb{R})$ is given by piecewise constant functions. Consider the characteristic function $\phi = \chi_{[0,1)}$ of the interval semi-open interval $[0, 1)$. Then ϕ generates a dyadic multiresolution analysis, i.e., for $A = 2$. The approximation spaces are

$$V_j = \overline{\text{span } \{\chi_{[0,1)}(2^j \bullet -k)\}_{k \in \mathbb{Z}}}^{L^2(\mathbb{R})}.$$

They consist of functions constant on intervals of the form $[k2^{-j}, (k+1)2^{-j})$. The spaces are obviously nested and separate $L^2(\mathbb{R})$ in the sense of Definition 1 (ii).

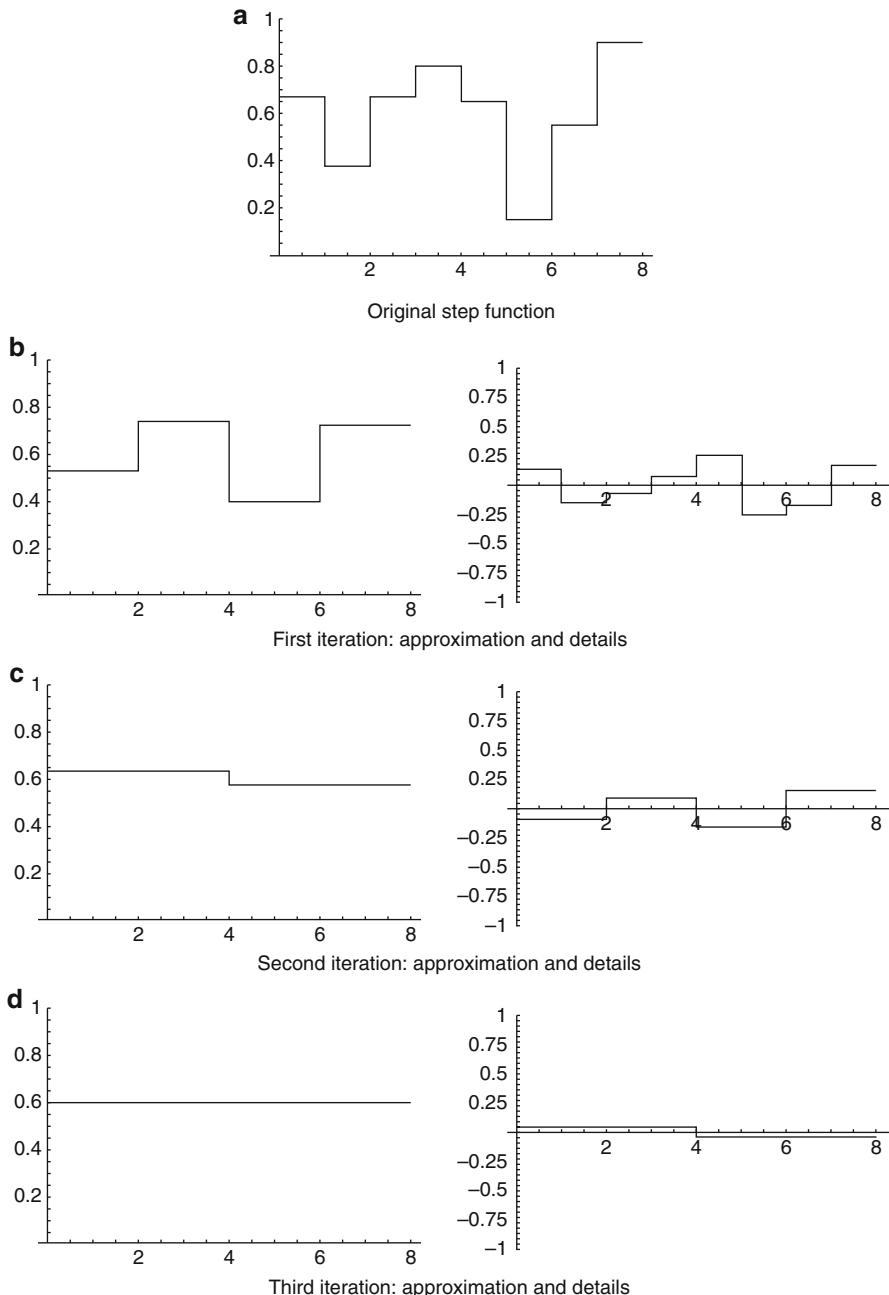

Fig. 3 Multiresolution decomposition of the step function (a) with β^0 as scaling function and with the Haar wavelet. The approximations (left column) are further iterated and decomposed into a coarser approximation and details (right column), until the coarsest approximation step, here the mean value, is reached. The sum of the coarsest approximation in the third iteration and of all details yields the original function (a). No information is lost in a multiresolution decomposition

Since piecewise constant functions with compact support are dense in $L^2(\mathbb{R})$, (iii) holds. (iv) – (vi) hold by construction. In fact, this multiresolution analysis is generated by the B-spline β^0 as scaling function. The B-spline basis operates as mean-value operator over the support interval. The corresponding wavelet extracts the details, i.e., the deviation from the mean value. To this end, it operates as a difference operator. Figure 2 shows the scaling function β^0 and the corresponding wavelet, the so-called Haar wavelet. In Fig. 3, an example of a multiresolution is given.

2 Historical Notes

The idea of piecewise polynomial functions and splines goes back to Schoenberg [59, 60]. In the 1960s, when computer power started to be used for numerical procedures such as data fitting, interpolation, solving differential equations, and computer-aided geometric design, splines experienced an extreme upsurge. Schoenberg invented and strongly contributed to the concept of cardinal splines, which have equidistant nodes on the integers; see, e.g., [40, 61, 62] and many more.

As a parallel development, in the 1980s, the adaption of signal resolution to only process relevant details for a particular task evolved. For example, for computer vision, a multiresolution pyramid was introduced by Burt and Adelson [8]. It allowed to process an image first on a low-resolution level and then selectively increase the resolution and add more detailed information when needed. The definition of a dyadic multiresolution analysis, i.e., $A = 2Id$, was contributed by Mallat [43] and Meyer [46]. An interesting and in some parts historical collection on the most important articles in multiresolution and wavelet theory was assembled by Heil and Walnut [33].

The concepts of splines and multiresolution were joined by Lemarié [38] and Battle [4], when they showed that cardinal B-splines are scaling functions for multiresolution analyses. This led to many more developments of piecewise polynomial scaling functions for various settings and also multidimensions [15], as, e.g., polyharmonic B-splines [53, 54] and other functions inspired from radial basis functions [7].

In 1989, S. Mallat published his famous algorithm for multiresolution and wavelet analysis [43]. He had developed an efficient numerical method such that multiresolution decompositions could be calculated in a fast way. For the splines, M. Unser et al. proposed a fast implementation [66, 68, 69] which strongly contributed to the breakthrough of splines for signal and image analysis. In the last years, periodic, fractional, and complex versions of splines for multiresolution were developed, e.g., [11, 27, 28, 51, 65]. Many of them use a Fourier domain filter algorithm which allows for infinite impulse response filters. The former important feature of compact support of the cardinal B-splines and other functions is no longer a limiting criterion. Therefore, it can be expected that many new contributions on splines will still be made in the future by modeling signal and image features in Fourier domain.

3 Fourier Transform, Multiresolution, Splines, and Wavelets

Mathematical Foundations

Regularity and Decay Under the Fourier Transform

An important idea behind splines and multiresolution is the relation between regularity in time domain and decay in frequency domain and, respectively, between decay in time domain and regularity in frequency domain. To illustrate this, the notion of the Schwartz space is very useful [10, 34, 56, 63].

Definition 3. The subspace of functions $f \in C^\infty(\mathbb{R}^n)$ with

$$\sup_{|\alpha| \leq N} \sup_{x \in \mathbb{R}^n} (1 + \|x\|^2)^N |D^\alpha f(x)| < \infty \quad \text{for all } N = 0, 1, 2, \dots$$

is called the space of rapidly decreasing functions or Schwartz space $\mathcal{S}(\mathbb{R}^n)$. The norms induce a Fréchet space topology, i.e., the space $\mathcal{S}(\mathbb{R}^n)$ is complete and metrizable.

Here, $D^\alpha = \left(\frac{\partial}{\partial x_1}\right)^{\alpha_1} \cdots \left(\frac{\partial}{\partial x_n}\right)^{\alpha_n}$ for every multi-index $\alpha = (\alpha_1, \dots, \alpha_n) \in \mathbb{N}_0^n$.

The dual space $\mathcal{S}'(\mathbb{R}^n)$, endowed with the weak-* topology, is called space of tempered distributions.

The following famous linear transform relates the viewpoints of the space domain and of the frequency domain:

Definition 4. The Fourier transform, defined by

$$\mathcal{F}f(\omega) := \hat{f}(\omega) := \int_{\mathbb{R}^n} f(x) e^{-i\langle \omega, x \rangle} dx, \quad \omega \in \mathbb{R}^n,$$

is a topological isomorphism on $L^2(\mathbb{R}^n)$ and on $\mathcal{S}(\mathbb{R}^n)$. Its inverse is given by

$$f(x) = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} \hat{f}(\omega) e^{i\langle \omega, x \rangle} d\omega \quad \text{in } L^2(\mathbb{R}^n) \text{ resp. in } \mathcal{S}(\mathbb{R}^n).$$

The Fourier transform can be extended to the space of tempered distributions. For $T \in \mathcal{S}'(\mathbb{R}^n)$, the Fourier transform is defined in a weak sense as

$$\mathcal{F}T(\phi) := \hat{T}(\phi) := T(\hat{\phi}) \text{ for all } \phi \in \mathcal{S}(\mathbb{R}^n).$$

Also on $\mathbb{S}'(\mathbb{R}^n)$, the Fourier transform is a topological isomorphism.

The Fourier transform has the nice property to relate polynomials and differential operators.

Theorem 1.

(i) Let $f \in \mathcal{S}(\mathbb{R})$. Then for all $k \in \mathbb{N}$

$$\mathcal{F}(f^{(k)})(\omega) = (i\omega)^k \hat{f}(\omega),$$

and

$$\hat{f}^{(k)}(\omega) = \mathcal{F}((-i\bullet)^k f)(\omega).$$

(ii) Let P be an algebraic polynomial in \mathbb{R}^n , say $P(x) = \sum_{\alpha} c_{\alpha} x_1^{\alpha_1} \dots x_n^{\alpha_n}$, and let $f \in \mathcal{S}(\mathbb{R}^n)$. Then

$$\mathcal{F}\left(P\left(\frac{1}{i}D\right)f\right) = P\hat{f} \quad \text{and} \quad \widehat{Pf} = P(iD)\hat{f},$$

where $P(iD) = \sum_{\alpha} c_{\alpha} i^{|\alpha|} D^{\alpha}$.

(iii) Part (ii) also holds for $f \in \mathcal{S}'(\mathbb{R}^n)$.

Example 2. The Fourier transform of the polynomial x^k is the tempered distribution $i^k \frac{d^k}{dx^k} \delta$, $k \in \mathbb{N}_0$.

For the construction of a multiresolution analysis, the scaling function can be used as a starting point. The idea is to choose a scaling function of a certain regularity, such that the generated multiresolution analysis inherits the smoothness properties. In particular, for the splines, the idea is to model the regularity via decay in Fourier domain. The following theorem gives a motivation for this. The result can be deduced from the considerations above, and the fact that $\mathcal{S}(\mathbb{R}^n)$ is dense in $L^2(\mathbb{R}^n)$:

Theorem 2. Let $f \in L^2(\mathbb{R}^n)$ and its Fourier-transform decay as

$$|\hat{f}(\omega)| \leq C(1 + \|\omega\|)^{-N-\epsilon}$$

for some $\epsilon > 0$. Then all partial derivatives of order $\leq N - n$ are continuous and in $L^2(\mathbb{R}^n)$.

These results allow to construct a scaling function with explicit regularity and decay properties, in space and in frequency domain. However, some criteria are needed to verify that the constructed function generates a multiresolution analysis.

Criteria for Riesz Sequences and Multiresolution Analyses

The following is an explicit criterion to verify whether some function ϕ is a scaling function.

Theorem 3. Let A be a dilation matrix and let $\phi \in L^2(\mathbb{R}^n)$ be some function satisfying the following properties:

- (i) $\{\phi(\bullet - k)\}_{k \in \mathbb{Z}^n}$ is a Riesz sequence in $L^2(\mathbb{R}^n)$.
- (ii) ϕ satisfies a scaling relation. That is, there is a sequence of coefficients $(a_k)_{k \in \mathbb{Z}^n}$ such that

$$\phi(A^{-1}x) = \sum_{k \in \mathbb{Z}^n} a_k \phi(x + k) \quad \text{in } L^2(\mathbb{R}^n). \quad (3)$$

- (iii) $|\hat{\phi}|$ is continuous at 0 and $\hat{\phi}(0) \neq 0$.

Then the spaces

$$V_j = \text{span} \{\phi(A^j \bullet -k)\}_{k \in \mathbb{Z}^n}, \quad j \in \mathbb{Z},$$

form a multiresolution analysis of $L^2(\mathbb{R}^n)$ with respect to the dilation matrix A .

Proof. See, e.g., [74, Theorem 2.13] for the 1D case.

For particular applications, the Riesz basis property (i) of $\{\phi(\bullet - k)\}_{k \in \mathbb{Z}^n}$ in V_0 is not enough, but an orthonormal basis is needed. An example for such an application is the denoising of signals contaminated with Gaussian white noise [44, Chap. X, Sect. 10.2.1]. However, there is an elegant mathematical method to orthonormalize Riesz bases generated by shifts of a single function.

Theorem 4. Let $\phi \in L^2(\mathbb{R}^n)$. Then the following holds:

- (i) $\{\phi(\bullet - k)\}_{k \in \mathbb{Z}^n}$ is a Riesz sequence in $L^2(\mathbb{R}^n)$ if and only if there are constants c and C , such that

$$0 < c \leq \sum_{k \in \mathbb{Z}^n} |\hat{\phi}(\omega + 2\pi k)|^2 \leq C < \infty \text{ almost everywhere.}$$

That is, the autocorrelation filter $M(\omega) := \sum_{k \in \mathbb{Z}^n} |\hat{\phi}(\omega + 2\pi k)|^2$ is strictly positive and bounded from above.

- (ii) $\{\phi(\bullet - k)\}_{k \in \mathbb{Z}^n}$ is an orthonormal sequence if and only if

$$\sum_{k \in \mathbb{Z}^n} |\hat{\phi}(\omega + 2\pi k)|^2 = 1 \text{ almost everywhere.}$$

- (iii) If $\{\phi(\bullet - k)\}_{k \in \mathbb{Z}^n}$ is a Riesz basis of a subspace X of $L^2(\mathbb{R}^n)$, then there exists a function $\Phi \in L^2(\mathbb{R}^n)$, namely,

$$\hat{\Phi}(\omega) = \frac{\hat{\phi}(\omega)}{\sqrt{\sum_{k \in \mathbb{Z}^n} |\hat{\phi}(\omega + 2\pi k)|^2}} \quad (4)$$

such that $\{\Phi(\bullet - k)\}_{k \in \mathbb{Z}^n}$ is an orthonormal basis of X .

Proof. See, e.g., [74] and [44, Chap. VII].

Due to this theorem, every scaling function can be orthonormalized. Let $\phi \in L^2(\mathbb{R}^n)$ be some scaling function that generates a multiresolution analysis $\{V_j\}_{j \in \mathbb{Z}}$ of $L^2(\mathbb{R}^n)$. Then the family $\{\Phi_{j,k}\}_{k \in \mathbb{Z}^n}$ with

$$\Phi_{j,k}(x) = 2^{-j/2} \phi(2^{-j}(x - k)),$$

and Φ as defined in (4) is an orthonormal basis of the space V_j , $j \in \mathbb{Z}$.

Example 3. A simple possibility to construct a dyadic multiresolution analysis in $L^2(\mathbb{R}^n)$ is the tensor product approach. Let $(V_j)_{j \in \mathbb{Z}}$ be a dyadic (i.e., $A = 2$) multiresolution analysis of $L^2(\mathbb{R})$ with scaling function ϕ . Then $(V_j)_{j \in \mathbb{Z}}$ with $V_j = \underbrace{V_j \otimes \cdots \otimes V_j}_{n-\text{times}}$ together with the scaling function $\phi(x_1, \dots, x_n) = \phi(x_1) \cdot \dots \cdot \phi(x_n)$ forms a multiresolution analysis of $L^2(\mathbb{R}^n)$ and dilation matrix $2Id$.

In the same way, the scaling function $\phi(x_1, \dots, x_n) = \phi_1(x_1) \cdot \dots \cdot \phi_n(x_n)$ generates a multiresolution analysis of $L^2(\mathbb{R}^n)$, if every ϕ_k , $k = 1, \dots, n$, is a scaling function of some 1D multiresolution analysis with dilation factor $a \in \mathbb{N} \setminus \{1\}$.

Regularity of Multiresolution Analysis

In signal and image analysis, the choice of an appropriate analysis basis is crucial. Here, appropriate means that the features of the basis such as smoothness should be in accordance with the properties of the functions to analyze. To give a blatant example: Analyzing a smooth signal or image with a fractal basis in general yields results that are difficult to interpret and to work with in practice. In this case, the signal resp. the image model does not match the model of the basis.

The next section will show that the family of spline bases helps to avoid such difficulties, because the splines allow for a good adjustment due to their regularity parameter m ; cf. (1) and (2). The following definition specifies the term “regular.” (See [74].)

Definition 5. Denote C^r the class of r -times continuously differentiable functions in \mathbb{R}^n , C^0 the class of continuous functions, and C^{-1} the class of measurable functions.

(i) Let $r = -1, 0, 1, \dots$. A function $f : \mathbb{R}^n \rightarrow \mathbb{C}$ is called r -regular, iff $\in C^r$ and

$$\left| \frac{\partial^\alpha}{\partial x^\alpha} f(x) \right| \leq \frac{A_k}{(1 + \|x\|)^k}$$

- for every $k \in \mathbb{N}_0$, every multi-index α with $|\alpha| \leq \max(r, 0)$ and constants A_k .
(ii) A multiresolution analysis of $L^2(\mathbb{R}^n)$ is called r -regular if it is generated by an r -regular scaling function.

It is important to note that the orthonormalization procedure (4) does not affect the regularity of the corresponding basis. For the orthonormalized scaling function Φ of a multiresolution analysis, the same regularity properties hold.

Proposition 1. *Let $\phi \in L^2(\mathbb{R}^n)$ be an r -regular function, such that $\{\phi(\bullet - k)\}_{k \in \mathbb{Z}^n}$ forms a Riesz sequence. Then the via (4) orthonormalized function Φ is also r -regular [74].*

Order of Approximation

Having found a scaling function that generates a multiresolution analysis, how good do the corresponding approximation spaces V_j approximate some function $f \in L^2(\mathbb{R}^n)$ of a certain regularity? Let

$$H^k(\mathbb{R}^n) = \{f \in L^2(\mathbb{R}^n) : \|f\|_{H^k} := \frac{1}{(2\pi)^n} \|(1 + \|\bullet\|_{\mathbb{R}^n})^k \hat{f}\|_{L^2} < \infty\}, \quad k \in \mathbb{N}_0$$

denote the Sobolev spaces. The following criterion for the order of approximation turns out to be easy to verify for splines.

Theorem 5. *Let $\phi \in L^2(\mathbb{R}^n)$ satisfy the following properties [23, Theorem 1.15]:*

- (i) $1/\hat{\phi}$ is bounded on some neighborhood of the origin.
- (ii) Let B_ε be some open ball centered at the origin and let $E := B_\varepsilon + (2\pi\mathbb{Z}^n \setminus \{0\})$. For some $\alpha > k + n/2$, all derivatives of $\hat{\phi}$ of order $\leq \alpha$ are in $L^2(E)$.
- (iii) $D^\gamma \hat{\phi}(\omega) = 0$ for all $|\gamma| < k$ and all $\omega \in 2\pi\mathbb{Z}^d \setminus \{0\}$.

Then $V_0 = \overline{\text{span } \{\phi(\bullet - k)\}_{k \in \mathbb{Z}^n}}$ provides an approximation order k :
For $f \in H^k(\mathbb{R}^n)$,

$$\min\{\|f - s(\bullet/h)\|_{L^2}, s \in V_0\} \leq \text{const. } h^k \|f\|_{H^k} \quad \text{for all } h > 0.$$

Wavelets

For the step from a coarser approximation space V_j to a finer one V_{j+1} , information has to be added. It is contained in the wavelet space or detail space W_j , which is the orthonormal complement of V_j in V_{j+1} :

$$V_{j+1} = V_j \oplus W_j.$$

It follows that $V_{j+m} = V_j \oplus \bigoplus_{l=0}^{k-1} W_{j+l}$, and hence

$$L^2(\mathbb{R}^n) = \bigoplus_{j \in \mathbb{Z}} W_j \quad (5)$$

can be decomposed in a direct sum of mutually orthogonal detail spaces. Moreover, the detail spaces W_j inherit the scaling property from Definition 1(iv) for the approximation spaces V_j . For all $j \in \mathbb{Z}$,

$$f \in W_j \Leftrightarrow f(A^{-j} \bullet) \in W_0.$$

The question now is whether there is also a simple basis generated by the shifts of one or few functions, the wavelets. The following definition is motivated from Eq. (5).

Definition 6. Let A be a dilation matrix, and let $\{\psi_l\}_{l=1,\dots,q}, q \in \mathbb{N}$, be a set of functions in $L^2(\mathbb{R}^n)$, such that the family

$$\{|\det A|^{j/2} \psi_l(A^j \bullet -k)| l = 1, \dots, q, j \in \mathbb{Z}, k \in \mathbb{Z}^n\}$$

forms an orthonormal basis of $L^2(\mathbb{R}^n)$. Then $\{\psi_l\}_{l=1,\dots,q}$ is called a wavelet set associated with A .

What qualitative properties do the wavelets have? The approximation spaces V_j are generated by the scaling function, which operates as a low-pass filter. This can be seen from Theorem 3(iii) $\hat{\phi}(0) \neq 0$ and resp. from Theorem 5(i): $1/\hat{\phi}$ is bounded in some neighborhood of the origin. Therefore, the added details and thus the wavelets have to carry the high-frequency information. In addition, the wavelets ψ in W_0 are elements of V_1 and therefore have the form

$$\psi(A^{-1}x) = \sum_{k \in \mathbb{Z}^n} a_k \phi(x - k) \quad (6)$$

in L^2 norm, where $\{a_k\}_{k \in \mathbb{Z}^n}$ are the Fourier coefficients of a certain $2\pi\mathbb{Z}^n$ -periodic function.

Proposition 2. Let $(V_j)_{j \in \mathbb{Z}}$ be a multiresolution analysis of $L^2(\mathbb{R}^n)$ with respect to the dilation matrix A and with scaling function ϕ . Then for a function $f \in L^2(\mathbb{R}^n)$ the following are equivalent: $f \in V_1$ id and only if

$$\hat{f}(A^T \omega) = m_f(\omega) \hat{\phi}(\omega) \text{ almost everywhere.}$$

Here, $m_f \in L^2([0, 2\pi]^n)$ and

$$\|m_f\|_{L^2([0, 2\pi]^n)}^2 = \frac{1}{|\det A|} \|f\|_{L^2(\mathbb{R}^n)}^2.$$

For a proof, see, e.g., [21, 74]. Note that for a wavelet ψ as in Eq. (6), there holds

$$m_\psi(\omega) = \frac{1}{|\det A|} \sum_{k \in \mathbb{Z}^n} a_k e^{i \langle \omega, k \rangle}.$$

How many wavelets, i.e., generators of W_0 , are needed to span the space? The parameter q in Definition 6 is yet unspecified. In fact, q depends on the scaling matrix. A leaves the lattice \mathbb{Z}^n invariant, $A\mathbb{Z}^n \subset \mathbb{Z}^n$. The number of cosets is $|\det A| = |\mathbb{Z}^n / A\mathbb{Z}^n|$ (see [74, Proposition 5.5]). It turns out that $q = |\det A| - 1$ wavelets are needed to generate the space W_0 . To motivate this, for a start, let $f \in V_1$ be an arbitrary function. Denote $\gamma_0, \dots, \gamma_q$ representatives of the $q + 1$ cosets of $A\mathbb{Z}^n$ in \mathbb{Z}^n . Then each coset can be written as $\gamma_m + A\mathbb{Z}^n$, $m = 0, \dots, q$. The function f has the representation

$$\frac{1}{|\det A|^{1/2}} f(A^{-1}x) = \sum_{k \in \mathbb{Z}^n} c_k(f) \phi(x - k), \quad (7)$$

or in Fourier domain

$$\hat{f}(A^T \omega) = \frac{1}{|\det A|^{1/2}} c_f(\omega) \hat{\phi}(\omega), \quad (8)$$

in L^2 sense and with an appropriate $2\pi\mathbb{Z}^n$ -periodic function $c_f(\omega)$ with Fourier coefficients $(c_k(f))_{k \in \mathbb{Z}^n}$. Then $c_f(\omega)$ can be decomposed with respect to the cosets:

$$\begin{aligned} c_f(\omega) &= \sum_{k \in \mathbb{Z}^n} c_k(f) e^{i \langle \omega, k \rangle} = \sum_{m=0}^q \sum_{k \in \gamma_m + A\mathbb{Z}^n} c_k(f) e^{i \langle \omega, k \rangle} \\ &= \sum_{m=0}^q e^{i \langle \omega, \gamma_m \rangle} \sum_{k \in A\mathbb{Z}^n} c_{k+\gamma_m}(f) e^{i \langle \omega, k \rangle} = \sum_{m=0}^q c_f^m(\omega), \end{aligned}$$

where

$$\begin{aligned} c_f^m(\omega) &= e^{i \langle \omega, \gamma_m \rangle} \sum_{k \in A\mathbb{Z}^n} c_{k+\gamma_m}(f) e^{i \langle \omega, k \rangle} = e^{i \langle \omega, \gamma_m \rangle} \sum_{k \in \mathbb{Z}^n} c_{Ak+\gamma_m}(f) e^{i \langle \omega, Ak \rangle} \\ &= e^{i \langle \omega, \gamma_m \rangle} \sum_{k \in \mathbb{Z}^n} c_{Ak+\gamma_m}(f) e^{i \langle A^T \omega, k \rangle} = e^{i \langle \omega, \gamma_m \rangle} \kappa_f^m(A^T \omega). \end{aligned}$$

This representation exists for all functions V_1 , in particular for ϕ and the wavelets. The following theorem indicates how the wavelets are constructed that generate the space W_0 , such that $W_0 \oplus V_0 = V_1$.

Theorem 6. Let $\phi \in V_0$ be a scaling function and let $\psi_1, \dots, \psi_q \in V_1$. Then the family $\{\phi(\bullet - k)\}_{k \in \mathbb{Z}^n}$ is an orthonormal system if and only if

$$\sum_{m=0}^q \left| \kappa_\phi^m(\omega) \right|^2 = 1 \quad \text{almost everywhere.} \quad (9)$$

The system $\{\phi(\bullet - k)\}_{k \in \mathbb{Z}^n} \cup \bigcup_{m=1}^q \{\psi_m(\bullet - k)\}_{k \in \mathbb{Z}^n}$ is an orthonormal basis in V_1 if and only if the so-called polyphase matrix

$$\begin{pmatrix} \kappa_\phi^0(\omega) & \kappa_{\psi_1}^0(\omega) & \cdots & \kappa_{\psi_q}^0(\omega) \\ \vdots & \vdots & \ddots & \vdots \\ \kappa_\phi^q(\omega) & \kappa_{\psi_1}^q(\omega) & \cdots & \kappa_{\psi_q}^q(\omega) \end{pmatrix}$$

is unitary for almost all $\omega \in \mathbb{R}^n$.

The proof for a more general version of this theorem is given in [74, Sect. 5.2].

A summary and a condition for r -regular wavelets yields in the following theorem.

Theorem 7. Consider a multiresolution analysis on \mathbb{R}^n associated with a dilation matrix A .

- (i) Then there exists an associated wavelet set consisting of $q = |\det A| - 1$ functions.
- (ii) If the multiresolution analysis is r -regular and in addition $2q + 1 > n$, then there exists an associated wavelet set consisting of q functions, which all are r -regular.

The idea of the proof is that for an r -regular function ϕ on \mathbb{R}^n and a $2\pi\mathbb{Z}^n$ -periodic C^∞ -function $\eta(\omega)$, the convolution ψ defined by $\hat{\psi}(\omega) = \eta(\omega)\hat{\phi}(\omega)$ is an r -regular function. For an explicit proof, see again [74].

Example 4. As a continuation of Example 1, the wavelet function corresponding to $\phi = \chi_{[0,1]}$ is derived. To this end, consider the space $L^2(\mathbb{R})$ and the dilation $A = 2$. Then $q = \det A - 1 = 1$; thus $\gamma_0 = 0$ and $\gamma_1 = 1$ are representatives of the cosets of A . That is, there is only a single wavelet needed to generate W_0 . Equation (7) yields

$$\frac{1}{\sqrt{2}}\phi\left(\frac{x}{2}\right) = \frac{1}{\sqrt{2}}\phi(x) + \frac{1}{\sqrt{2}}\phi(x-1)$$

for the normalized generator of V_1 . Thus, $c_0(\phi) = \frac{1}{\sqrt{2}}$ and $c_1(\phi) = \frac{1}{\sqrt{2}}e^{i\omega}$. This implies $\kappa_\phi^0\left(\frac{\omega}{2}\right) = \kappa_\phi^1\left(\frac{\omega}{2}\right) = \frac{1}{\sqrt{2}}$. Then by Eq. (9) of Theorem 6, the family $\{\phi(\cdot - k)\}_{k \in \mathbb{Z}}$ is orthogonal, since $\kappa_\phi^0(\omega)^2 + \kappa_\phi^1(\omega)^2 = 1$. The polyphase matrix

$$\begin{pmatrix} \kappa_\phi^0(\omega) & \kappa_\psi^0(\omega) \\ \kappa_\phi^1(\omega) & \kappa_\psi^1(\omega) \end{pmatrix}$$

can be completed to a unitary matrix by choosing $\kappa_\psi^0(\omega) = \frac{1}{\sqrt{2}} = -\kappa_\psi^1(\omega)$. The corresponding wavelet then has the representation

$$\frac{1}{\sqrt{2}}\psi\left(\frac{x}{2}\right) = \frac{1}{\sqrt{2}}\phi(x) - \frac{1}{\sqrt{2}}\phi(x-1),$$

corresponding to (7). This yields the Haar wavelet ψ as illustrated in Fig. 2.

B-Splines

Several of the criteria for scaling functions and multiresolution analyses given in the previous section are based on the Fourier representation of the scaling function, e.g., the Riesz sequence criterion and the orthonormalization trick in Theorem 4, as well as the criterion for the order of approximation in Theorem 5. For this reason, the modeling of a scaling function in the Fourier domain to achieve certain specific properties is promising.

Aiming at constructing a scaling function $\phi \in L^2(\mathbb{R})$ of regularity $r = -1, 0, 1, \dots$, this property is considered in the Fourier domain: It is a decay property of the Fourier transform $\hat{\phi}$ (compare with section ‘‘Regularity and Decay Under the Fourier Transform’’):

$$\hat{\phi}(\omega) = \mathcal{O}\left(\frac{1}{\|\omega\|^{r+2}}\right) \quad \text{for } \|\omega\| \rightarrow \infty.$$

Taking into account Theorem 2, a first model for the scaling function in the Fourier domain is

$$\hat{\phi}(\omega) = \frac{\nu(\omega)}{\omega^{r+2}}, \quad \omega \in \mathbb{R}, \tag{10}$$

where the function ν still has to be specified. Since scaling functions satisfy a scaling relation (3)

$$\phi\left(\frac{x}{2}\right) = \sum_{k \in \mathbb{Z}} h_k \phi(x-k) \quad \text{in } L^2(\mathbb{R}),$$

the Fourier transform of this equation yields

$$2\hat{\phi}(2\omega) = H(\omega)\hat{\phi}(\omega),$$

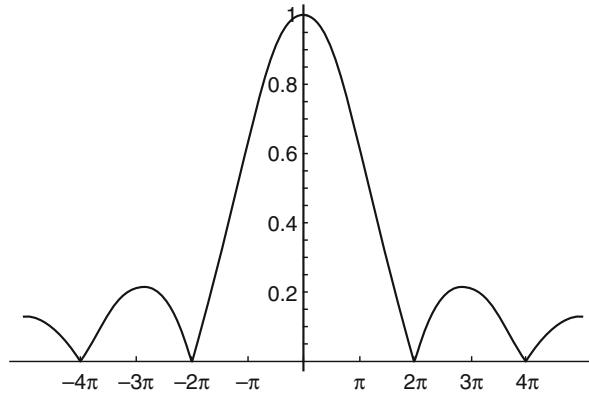

Fig. 4 The function $|\beta^0|^{\lambda}$ is strictly positive in the interval $[-\pi, \pi]$

where $(h_k)_{k \in \mathbb{Z}}$ is the sequence of Fourier coefficients of the 2π -periodic function H . For the ansatz (10),

$$H(\omega) = 2 \frac{\widehat{\phi}(2\omega)}{\widehat{\phi}(\omega)} = 2 \frac{\nu(2\omega)}{(2\omega)^{r+2}} \frac{\omega^{r+2}}{\nu(\omega)} = \frac{1}{2^{r+1}} \frac{\nu(2\omega)}{\nu(\omega)}. \quad (11)$$

This gives the criteria for the choice of the function ν :

- (i) ν vanishes at the origin and there is a zero of order $r + 2$. This ensures that $\widehat{\phi} \in L^2(\mathbb{R})$ and that Theorem 3(iii) is satisfied.
- (ii) $\nu(2\omega)$ is a trigonometric function, to ensure that $H(\omega)$, the so-called scaling filter, is 2π periodic.
- (iii) ν has no other zeros in $[-\pi, \pi]$, except at the origin. Otherwise, the auto-correlation filter $A(\omega) = \sum_{k \in \mathbb{Z}} |\widehat{\phi}(\omega + 2\pi k)|^2$ would vanish somewhere, and the shifts of the function ϕ would fail to generate a Riesz sequence; see Theorem 4(i).

A simple function ensuring all three requirements (i), (ii), and (iii) is

$$\nu(\omega) = (\sin(\omega/2)\theta(\omega/2))^{r+2},$$

where θ is a 2π -periodic phase factor such that $|\theta| = 1$, i.e., a shift in time domain. Choosing $\theta(\omega) = e^{-i\omega}$ yields the cardinal B-splines as given in (1) resp. (2):

$$\widehat{\beta^0}(\omega) = \int_0^1 e^{-i\omega t} dt = \frac{1 - e^{-i\omega}}{i\omega} = \frac{\sin(\omega/2)}{\omega/2} e^{-i\omega/2}.$$

Since β^0 has compact support, $\widehat{\beta^0} \in C^\infty$ [56]. Due to the convolution formula (2),

$$\hat{\beta}^m(\omega) = \left(\frac{1 - e^{-i\omega}}{i\omega} \right)^{m+1} = \left(\frac{\sin(\omega/2)}{\omega/2} e^{-i\omega/2} \right)^{m+1}. \quad (12)$$

The β^m are scaling functions of regularity $r = m - 1$, as the verification of the criteria in Theorem 3 shows. In fact, the following holds. Let $A = 2$.

Integrability: Since by (12) the functions $\hat{\beta}^m$ are L^2 integrable, so are the β^m , $m \in \mathbb{N}_0$.

Riesz sequence property: The shifted characteristic functions $\beta^0(x - k) = \chi_{[0,1)}(x - k)$, $k \in \mathbb{Z}$, are clearly orthonormal. Theorem 4(ii) thus yields

$$\sum_{k \in \mathbb{Z}} |\hat{\beta}^0(\omega + 2\pi k)|^2 = 1 \quad \text{almost everywhere.}$$

To verify the Riesz sequence property for β^m , the autocorrelation filter must be bounded with strictly positive constants from above and from below. It is

$$\sum_{k \in \mathbb{Z}} |\hat{\beta}^m(\omega + 2\pi k)|^2 = \sum_{k \in \mathbb{Z}} |\hat{\beta}^0(\omega + 2\pi k)|^{2m+2}.$$

In $[-\pi, \pi]$, $|\hat{\beta}^0|$ is clearly positive (cf. Fig. 4), which gives $|\hat{\beta}^0(\pi)| = 2/\pi$ as a positive bound from below. There is a constant c , such that

$$0 < c = (2/\pi)^{2m+2} < |\hat{\beta}^0(\omega)|^{2m+2} \leq \sum_{k \in \mathbb{Z}} |\hat{\beta}^m(\omega + 2\pi k)|^{2m+2}.$$

Since the sequence $(|\hat{\beta}^0(\omega + 2\pi k)|)_{k \in \mathbb{Z}} \in l^2(\mathbb{Z})$ for all $\omega \in \mathbb{R}$, the same is true for the sequence $|\hat{\beta}^m(\omega + 2\pi k)| = |\hat{\beta}^0(\omega + 2\pi k)|^{m+1}$. This yields the existence of the requested upper bound $c_2 < \infty$. Thus $\{\hat{\beta}^m(\bullet - k)\}_{k \in \mathbb{Z}}$ forms a Riesz sequence in $L^2(\mathbb{R})$.

Scaling relation: The scaling filter (11)

$$H(\omega) = 2^{-m} \frac{(1 - e^{-i2\omega})^{m+1}}{(1 - e^{-i\omega})^{m+1}} = 2^{-m} (1 + e^{-i\omega})^{m+1} = 2^{-m} \sum_{k=0}^{m+1} \binom{m+1}{k} e^{-i\omega k}$$

is obviously 2π -periodic and has Fourier coefficients $\left(2^{-m} \binom{m+1}{k} \right)_{k \in \mathbb{Z}} \in l^2(\mathbb{Z})$. Hence, the B-splines satisfy the scaling relation (3)

$$\beta^m(x/2) = \sum_{k=0}^{m+1} 2^{-m} \binom{m+1}{k} \beta^m(x + k).$$

For β^0 this equation reads

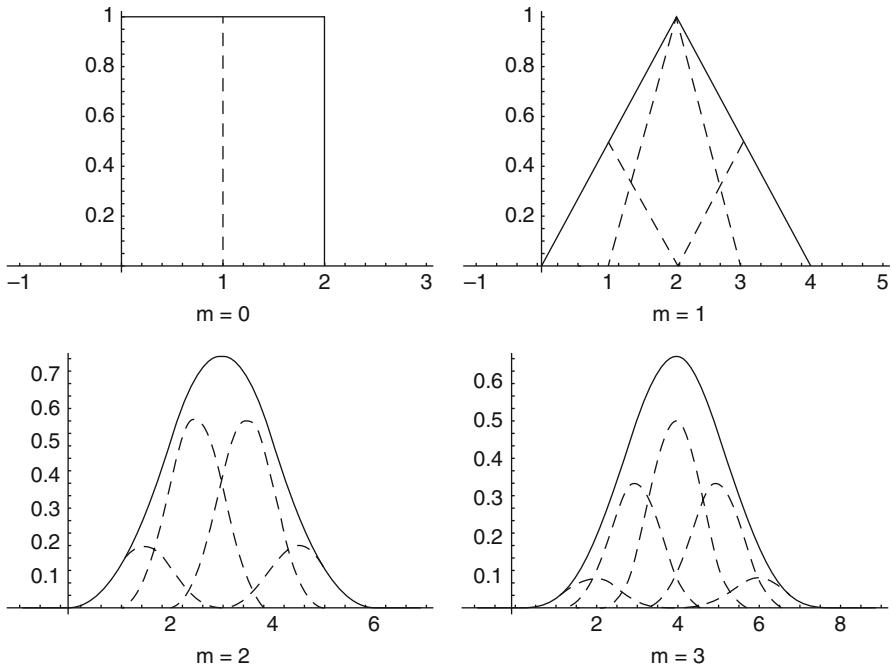

Fig. 5 Scaling relation for B-splines β^m , $m = 0, \dots, 3$. The B-spline versions $\beta^m(x/2) \in V_{-1}$ are displayed with solid lines; the scaled translates in V_0 are depicted with dashed lines. The sum of the dashed functions gives the B-spline at the lower scale $\beta^m(x/2)$

$$\beta^0(x/2) = \beta^0(x) + \beta^0(x+1),$$

which is true since $\beta^0(x/2) = \chi_{[0,1]}(x/2) = \chi_{[0,2]}(x)$. This equation and examples for scaling relations of other B-splines are illustrated in Fig. 5.

Continuity and positivity of $\hat{\phi}$ at the origin: From Eq. (12),

$$|\hat{\beta}^m(\omega)| = \left| \frac{\sin(\omega/2)}{\omega/2} \right|^{m+1},$$

which has a continuous continuation at the origin, and $\hat{\beta}^m(0) = 1$. Thus we have proved the following conclusion:

Theorem 8. *The cardinal B-spline β^m , $m \in \mathbb{N}_0$, is a scaling function of an $m - 1$ -regular multiresolution analysis with dilation 2. The order of approximation is $m + 1$.*

Note that the cardinal B-splines β^m with Fourier transform of the form (12) are scaling functions, but they are not yet orthonormalized: The family $\{\beta^m(\cdot - k)\}_{k \in \mathbb{Z}}$ spans V_0 and is a Riesz basis, but it is not an orthonormal basis of V_0 . Orthonormality can be achieved with Theorem 8 and Eq. (4):

$$\hat{B}^m(\omega) := \frac{\hat{\beta}^m(\omega)}{\sqrt{\sum_{k \in \mathbb{Z}} |\hat{\beta}^m(\omega + 2\pi k)|^2}}.$$

Figure 6 shows some orthonormalized B-spline scaling functions and the corresponding wavelets.

Polyharmonic B-Splines

The same approach to model scaling functions in Fourier domain can be done in higher dimensions. We aim at constructing a scaling function for a multiresolution analysis of $L^2(\mathbb{R}^n)$ of the form

$$\hat{\phi}(\omega) = \frac{\nu(\omega)}{\|\omega\|^{2r}}, \quad r \in \mathbb{N}, \quad r > n/2, \quad x \in \mathbb{R}^n.$$

With an appropriate trigonometric polynomial

$$\nu(\omega) = \left(4 \sum_{k=1}^n \sin^2(\omega_k/2) \right)^r, \quad \omega = (\omega_1, \dots, \omega_n),$$

$\hat{\phi}$ is a nonseparable scaling function for a multiresolution analysis of $L^2(\mathbb{R}^n)$ with respect to dilation matrices A that are scaled rotations. The corresponding function in space domain ϕ is called elementary r -harmonic cardinal B-spline, or short polyharmonic B-spline \mathcal{P}^r . This terminology can be justified as follows. The Fourier transform in the sense of tempered distributions of the function $1/\|\omega\|^{2r}$ is indeed a polynomial – up to a logarithmic factor for $2r - n$ even. In fact, in $\mathcal{S}'(\mathbb{R}^n)$,

$$\mathcal{F}^{-1}(1/\|\bullet\|^{2r})(x) = \|x\|^{2r-n} (A(n, r) \ln \|x\| + B(n, r)) =: \rho(x),$$

with constants $A(n, r)$, $B(n, r)$ as given in [63, Chap. VII, §7], and $A(n, r) = 0$ except for $2r - n$ even. (Note that for $r > n/2$ on the right-hand side, the Hadamard finite parts have to be considered.) The term polyharmonic comes from the fact that ρ is the Green function of the r -iterated Laplace operator Δ^r . However, with these considerations,

$$\phi(x) = \mathcal{P}^r(x) = \sum_{k \in \mathbb{Z}^2} v_k \rho(x + k) \quad \text{almost everywhere}$$

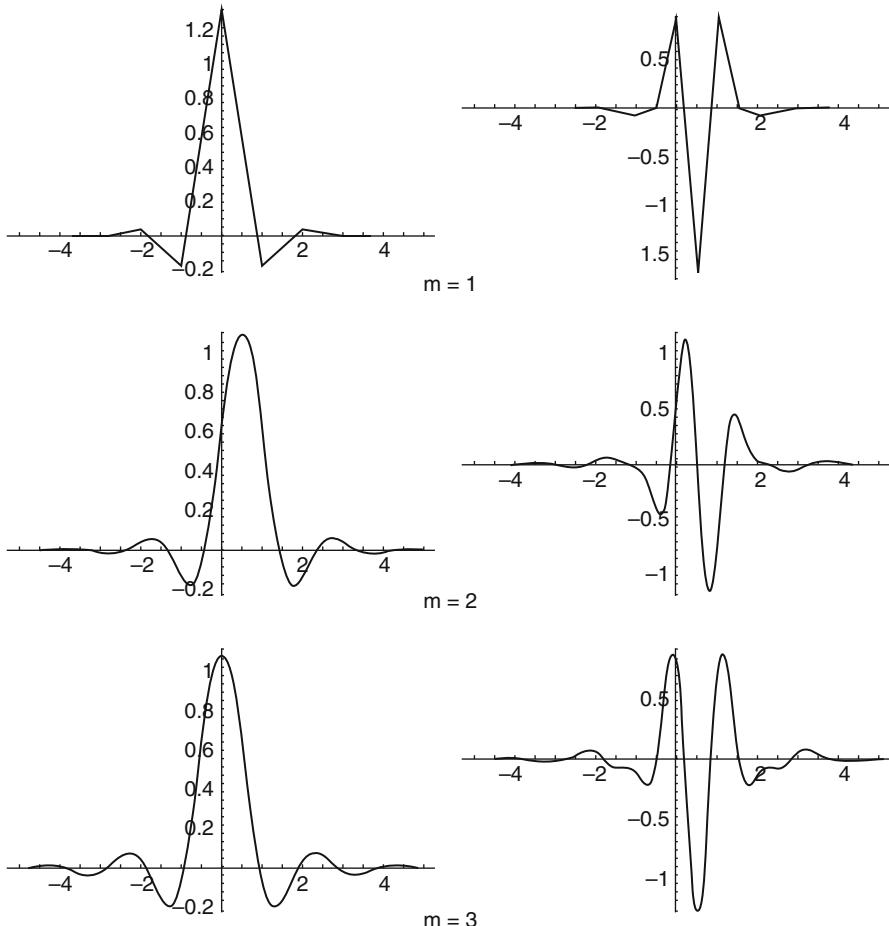

Fig. 6 Orthonormalized B-splines B^m (left column) and corresponding wavelets (right column) for $m = 1, 2, 3$ in time domain. Note that the orthonormalized B-splines and wavelets do not have compact support. Due to the orthonormalization procedure (4), the orthonormalized B-spline is an infinite series of shifted, compactly supported B-splines

becomes an n D spline. Here $(v_k)_{k \in \mathbb{Z}}$ is the sequence of the Fourier coefficients of v . Due to the decay in Fourier domain, the polyharmonic B-spline \mathcal{P}^r has continuous derivatives D^β for multi-indices $|\beta| < 2r - n$. In the same way as for the B-splines, it can be shown with the theorems given in section “Mathematical Foundations” that ϕ forms indeed a scaling function with approximation order $2r$ [53,54,71]. Figure 7 shows the polyharmonic B-spline scaling function in space domain and in frequency domain.

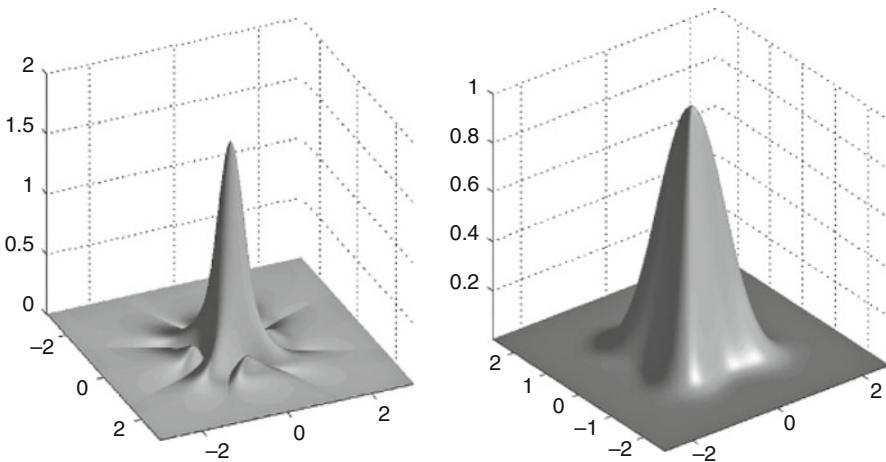

Fig. 7 Polyharmonic B-spline for $r = 3$ in space domain (left) and frequency domain (right)

4 Survey on Spline Families

There are many function families that consist of piecewise polynomials and that are called splines, which in addition fulfill a multiresolution condition in the one or the other sense. These families can be classified by various aspects, e.g., by their dimensionality, by the lattice which is invariant under the corresponding dilation matrix, by the geometries they are defined on, or whether they provide phase information or not, and so on. The following sections list some of these spline approaches and illustrates their mathematical properties and features.

Schoenberg's B-Splines for Image Analysis: The Tensor Product Approach

As mentioned in Example 3, multiresolution analyses for $L^2(\mathbb{R}^n)$ and dilation matrix $2Id$ can be generated from tensor products of 1D dyadic multiresolution analyses. To analyze images with B-splines, the tensor product $\beta^m(x)\beta^m(y)$ of B-splines is a scaling function for $L^2(\mathbb{R}^2)$ and the dilation matrix $A = 2Id$. Since in 2D the determinant $\det A = 4$, the corresponding detail space W_0 is spanned by three wavelet functions:

$$\psi(x)\beta^m(y), \quad \beta^m(x)\psi(y), \quad \psi(x)\psi(y), \quad x, y \in \mathbb{R}. \quad (13)$$

A drawback of this approach is the fact that these wavelets prefer horizontal, vertical, and diagonal directional features and are not sensitive to other directions; see Fig. 8. For the analysis of images with many isotropic features, the use of

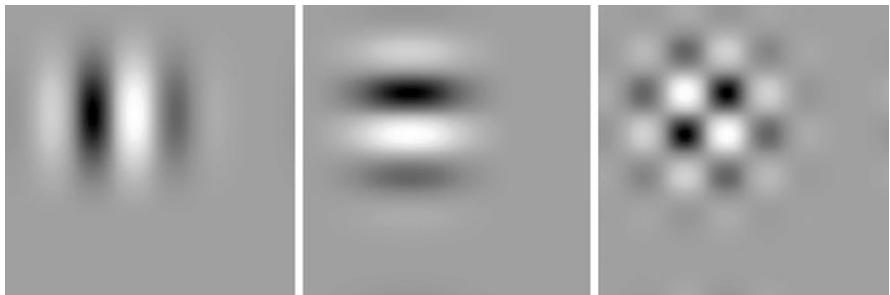

Fig. 8 The three B-spline tensor wavelets (13) show a preference for horizontal, vertical, and diagonal directions. Here, $m = 2$. Minimal resp. maximal function values are given in black resp. white

isotropic or steerable wavelets is recommended. However, the tensor approach is a simple and widely used wavelet approach. For an illustration of the respective image decomposition in coarse approximations and details of various sizes, see Fig. 9.

Fractional and Complex B-Splines

The B-splines as described up to now have a discrete order of smoothness, i.e., they are C^n functions with $n \in \{-1, 0, 1, 2, \dots\}$. For some applications, e.g., in medical imaging, where the order of smoothness of certain image classes is fractional, it would be favorable to have a spline and wavelet basis that is adaptable with respect to this regularity [1, 37, 73]. A first step in this direction was done by T. Blu and M. Unser, who proposed B-splines and wavelets of fractional orders [5]. They defined two variants of fractional B-splines, the causal ones and the symmetrical ones.

The causal fractional B-spline is generated by applying the $(\alpha + 1)$ fractional difference operator to the one-sided power function t_+^α :

$$\beta_+^\alpha(t) := \frac{1}{\Gamma(\alpha + 1)} \Delta_+^{\alpha+1} t_+^\alpha = \frac{1}{\Gamma(\alpha + 1)} \sum_{k \geq 0} (-1)^k \binom{\alpha + 1}{k} (t - k)_+^\alpha.$$

The Fourier-transform representation is similar to the one of the classical B-splines (cf. Eq. 12):

$$\hat{\beta}_+^\alpha(\omega) = \left(\frac{1 - e^{-i\omega}}{i\omega} \right)^{\alpha+1}.$$

Here again, the smoothness property $\beta_+^\alpha \in C^{m,\gamma}(\mathbb{R})$ in the time domain is gained by the fractional polynomial decay of order $\mathcal{O}(|\omega|^{\alpha+1})$ in the frequency domain. Note that $C^{m,\gamma}(\mathbb{R})$ denotes the Hölder space with exponent $m = \lfloor \alpha + 1 \rfloor$ and

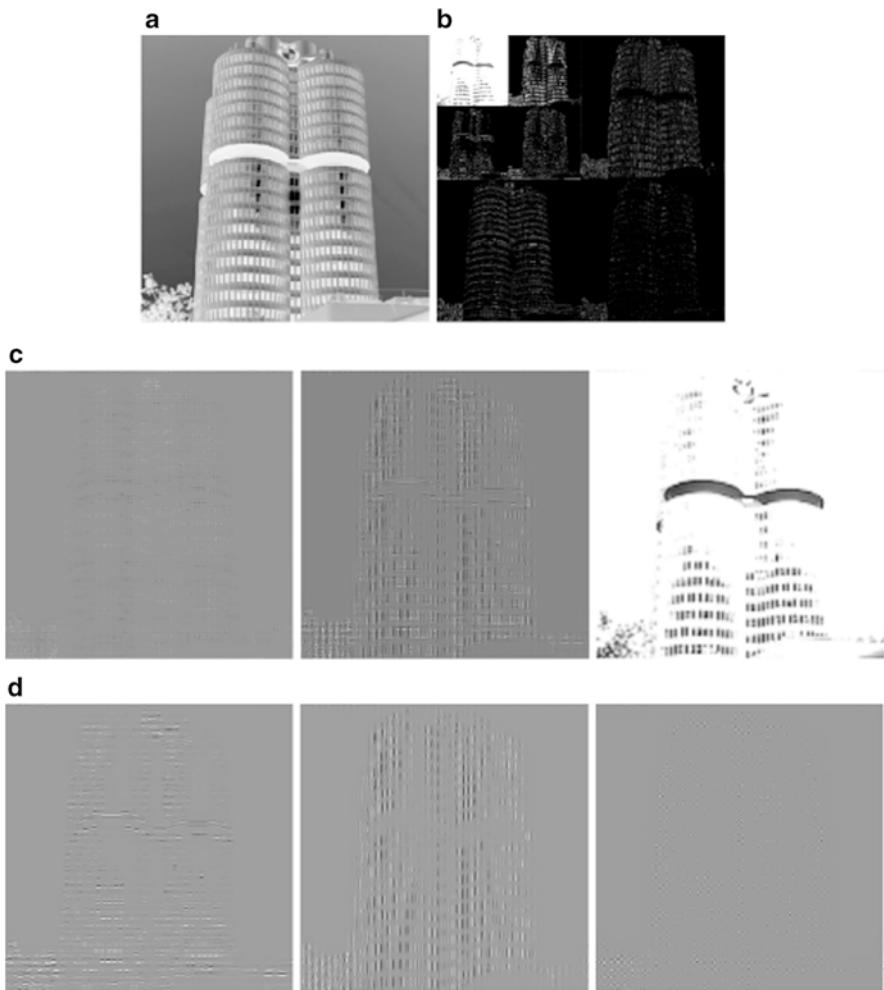

Fig. 9 Decomposition of an image [18, Part of IM008.tif] into coarse approximations and details of various sizes. (a) Original image. (b) Matrix of the absolute values of the multiresolution coefficients. Large coefficients are white. The wavelet coefficients are depicted in the lower two and the upper right band of each scale and the approximation coefficients in the upper left band. (c) Two steps of the multiresolution decomposition. From left to right: finest details and second finest details, remaining approximation of the original image. (d) Second finest details (c, center) split into the contribution of the three wavelets. From left to right: the decomposition into horizontal, vertical, and diagonal details

$\gamma = \alpha + 1 - m$, i.e., the space of m -times continuously differentiable functions f that are Hölder regular with exponent $0 < \gamma \leq 1$ such that there is a constant $C > 0$ with

$$|D^m f(t) - D^m f(s)| \leq C |t-s|^\gamma \quad \forall s, t \in \mathbb{R}.$$

Although the fractional B-splines are not compactly supported, they decay in the order $\mathcal{O}(|t|^{-(\alpha+2)})$ as $t \rightarrow \infty$. They are elements of $L^1(\mathbb{R})$ for $\alpha > 0$, of $L^2(\mathbb{R})$ for $\alpha > -\frac{1}{2}$, and of the Sobolev spaces $W_2^r(\mathbb{R})$ for $r < \alpha + \frac{1}{2}$. They share many properties with their classical B-spline relatives, such as the convolution property, and their relation to difference operators, i.e., they are integral kernels for fractional difference operators [26] and they are scaling functions for dyadic multiresolution analyses. This can be verified by the procedure given in the section “B-Splines”.

The causal fractional B-spline is not symmetric. Since for some signal and image analysis tasks symmetrical bases are preferred, in [5] the symmetrical fractional B-splines β_*^α are proposed. They are defined in Fourier domain as follows:

$$\hat{\beta}_*^\alpha(\omega) = \left(\frac{1 - e^{-i\omega}}{i\omega} \right)^{\frac{\alpha+1}{2}} \left(\frac{1 + e^{i\omega}}{-i\omega} \right)^{\frac{\alpha+1}{2}} = \left| \frac{\sin(\omega/2)}{\omega/2} \right|^{\alpha+1}, \quad (14)$$

and therefore obviously are symmetrical in the time domain. The same regularity and decay properties apply as for the causal fractional B-splines. The symmetrical fractional B-splines are also piecewise polynomials, as long as $\alpha \notin 2\mathbb{N}_0$. For even integer degrees, the singularity introduced through the absolute value in Eq. (14) causes that β_*^{2m} is a sum of integer shifts of the logarithmic term $|t|^{2m} \ln(t)$ for $m \in \mathbb{N}_0$. For the explicit time-domain representation and further details on these splines, cf. [5].

In [6], Blu and Unser defined another variant, the generalized fractional B-spline or (α, τ) -fractional spline β_τ^α with a parameter $\tau \in \mathbb{R}$. Also, these splines are defined via their Fourier domain representation:

$$\hat{\beta}_\tau^\alpha(\omega) = \left(\frac{1 - e^{-i\omega}}{i\omega} \right)^{\frac{\alpha+1}{2} + \tau} \left(\frac{1 - e^{i\omega}}{-i\omega} \right)^{\frac{\alpha+1}{2} - \tau}.$$

As above, the parameter $\alpha > 0$ controls the regularity of the splines. The parameter τ , in contrast, controls the position of the splines with respect to the grid $2\mathbb{Z}$. This can be justified by the following fact. All variants of the B-splines considered in this section converge to the optimally time-frequency-localized functions in the sense of Heisenberg, i.e., to Gaussians or Gabor functions, if the degree α becomes large. For a proof for the classical cardinal B-splines, see [67]. In the case of the (α, τ) -fractional splines [6],

$$\beta_\tau^\alpha(t) = \mathcal{O}\left(e^{-\frac{6}{\alpha+1}(t-\tau)^2}\right) \quad \text{for } \alpha \rightarrow \infty.$$

This explains the notion “shift parameter” for τ . Moreover, the parameter τ allows to interpolate the spline family between the two “knots,” the symmetrical ones ($\tau = 0$) and the causal ones ($\tau = \frac{\alpha+1}{2}$); see Fig. 10. Both parameters α and τ can be tuned

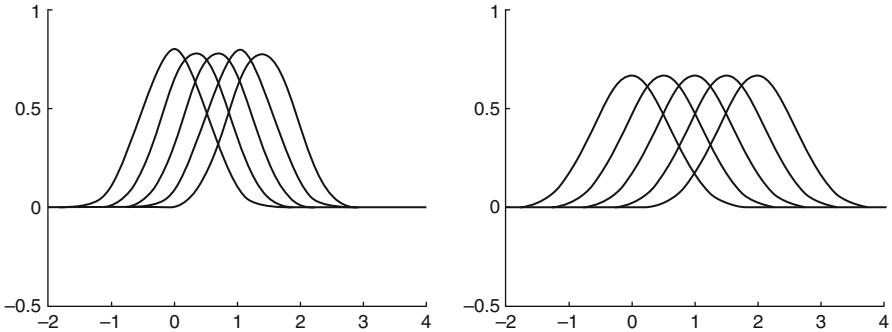

Fig. 10 The fractional (α, τ) -splines interpolate the families of the causal and the symmetric fractional splines. $\tau = \frac{\alpha+1}{2}k$ for $k = 0, \frac{1}{4}, \frac{1}{2}, \frac{3}{4}, 1$ from the most right (causal) to the most left (symmetrical) function in each image. Right: $\alpha = 1.8$. Left: $\alpha = 3$

independently and therefore allow for an individual adjustment of the analyzing basis.

Another generalization are the complex B-splines [27]. There are two variants, both defined via their Fourier domain representation. Let $z = \alpha + i\gamma \in \mathbb{C}$, $\alpha > -\frac{1}{2}$, $\gamma \in \mathbb{R}$, and $y \in \mathbb{C}$. Then

$$\begin{aligned}\hat{\beta}^z(\omega) &= \left(\frac{1-e^{-i\omega}}{i\omega} \right)^{z+1}, \\ \hat{\beta}_y^z(\omega) &= \left(\frac{1-e^{-i\omega}}{i\omega} \right)^{\frac{z+1}{2}-y} \left(\frac{1-e^{i\omega}}{-i\omega} \right)^{\frac{z+1}{2}+y}\end{aligned}$$

are complex B-splines of complex degree z . The functions are well defined, because the function $\Omega(\omega) = \frac{1-e^{-i\omega}}{i\omega}$ never touches the negative real axis such that $\Omega(\omega)^z$ is uniquely defined. β^z and β_y^z are elements of the Sobolev spaces $W_2^r(\mathbb{R})$ for $r < \alpha + \frac{1}{2}$. β^z has the time-domain representation

$$\beta^z(t) = \frac{1}{\Gamma(z+1)} \sum_{k \geq 0} (-1)^k \binom{z+1}{k} (t-k)_+^z,$$

i.e., β^z is a piecewise polynomial of complex degree. For more details on the properties of these families of complex splines, cf. [27].

The idea behind the complex degree is as follows: The real part $\operatorname{Re} z = \alpha$ operates as regularity and decay parameter in the same way as for the fractional B-splines. The imaginary part, however, causes an enhancement resp. damping of positive or negative frequencies. In fact,

$$\hat{\beta}^z(\omega) = \hat{\beta}_+^\alpha(\omega) e^{-i\gamma \ln |\Omega(\omega)|} e^{\gamma \arg \Omega(\omega)}.$$

The imaginary part γ of the complex degree introduces a phase and a scaling factor in the frequency domain. The frequency components on the negative and positive

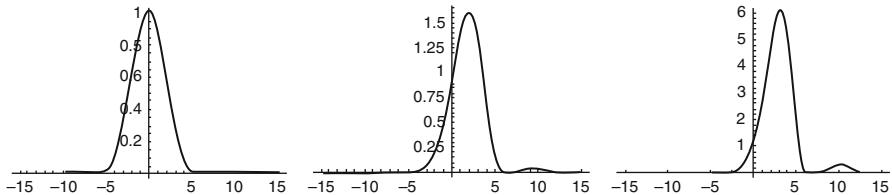

Fig. 11 The frequency spectrum $|\beta^{z^3}|$ for $z = 3 + i\gamma$, $\gamma = 0, 1, 2$ (from left to right). The spectrum of $\beta^3 = \beta_+^3$ is symmetric (right), whereas the spectra of β^{3+i} (center) and β^{3+2i} (left) show an enhancement of the positive frequency axis

real axis are enhanced with different signs, because $\arg \Omega(\omega) \geq 0$ for negative ω and $\arg \Omega(\omega) \leq 0$ for positive ω . Figure 11 illustrates this effect.

With real-valued functions, only symmetric spectra can be analyzed. The complex B-splines, however, allow for an approximate analysis of the positive or the negative frequencies, because the respective symmetric bands are damped due to the complex exponent. However, the complex B-splines inherit many properties of their classical and fractional relatives.

All of the generalized B-spline families mentioned in this section have in common that they are scaling functions of dyadic multiresolution analyses. They are one-dimensional functions, but with the tensor approach mentioned in Example 3 and the section “Schoenberg’s B-Splines for Image Analysis – the Tensor Product Approach”, they are also suitable for image processing tasks. Although the fractional and the complex splines, in general, do not have compact support, they allow for fast analysis and synthesis algorithms. Due to their closed form in Fourier domain, they invite for an implementation of these algorithms in Fourier domain.

Polyharmonic B-Splines and Variants

In the section “Polyharmonic B-Splines”, the so-called polyharmonic B-splines in \mathbb{R}^n were introduced. They are defined in the Fourier domain by the representation

$$\hat{\mathcal{P}}^r(\omega) = \left(\frac{4 \sum_{k=1}^n \sin^2(\omega_k/2)}{\sum_{k=1}^n \omega_k^2} \right)^r, \quad r > n/2, \quad \omega = (\omega_1, \dots, \omega_n).$$

These polyharmonic B-splines satisfy many properties of the classical Schoenberg splines; e.g., they are piecewise polynomial functions, they satisfy a convolution relation $\mathcal{P}^{r_1+r_2} = \mathcal{P}^{r_1} * \mathcal{P}^{r_2}$, they are positive functions, etc. However, they do not share the property that they converge to the optimally space-frequency-localized Gaussians as r increases [71]. This is due to the fact that the trigonometric polynomial in the numerator regularizes insufficiently at the origin: The second-order derivative of

$$\frac{4 \sum_{k=1}^n \sin^2(\omega_k/2)}{\sum_{k=1}^n \omega_k^2}$$

is not continuous. Van De Ville et al. [71] therefore proposed another localizing trigonometric polynomial:

$$\mu(\omega) = 4 \sum_{k=1}^n \sin^2(\omega_k/2) - \frac{8}{3} \sum_{k=1}^{n-1} \sum_{l=k+1}^n \sin^2(\omega_k/2) \sin^2(\omega_l/2). \quad (15)$$

A new function family then is defined in the Fourier domain via

$$\hat{\mathcal{Q}}^r(\omega) = \left(\frac{\mu(\omega)}{\|\omega\|^2} \right)^r, \quad r > \frac{n}{2}. \quad (16)$$

$\hat{\mathcal{Q}}^r$ is called isotropic polyharmonic B-spline. The function is piecewise polynomial (except for $2r-n$ even, where a logarithmic factor has to be added; see below) and shares with the polyharmonic splines their decay properties in Fourier domain and their regularity properties in space domain. $\hat{\mathcal{Q}}^r$ converges to a Gaussian as r increases, which makes the function family better suitable for image analysis than $\hat{\mathcal{P}}^r$, because of the better space-frequency localization. This effect is due to the higher-order rotation invariance or isotropy of the localizing trigonometric polynomial (15):

$$v(\omega) = 1 + \mathcal{O}(\|\omega\|^2) \text{ vs. } \mu(\omega) = 1 + \frac{1}{12} \|\omega\|^2 + \mathcal{O}(\|\omega\|^4) \quad \text{as } \|\omega\| \rightarrow 0.$$

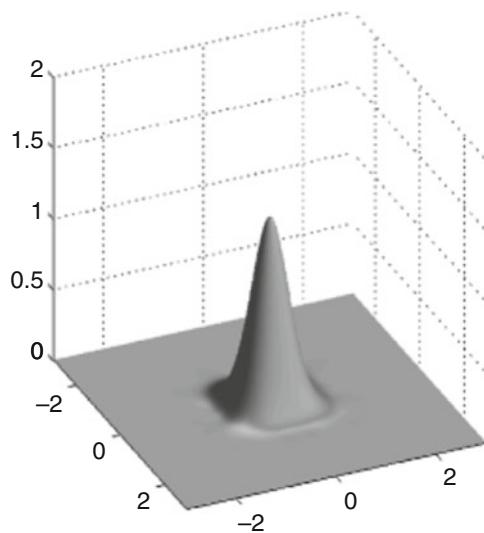

This causes that $\hat{\mathcal{Q}}^r$ has a second-order moment, and thus the central limit theorem can be applied to proof the convergence to the Gaussian function. In addition, $\hat{\mathcal{Q}}^r$ has a higher regularity than $\hat{\mathcal{P}}^r$; therefore, $\hat{\mathcal{Q}}^r$ decays faster. For a complete proof of the localization property, see [71]. An example of the isotropic polyharmonic spline is given in Fig. 12.

The polyharmonic B-splines and the isotropic polyharmonic B-splines both are real-valued functions. The isotropic B-spline is approximately rotation invariant and therefore is suited for image analysis of isotropic features. A complex-valued variant of these B-splines in 2D was introduced in [28]. The idea is to design a spline scaling function that is approximately rotation covariant, instead of rotation invariant. Rotation covariant here means that the function intertwines with rotations up to a phase factor.

Again, the design of the scaling function is done in the Fourier domain, now using a perfectly rotation-covariant function

$$\hat{\rho}_{r,N}(\omega_1, \omega_2) = \frac{1}{(\omega_1^2 + \omega_2^2)^r (\omega_1 - i\omega_2)^N},$$

Fig. 12 The isotropic polyharmonic spline \mathcal{Q}^3 .
Compare with Fig. 7 of the classical polyharmonic B-spline \mathcal{P}^3

where $r \geq 0$ and $N \in \mathbb{N}$. In fact, for some rotation matrix $R_\theta \in GL(2, \mathbb{R})$, $\hat{\rho}_{r,N}(R_\theta \omega) = e^{-iN\theta} \hat{\rho}_{r,N}(\omega)$. For localizing the function $\hat{\rho}_{r,N}$, the same trigonometric polynomials v and μ as above can be used. The corresponding complex polyharmonic B-splines are then defined in the frequency domain as

$$\begin{aligned}\hat{\mathcal{R}}_v^{r,N}(\omega_1, \omega_2) &= \frac{(v(\omega_1, \omega_2))^{r+\frac{N}{2}}}{(\omega_1^2 + \omega_2^2)^r (\omega_1 - i\omega_2)^N}, \quad \text{or as} \\ \hat{\mathcal{R}}_\mu^{r,N}(\omega_1, \omega_2) &= \frac{(\mu(\omega_1, \omega_2))^{r+\frac{N}{2}}}{(\omega_1^2 + \omega_2^2)^r (\omega_1 - i\omega_2)^N}.\end{aligned}\quad (17)$$

The case $N = 0$ yields the real-valued polyharmonic splines.

There are also other trigonometric polynomials that are suitable as localizing numerators for the real and the complex polyharmonic B-splines. With an appropriate choice, the features of the polyharmonic splines can be tuned [28]. However, for both the real and the complex variant, the localizing multiplier has to fulfill moderate conditions to make the respective polyharmonic B-splines become a scaling function. In 2D, the following result holds (cf. [28]):

Theorem 9. Let $r > 0$ and $N \in \mathbb{N}_0$. Let $\eta(\omega_1, \omega_2)$ be a bounded, $2\pi\mathbb{Z}^2$ -periodic function, such that

$$\left| \frac{(\eta(\omega_1, \omega_2))^{r+\frac{N}{2}}}{(\omega_1^2 + \omega_2^2)^r (\omega_1 - i\omega_2)^N} \right|$$

is bounded in a neighborhood of the origin and such that $\eta(\omega_1, \omega_2) \neq 0$ for all $(\omega_1, \omega_2) \in [-\pi, \pi]^2 \setminus \{(0, 0)\}$.

Then $\hat{\phi} = \eta^{r+\frac{N}{2}} \cdot \hat{\rho}$ is the Fourier transform of a scaling function ϕ which generates a multiresolution analysis $\dots V_{-1} \subset V_0 \subset V_1 \dots$ of $L^2(\mathbb{R}^2)$ with dilation matrix $A = \begin{pmatrix} a & b \\ -b & a \end{pmatrix}$, $a, b \in \mathbb{Z}$:

$$V_j = \overline{\text{span} \{ |\det A|^{j/2} \phi(A^j \bullet -k), k \in \mathbb{Z}^2 \}}.$$

From the Fourier domain representation immediately follows that $\hat{\phi} \in L^2(\mathbb{R}^2)$ for $r + \frac{N}{2} > \frac{1}{2}$ and that $\hat{\phi}$ decays as $|\hat{\phi}(\omega_1, \omega_2)| = \mathcal{O}(\|(\omega_1, \omega_2)\|^{-2r-N})$ when $\|(\omega_1, \omega_2)\| \rightarrow \infty$.

As a result, for all three variants of the polyharmonic B-splines, the classical ones \mathcal{P}^r , the isotropic ones \mathcal{Q}^r , and the complex ones $\mathcal{R}^{r,N}$, the following properties hold: They are scaling functions for multiresolution analysis. Their smoothness parameter r can be chosen fractional and must fulfill $r + \frac{N}{2} > n/2$ for integrability reasons. Then the scaling function in space domain is an element of the Sobolov space $\phi \in W_2^s(\mathbb{R}^2)$ for all $s < 2r + N - 1$. The explicit space domain representation is

$$\phi(x) = \sum_{k \in \mathbb{Z}^2} \eta_k \rho_{r,N}(x + k)$$

for almost all $x \in \mathbb{R}^2$. Here, $(\eta_k)_{k \in \mathbb{Z}^2}$ denotes the Fourier coefficients of $\eta^{r+\frac{N}{2}} \cdot \rho_{r,N}$ is the inverse Fourier transform of the Hadamard finite part $Pf(\hat{\rho}_{r,N}) \in \mathcal{S}'(\mathbb{R}^2)$. In fact, for $r \notin \mathbb{N}_0$,

$$\rho_{r,N}(x_1, x_2) = c_1 (x_1^2 + x_2^2)^{r-1} (x_1 + ix_2)^N$$

and for $r \in \mathbb{N}_0$,

$$\rho_{r,N}(x_1, x_2) = c_2 (x_1^2 + x_2^2)^{r-1} (x_1 + ix_2)^N \left(\ln \pi \sqrt{\ln(\pi x_1^2 + x_2^2)} + c_3 \right)$$

with appropriate constants $c_1, c_2, c_3 \in \mathbb{C}$. This justifies the notion spline for the function families. They all have a closed form in the frequency domain. As in the case of the 1D cardinal B-splines, there is a fast analysis and synthesis algorithm using the frequency domain representation and the fast Fourier transform; cf. Sect. 5.

Splines on Other Lattices

Splines on the Quincunx Lattice

The tensor product of two 1D dyadic multiresolution analyses yields a 2D multiresolution analysis with dilation matrix $A = 2Id$; cf. Example 3. As a consequence, the scaling factor while moving from one approximation space V_0 to the next coarser space V_1 is $|\det A| = 4$. For some image processing applications, especially in

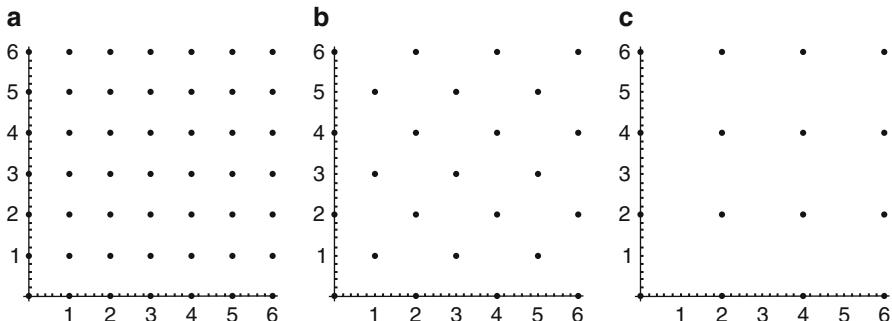

Fig. 13 Three iterations of the quincunx subsampling scheme. (a) \mathbb{Z}^2 , (b) $A_q\mathbb{Z}^2$, (c) $A_q^2\mathbb{Z}^2$. The thinning of the \mathbb{Z}^2 lattice using the dilation matrix A_q is finer than dilation with the dyadic matrix $A = 2Id$, which in one step leads from (a) to (c)

medical imaging, this scaling step size is too large. A step size of 2 as in the 1D case would be preferred. Moreover, the decomposition of the wavelet space into three subspaces then would be avoided, and the eventual problematic of the directionality of the three involved wavelets would not arise. An example of a dilation matrix satisfying these requirement is the scaled rotation matrix

$$A_q = \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}$$

with $\det A_q = 2$. It leads to the so-called quincunx lattice. This lattice is generated by applying A_q to the Cartesian lattice. It holds $A_q\mathbb{Z}^2 \subset \mathbb{Z}^2$; see Fig. 13.

Since A_q falls into the class of scaled rotations, the polyharmonic B-spline construction including all variants is applicable for this case; cf. Theorem 9. Note that the tensor product approach in general is not suitable for the quincunx subsampling scheme.

Splines on the Hexagonal Lattice

Images as 2D objects are normally processed on the Cartesian lattice, i.e., the image pixels are arranged on a rectangular grid. For image processing, this arrangement has the drawback that not all neighbors of a pixel have the same relation: The centers of the diagonal neighbors have a larger distance to the center pixel than the adjacent ones. A higher degree of symmetry has the hexagonal lattice. It is therefore ideal for isotropic feature representation. The hexagonal lattice gives an optimal tessellation of \mathbb{R}^2 in the sense of the classical honeycomb conjecture, which says that any partition of the plane into regions of equal area has a perimeter at least that of regular hexagonal tiling [32]. The better isotropy of the hexagonal lattice is attractive for image analysis and has led to a series of articles on image processing methods (e.g., [31, 45, 52]) as well as on applications (e.g., [30, 36, 47, 72]).

The hexagonal lattice is generated by applying the matrix

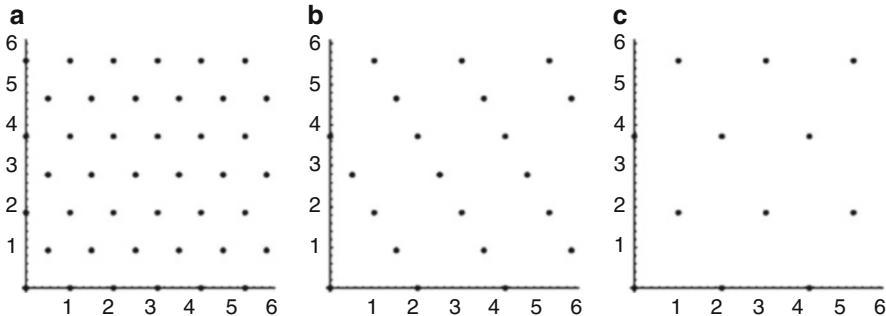

Fig. 14 Three iterations of subsampling of the hexagonal grid with $A = R_h B R_h^{-1}$, where $B = \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}$. (a) Λ_h , (b) $A\Lambda_h = R_h B R_h^{-1} \Lambda_h = R_h B \mathbb{Z}^2$, (c) $A^2 \Lambda_h$

$$R_h = \sqrt{\frac{2}{\sqrt{3}}} \begin{pmatrix} 1 & 1/2 \\ 0 & \sqrt{3}/2 \end{pmatrix}$$

on the Cartesian lattice $\Lambda_h = R_h \mathbb{Z}^2$. A scaling function of a multiresolution analysis of $L^2(\mathbb{R}^2)$ in the hexagonal lattice fulfills all properties of Definition 1, but the last two. They change to

- (iv) $f \in V_0 \Leftrightarrow f(\cdot - R_h k) \in V_0$ for all $k \in \mathbb{Z}^2$.
- (v) There exists a scaling function $\phi \in V_0$, such that the family $\{\phi(\bullet - R_h k)\}_{k \in \mathbb{Z}^2}$ of translates of ϕ forms a Riesz basis of V_0 .

Let A be a dilation matrix which leaves the hexagonal lattice invariant $A\Lambda_h \subset \Lambda_h$. Then A is of the form [19]

$$A = R_h B R_h^{-1}$$

with $B \in GL(2, \mathbb{R})$ having only integer entries and with eigenvalues strictly larger than one. Figure 14 gives an example of two subsampling steps on the hexagonal lattice.

There are several possible approaches to define spline functions on the hexagonal lattice. Sablonnière and Sbibih [57] proposed to convolve piecewise linear pyramids to generate higher-order B-splines. Van De Ville et al. [70] started with the characteristic function of one hexagon and also used an iterative convolution procedure to construct B-splines of higher degree. However, both approaches lead to discrete-order hexagonal B-splines. If A is a scaled rotation, then fractional and complex B-splines on the hexagonal lattice can be defined in an analog way as in the section ‘‘Polyharmonic B-Splines and Variants’’ for polyharmonic splines and their (complex) variants [19]. Consider again the perfectly rotation-covariant (or for $N = 0$ rotation-invariant) function

$$\hat{\rho}_{r,N}(\omega_1, \omega_2) = \frac{1}{(\omega_1^2 + \omega_2^2)^r (\omega_1 - i\omega_2)^N},$$

where $r > 0$ and $N \in \mathbb{N}_0$. The idea is now to use a hexagonal-periodic trigonometric polynomial for localizing this function and to eliminate the singularity at the origin. Condat et al. [19] proposed

$$\begin{aligned} \eta_h(\omega_1, \omega_2) &= \frac{1}{\sqrt{3}}(6 - 2(\cos(3^{1/4}(-\omega_1/\sqrt{3} + \omega_2)/\sqrt{2}) \\ &\quad + \cos(3^{1/4}(\omega_1/\sqrt{3} + \omega_2)/\sqrt{2}) + \cos(3^{-1/4}\sqrt{2}\omega_1))), \end{aligned}$$

and defined the elementary polyharmonic hexagonal rotation-covariant B-spline via its frequency domain representation as

$$\hat{\mathcal{R}}_h^{r,N}(\omega_1, \omega_2) = \frac{(\eta_h(\omega_1, \omega_2))^{r+\frac{N}{2}}}{(\omega_1^2 + \omega_2^2)^r (\omega_1 - i\omega_2)^N}.$$

The B-spline in space domain then has the representation

$$\mathcal{R}_h^{r,N}(x) = \sum_{k \in \mathbb{Z}^2} \eta_{h,k} \rho_{r,N}(x - R_h k).$$

Here, $(\eta_{h,k})_{k \in \mathbb{Z}^2}$ denotes the sequence of Fourier coefficients of $\eta_h^{r+\frac{N}{2}}$. Figure 15 shows the localizing trigonometric polynomial η and the Fourier spectra of two hexagonal splines.

For $N = 0$, the functions are the elementary polyharmonic hexagonal rotation-invariant B-splines. They are real-valued functions that converge to a Gaussian, as $r \rightarrow \infty$, and therefore are well localized in the space domain as well as in the frequency domain. For $N \in \mathbb{N}$, the splines are complex-valued functions and approximately rotation covariant in a neighborhood of the origin:

$$\hat{\mathcal{R}}_h^{r,N}(\omega) = e^{iN \arg(\omega)} \left(1 + C \|\omega\|^2 + \mathcal{O}(\|\omega\|^4) \right) \quad \text{for } \omega \rightarrow 0,$$

where $\omega = (\omega_1, \omega_2)$ and $C \in \mathbb{R}$ is a constant.

The translates of the complex B-spline $\mathcal{R}_h^{r,N}$ form a Riesz basis of the approximation spaces

$$V_j = \overline{\text{span} \left\{ \mathcal{R}_h^{r,N}(A^j x - R_h k) : k \in \mathbb{Z}^2 \right\}}^{L^2(\mathbb{R}^2)}, \quad j \in \mathbb{Z}.$$

The ladder of spaces $(V_j)_{j \in \mathbb{Z}}$ generates a multiresolution analysis of $L^2(\mathbb{R}^2)$ for the hexagonal grid and for scaled rotations A . Also in this case, the implementation of

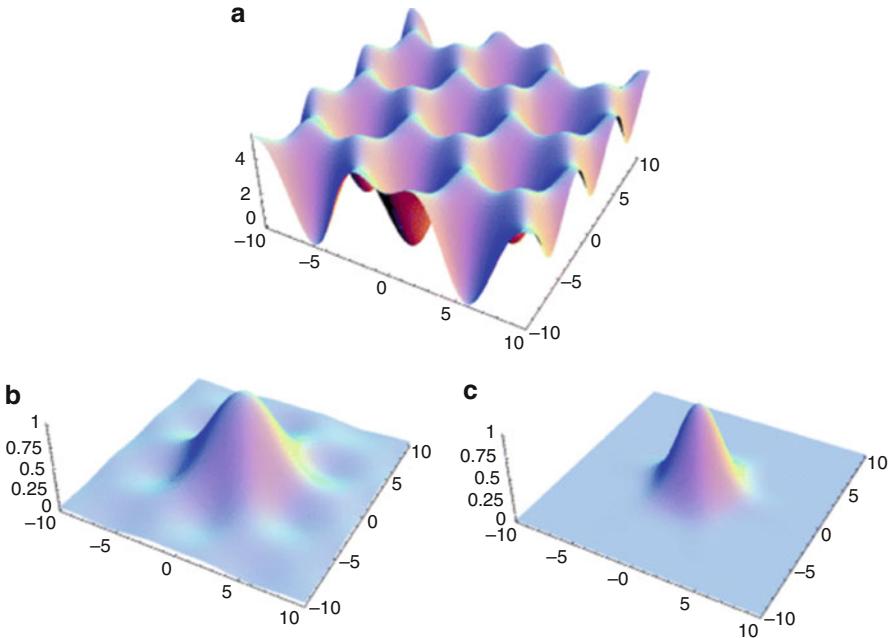

Fig. 15 Localization of $\hat{\rho}$ with (a) the hexagonal-periodic trigonometric polynomial η_h yields the elementary polyharmonic hexagonal rotation-covariant B-spline. Frequency spectrum of $\mathcal{R}_h^r r, N$ (or equivalently of $\mathcal{R}_h^r r + N/2, 0$), (b) for $r + \frac{N}{2} = 1$, and (c) for $r + \frac{N}{2} = 2.5$

the analysis and synthesis algorithm can be elegantly performed in the frequency domain [19, 71].

5 Numerical Implementation

For the illustration of the numerical method, we focus on the quincunx dilation matrix

$$A = \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix} \quad (18)$$

and consider the polyharmonic spline variants in 2D as defined in the section “Polyharmonic B-Splines and Variants”. Since $\det A = 2$, the generators of the multiresolution space and the corresponding wavelet space are two functions: the scaling function (here the variant of the polyharmonic spline) and the associated wavelet. We consider the scaling function $\phi(x) = Q_\mu^r(x)$ resp. $\phi(x) = \mathcal{R}_\mu^{r,N}(x)$. It spans the ladder of nested approximation spaces $\{V_j\}_{j \in \mathbb{Z}}$ via

$$V_j = \overline{\text{span} \{ |\det A|^{j/2} \phi(A^j \bullet -k), k \in \mathbb{Z}^2 \}}^{L^2(\mathbb{R}^2)}, \quad j \in \mathbb{Z}.$$

Denote

$$M(\omega) := \sum_{k \in \mathbb{Z}^2} |\hat{\phi}(\omega + 2\pi k)|^2 \quad (19)$$

the autocorrelation filter. It is bounded $0 < M(\omega) \leq C$ for some positive constant C [28]. The scaling functions can be orthonormalized, applying the procedure given in Theorem 4(iii):

$$\hat{\phi}(\omega) = \frac{\hat{\phi}(\omega)}{\sqrt{M(\omega)}}.$$

The scaled shifts of Φ span the same spaces $\{V_j\}_{j \in \mathbb{Z}}$.

The B-splines as scaling functions ϕ satisfy a refinement relation

$$\phi(A^{-1}x) = \sum_{k \in \mathbb{Z}^2} h_k \phi(x - k) \quad \text{almost everywhere and in } L^2(\mathbb{R}^2).$$

This relation in fact is a discrete convolution. The Fourier transform yields a $2\pi\mathbb{Z}^2$ -periodic function $H \in L^2(\mathbb{T}^2)$ of the form

$$\begin{aligned} H(e^{i\omega}) &= |\det A| \cdot \frac{\hat{\phi}(A^T \omega)}{\hat{\phi}(\omega)} = |\det A| \cdot \frac{\hat{\rho}_{r,N}(A^T \omega) \zeta(A^T \omega)}{\hat{\rho}_{r,N}(\omega) \zeta(\omega)} \\ &= \frac{\zeta(A^T \omega)}{\zeta(\omega)} \cdot \frac{1}{(a^2 + b^2)^{r-1} (a - ib)^N}, \quad \omega \in \mathbb{R}^2 \end{aligned}$$

Here, $\zeta(\omega) = (\mu(\omega))^{r+\frac{N}{2}}$ is the localizing multiplier for the isotropic polyharmonic B-spline in the case $N = 0$ and for the rotation-covariant polyharmonic B-splines in the case $N \in \mathbb{N}$; cf. (15)–(17).

The wavelet function ψ spanning a Riesz basis for the orthogonal complement

$$W_j = \overline{\text{span} \{ 2^{j/2} \psi(A^j \bullet -k), k \in \mathbb{Z}^2 \}}^{L^2(\mathbb{R}^2)}$$

in $V_{j+1} = W_j \oplus V_j$ can also be gained in the frequency domain. For the quincunx dilation matrix A as in (18), a wavelet (or sometimes called a prewavelet, since the functions are not yet orthonormalized) is given by

$$\hat{\psi}(\omega) = G(e^{i\omega}) \hat{\phi}(\omega) = e^{-i\omega_1} \overline{H(\omega + (\pi, \pi)^T)} M(\omega + (\pi, \pi)^T) \hat{\phi}(\omega),$$

compare with the section “Wavelets”. The (pre)wavelet Riesz basis for W_j is then given by the family $\{\psi_{j,k} = 2^{j/2} \psi(A^j \bullet -k), k \in \mathbb{Z}^2\}$.

This basis in general is not orthonormal: $\langle \psi_{j,k}, \psi_{j,l} \rangle \neq \delta_{k,l}$. A function $f \in L^2(\mathbb{R}^2)$ can then be represented by the series

$$f = \sum_{k \in \mathbb{Z}, k \in \mathbb{Z}^2} \langle f, \tilde{\psi}_{j,k} \rangle \psi_{j,k} = \sum_{j \in \mathbb{Z}, k \in \mathbb{Z}^2} \langle f, \tilde{\psi}_{j,k} \rangle \psi_{j,k},$$

where $\{\tilde{\psi}_{j,k}\}_{k \in \mathbb{Z}^2}$ denotes the dual basis for each $j \in \mathbb{Z}$: $\langle \tilde{\psi}_{j,k}, \psi_{j,l} \rangle = \delta_{k,l}$. Its generator in the frequency domain is

$$\hat{\tilde{\psi}}(\omega) = e^{-i\omega_1} \overline{H(\omega + (\pi, \pi)^T)} \frac{M(\omega + (\pi, \pi)^T)}{M(A^T \omega)} \frac{\hat{\phi}(\omega)}{M(\omega)}.$$

In contrast, the formula

$$\hat{\Psi}(\omega) = \sqrt{\frac{M(\omega + (\pi, \pi)^T)}{M(A^T \omega)}} \hat{\psi}(\omega)$$

generates an orthonormal wavelet basis. It corresponds to the orthonormal basis of V_0 generated by the integer shifts of the orthonormalized scaling function Φ . These considerations show that there are three variants of a multiresolution implementation: an ‘‘orthonormal’’ one with respect to the orthonormalized scaling functions and corresponding orthonormal wavelets; one with the B-splines on the analysis side,

$$f = \sum_{k \in \mathbb{Z}^2} \langle f, \phi_{j,k} \rangle \tilde{\phi}_{j,k} + \sum_{k \in \mathbb{Z}^2} \langle f, \psi_{j,k} \rangle \tilde{\psi}_{j,k} \quad \text{for } f \in V_{j+1},$$

and finally one with the B-splines on the synthesis side:

$$f = \sum_{k \in \mathbb{Z}^2} \langle f, \tilde{\phi}_{j,k} \rangle \phi_{j,k} + \sum_{k \in \mathbb{Z}^2} \langle f, \tilde{\psi}_{j,k} \rangle \psi_{j,k} \quad \text{for } f \in V_{j+1}.$$

Both, the scaling filters $H(e^{i\omega})$ and the wavelet filters

$$G(e^{i\omega}) = e^{-i\omega_1} \overline{H(\omega + (\pi, \pi)^T)} M(\omega + (\pi, \pi)^T)$$

as well as their orthogonal and dual variants in our case are nonseparable and infinitely supported. Therefore, a spatial implementation of the decomposition would lead to truncation errors due to the necessary restriction to a finite number of samples. However, because of the closed form of H and therefore of G , the corresponding multiresolution decomposition or wavelet transform can be efficiently implemented in the frequency domain. The respective image first undergoes an FFT and then is filtered in the frequency domain by multiplication with the scaling filter H and the wavelet filter G . This method automatically imposes periodic boundary conditions.

The coefficients resulting from the high-pass filtering with G are the detail coefficients. They are stored, whereas the coefficients resulting from the low-pass filtering H are reconsidered for the next iteration step.

$$\sum_{k \in \mathbb{Z}^2} \langle f, \phi_{j+1,k} \rangle \tilde{\phi}_{j+1,k} = \sum_{k \in \mathbb{Z}^2} \langle f, \phi_{j,k} \rangle \tilde{\phi}_{j,k} + \sum_{k \in \mathbb{Z}^2} \langle f, \psi_{j,k} \rangle \tilde{\psi}_{j,k}.$$

For the details and tricks of the frequency domain implementation, cf. [25, 48, 49, 71].

Figure 16 shows the multiresolution decomposition for the scaling function $\phi = \mathcal{R}_\mu^{2,1}$. There, it was assumed that the image is bandlimited and projected on the space V_0 , which has the advantage that the coefficients do not depend on the chosen flavor of the scaling function, i.e., orthogonal, B-spline, or dual. Qualitatively, the transform is very similar to a multiscale gradient with the real part corresponding to the x_2 derivative and the imaginary part corresponding to the x_1 derivative [28].

6 Open Questions

In this chapter, a method for the construction of spline multiresolution bases was described. It yields a nice variety of new bases with several parameters for adaption and tuning. In the last decade, the notion of compressive sampling or compressed sensing arose, which is footing on the existence of well-adaptable bases. In fact, the idea behind compressed sensing is that certain functions have a sparse representation, if the underlying basis is smartly chosen. In this case, the function can be reconstructed from very few samples because of the prior knowledge of sparsity in this underlying basis. As a consequence, the knowledge on sparsity allows to sample such a signal at a rate significantly under the Nyquist rate. (The Shannon-Nyquist sampling theorem says that a signal must be sampled at least two times faster than the signal's bandwidth to avoid loss of information.)

In the last 40 years, and virtually explosively in the last 10 years, many important theoretical results were proven in this field, in particular by D. Donoho, E. Candès, J. Romberg, and T. Tao. For an introduction and references on compressed sensing, see, e.g., [2, 9] and the website [55].

Compressed sensing is based upon two fundamental concepts: that of incoherence and that of sparsity. Let $\{x_i\}_{i=1,\dots,N}$ be an orthonormal basis of the vector space V . Let $f = \sum_{i=1}^N s_i x_i$ with $s_i = \langle f, x_i \rangle$. The signal f is called k -sparse, if only k of the coefficients are nonzero, $k \in \mathbb{N}$.

A general linear measurement process for signals consists in computing $M < N$ inner products $y_j = \langle f, y_j \rangle$ for a collection of vectors $\{y_j\}_j$. In matrix form,

$$g = Yf = YXs,$$

where Y and X are the matrixes with $\{y_i\}_i$ and $\{x_j\}_j$ as columns, and YX is an $M \times N$ matrix. If the function families Y and X are incoherent, i.e., if the incoherence measure

$$\mu(Y, X) = \sqrt{N} \max_{1 \leq i, j \leq N} |\langle y_i, x_j \rangle| \in [1, \sqrt{N}]$$

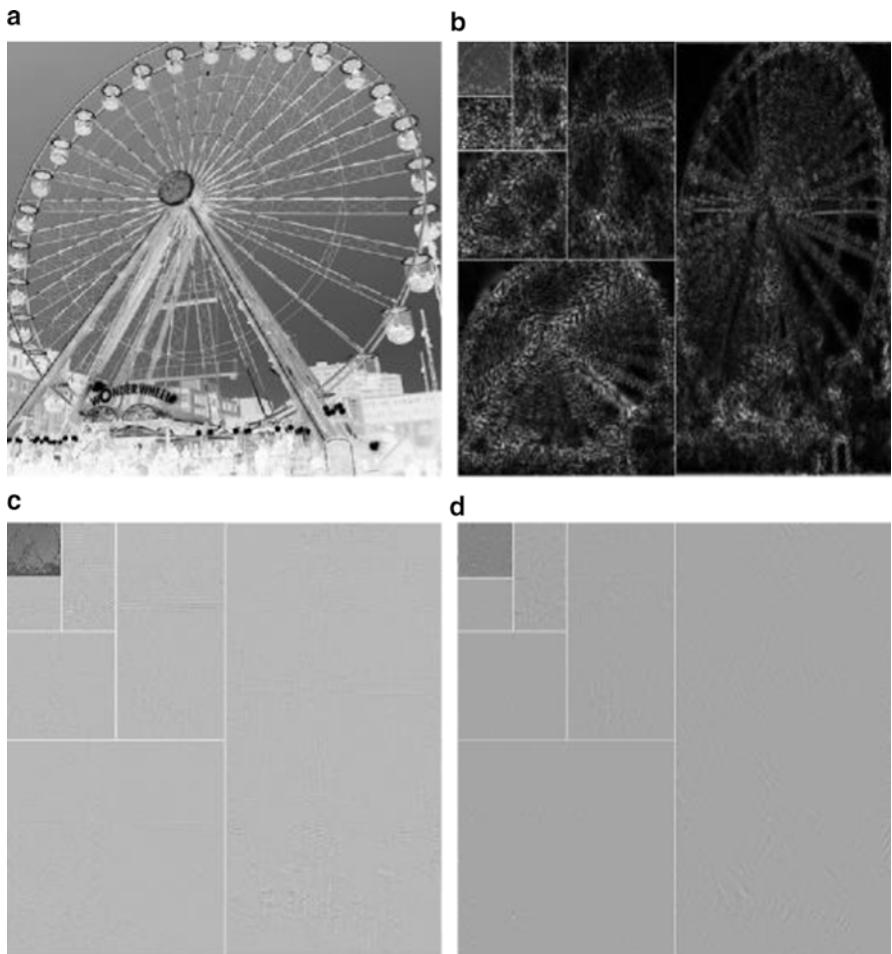

Fig. 16 Decomposition of an image [18, Part of IM115.tif] into approximation and wavelet coefficients. (a) Original image. (b) Matrix of the absolute values of the multiresolution coefficients. Large coefficients are white. The approximation coefficients are in the upper left band; the other bands are wavelet coefficients on six scales. (c) Real part of the coefficient matrix and (d) imaginary part of the decomposition matrix for $\phi = \mathcal{R}_\mu^{2,1}$ and the corresponding wavelets. The coefficients had their intensity rescaled for better contrast

is close to one, then under mild additional conditions, the k -sparse signal f can be reconstructed from $M > C\mu^2(Y, X)k \ln N$ samples with overwhelming probability.

Wavelet bases have proven to be very suitable for compressed sensing. It is an open question to classify the signals from certain applications and to estimate in which appropriate B-spline basis they have a k -sparse representation. Then adequate bases and function families incoherent with the spline bases have to be identified.

In the last years, the concept of sparsity entered image processing. It has proven to help immensely accelerate the solution of inverse problems and reconstruction algorithms, e.g., in medical imaging, such as in magnetic resonance imaging [42], computed tomography [12], photo-acoustic tomography [39], tomosynthesis [29], and others. In this area, as well as in other fields of imaging, it can be expected that the combination of splines – due to their easy modeling and the fast frequency domain algorithms – multiresolution and wavelets, and sparsity will lead to novel impressive fast algorithms for image reconstruction.

7 Conclusion

In the design procedure for scaling functions of multiresolution analyses, regularity and decay features, as well as symmetry properties, can be tuned by an appropriate modeling in frequency domain. The idea is to start in the frequency domain with a polynomial function P that fulfills the required symmetry features and that has a degree, such that $1/P$ decays sufficiently fast. This assures that the resulting scaling function has the desired regularity. However, $1/P$ in general is not an L^2 function and has to be multiplied with a localizing trigonometric polynomial v that eliminates the zeros in the denominator such that $\frac{v}{P}$ becomes square integrable. The choice of this trigonometric polynomial has to be taken carefully to be compatible with the required features modeled in $1/P$. Then under mild additional conditions, the fraction

$$\hat{\phi} = \frac{v}{P}$$

is the scaling function of a multiresolution analysis. This construction can be performed for 1D and higher dimensional spaces likewise. In the time domain, the resulting scaling function is a piecewise polynomial, thus a spline. This design procedure for scaling functions unites the concepts of splines and of multiresolution.

Interestingly, the polynomial in the denominator can be of a fractional or a complex degree and therefore allows a fine tuning of the scaling function's properties. However, the scaling function then becomes an infinite series of shifted (truncated) polynomials. The numerical calculation with the approximating basis of the multiresolution analysis in the time domain would cause truncation errors, which is unfavorable. But due to the construction of ϕ in the frequency domain and due to the closed form there, the implementation in the frequency domain with periodic boundary conditions yields a fast and stable multiresolution algorithm suitable for image analysis tasks.

1 Introduction

In contrast to classical Fourier analysis, time–frequency analysis is concerned with *localized Fourier transforms*. Gabor analysis is an important branch of time–frequency analysis. Although significantly different, it shares with the wavelet transform methods the ability to describe the smoothness of a given function in a location-dependent way.

The main tool is the *sliding window Fourier transform* or *short-time Fourier transform* (STFT) in the context of audio signals. It describes the correlation of a signal with the time–frequency shifted copies of a fixed function (or window or atom). Thus, it characterizes a function by its transform over phase space, which is the time–frequency plane (TF-plane) in a musical context or the location–wave-number domain in the context of image processing.

Since the transition from the signal domain to the phase space domain introduces an enormous amount of data redundancy, suitable subsampling of the continuous transform allows for complete recovery of the signal from the sampled STFT. The knowledge about appropriate choices of windows and sampling lattices has increased significantly during the last three decades. Since the suggestion goes back to the idea of D. Gabor [45], this branch of TF analysis is called *Gabor analysis*. Gabor expansions are not only of interest due to their very natural interpretation but also algorithmically convenient due to a good understanding of algebraic and analytic properties of Gabor families.

In this chapter, we describe some of the generalities relevant for an understanding of Gabor analysis of functions on \mathbb{R}^d . We pay special attention to the case $d = 2$, which is the most important case for image processing and image analysis applications.

The chapter is organized as follows. Section 2 presents central tools from functional analysis in Hilbert spaces, e.g., the pseudo-inverse of a bounded operator and the central facts from frame theory. In Sect. 3, we introduce several operators that play important roles in Gabor analysis. Gabor frames on $L^2(\mathbb{R}^d)$ are introduced in Sect. 4, and their discrete counterpart are treated in Sect. 5. Finally, the application of Gabor expansions to image representation is considered in Sect. 6.

2 Tools from Functional Analysis

In this section, we recall basic facts from functional analysis. Unless another reference is given, a proof can be found in [17]. In the entire section, \mathcal{H} denotes a separable Hilbert space with inner product $\langle \cdot, \cdot \rangle$.

The Pseudo-inverse Operator

It is well known that an arbitrary matrix has a pseudo-inverse, which can be used to find the minimal-norm least squares solution of a linear system. In the case of an operator on infinite-dimensional Hilbert spaces, one has to restrict the attention to linear operators with *closed range* in order to obtain a pseudo-inverse. Observe that a bounded operator (We will always assume *linearity*!) U on a Hilbert space \mathcal{H} is invertible if and only if it is injective and surjective, while injectivity combined with a dense range is not sufficient in the infinite-dimensional case. However, if the range of U is closed, there exists a “right-inverse operator” U^\dagger in the following sense:

Lemma 1. *Let \mathcal{H}, \mathcal{K} be Hilbert spaces, and suppose that $U : \mathcal{K} \rightarrow \mathcal{H}$ is a bounded operator with closed range \mathcal{R}_U . Then there exists a bounded operator $U^\dagger : \mathcal{H} \rightarrow \mathcal{K}$ for which*

$$UU^\dagger x = x, \quad \forall x \in \mathcal{R}_U. \quad (1)$$

Proof. Consider the operator obtained by taking the restriction of U to the orthogonal complement of the kernel of U , i.e., let

$$\tilde{U} := U|_{\mathcal{N}_U^\perp} : \mathcal{N}_U^\perp \rightarrow \mathcal{H}.$$

Obviously, \tilde{U} is linear and bounded. \tilde{U} is also injective: if $\tilde{U}x = 0$, it follows that $x \in \mathcal{N}_U^\perp \cap \mathcal{N}_U = \{0\}$. We prove next that the range of \tilde{U} equals the range of U . Given $y \in \mathcal{R}_U$, there exists $x \in \mathcal{K}$ such that $Ux = y$. By writing $x = x_1 + x_2$, where $x_1 \in \mathcal{N}_U^\perp$, $x_2 \in \mathcal{N}_U$, we obtain that

$$\tilde{U}x_1 = Ux_1 = U(x_1 + x_2) = Ux = y.$$

It follows from Banach’s theorem that \tilde{U} has a bounded inverse

$$\tilde{U}^{-1} : \mathcal{R}_U \rightarrow \mathcal{N}_U^\perp.$$

Extending \tilde{U}^{-1} by zero on the orthogonal complement of \mathcal{R}_U , we obtain a bounded operator $U^\dagger : \mathcal{H} \rightarrow \mathcal{K}$ for which $UU^\dagger x = x$ for all $x \in \mathcal{R}_U$. ■

The operator U^\dagger constructed in the proof of Lemma 1 is called the *pseudo-inverse* of U . In the literature, one will often see the pseudo-inverse of an operator U defined as the unique operator U^\dagger satisfying that

$$\mathcal{N}_{U^\dagger} = \mathcal{R}_U^\perp, \quad \mathcal{R}_{U^\dagger} = \mathcal{N}_U^\perp, \quad \text{and } UU^\dagger x = x, \quad x \in \mathcal{R}_U; \quad (2)$$

this definition is equivalent to the above construction. We collect some properties of U^\dagger and its relationship to U .

Lemma 2. Let $U : \mathcal{K} \rightarrow \mathcal{H}$ be a bounded operator with closed range. Then the following holds:

- (i) The orthogonal projection of \mathcal{H} onto \mathcal{R}_U is given by UU^\dagger .
- (ii) The orthogonal projection of \mathcal{K} onto \mathcal{R}_{U^\dagger} is given by $U^\dagger U$.
- (iii) U^* has closed range, and $(U^*)^\dagger = (U^\dagger)^*$.
- (iv) On \mathcal{R}_U , the operator U^\dagger is given explicitly by

$$U^\dagger = U^*(UU^*)^{-1}. \quad (3)$$

Bessel Sequences in Hilbert Spaces

When we deal with infinite-dimensional vector spaces, we need to consider expansions in terms of infinite series. The purpose of this section is to introduce a condition that ensures that the relevant infinite series actually converge. When speaking about a sequence $\{f_k\}_{k=1}^\infty$ in \mathcal{H} , we mean an *ordered* set, i.e., $\{f_k\}_{k=1}^\infty = \{f_1, f_2, \dots\}$. That we have chosen to index the sequence by the natural numbers is just for convenience.

Definition 1. A sequence $\{f_k\}_{k=1}^\infty$ in \mathcal{H} is called a Bessel sequence if there exists a constant $B > 0$ such that

$$\sum_{k=1}^{\infty} |\langle f, f_k \rangle|^2 \leq B \|f\|^2, \quad \forall f \in \mathcal{H}. \quad (4)$$

Any number B satisfying (4) is called a *Bessel bound* for $\{f_k\}_{k=1}^\infty$. The *optimal bound* for a given Bessel sequence $\{f_k\}_{k=1}^\infty$ is the smallest possible value of $B > 0$ satisfying (4). Except for the case $f_k = 0$, $\forall k \in \mathbb{N}$, the optimal bound always exists.

Theorem 1. Let $\{f_k\}_{k=1}^\infty$ be a sequence in \mathcal{H} and $B > 0$ be given. Then $\{f_k\}_{k=1}^\infty$ is a Bessel sequence with Bessel bound B if and only if

$$T : \{c_k\}_{k=1}^\infty \rightarrow \sum_{k=1}^{\infty} c_k f_k$$

defines a bounded operator from $\ell^2(\mathbb{N})$ into \mathcal{H} and $\|T\| \leq \sqrt{B}$.

The operator T is called the *synthesis operator*. The adjoint T^* is called the *analysis operator* and is given by

$$T^* : \mathcal{H} \rightarrow \ell^2(\mathbb{N}), \quad T^* f = \{\langle f, f_k \rangle\}_{k=1}^\infty.$$

These operators play key roles in the theory of frames, to be considered in section “Frames and Their Properties.”

The Bessel condition (4) remains the same, regardless of how the elements $\{f_k\}_{k=1}^{\infty}$ are numbered. This leads to a very important consequence of Theorem 1:

Corollary 1. *If $\{f_k\}_{k=1}^{\infty}$ is a Bessel sequence in \mathcal{H} , then $\sum_{k=1}^{\infty} c_k f_k$ converges unconditionally for all $\{c_k\}_{k=1}^{\infty} \in \ell^2(\mathbb{N})$, i.e., the series is convergent, irrespective of how and in which order the summation is realized.*

Thus, a reordering of the elements in $\{f_k\}_{k=1}^{\infty}$ will not affect the series $\sum_{k=1}^{\infty} c_k f_k$ when $\{c_k\}_{k=1}^{\infty}$ is reordered the same way: the series will converge toward the same element as before. For this reason, we can choose an arbitrary indexing of the elements in the Bessel sequence; in particular, it is not a restriction that we present all results with the natural numbers as index set. As we will see in the sequel, all orthonormal bases and frames are Bessel sequences.

General Bases and Orthonormal Bases

We will now briefly consider bases in Hilbert spaces. In particular, we will discuss orthonormal bases, which are the infinite-dimensional counterparts of the canonical bases in \mathbb{C}^n . Orthonormal bases are widely used in mathematics as well as physics, signal processing, and many other areas where one needs to represent functions in terms of “elementary building blocks.”

Definition 2. Consider a sequence $\{e_k\}_{k=1}^{\infty}$ of vectors in \mathcal{H} .

- (i) The sequence $\{e_k\}_{k=1}^{\infty}$ is a (Schauder) basis for \mathcal{H} if for each $f \in \mathcal{H}$, there exist unique scalar coefficients $\{c_k(f)\}_{k=1}^{\infty}$ such that

$$f = \sum_{k=1}^{\infty} c_k(f) e_k. \quad (5)$$

- (ii) A basis $\{e_k\}_{k=1}^{\infty}$ is an unconditional basis if the series (5) converges unconditionally for each $f \in \mathcal{H}$.
- (iii) A basis $\{e_k\}_{k=1}^{\infty}$ is an orthonormal basis if $\{e_k\}_{k=1}^{\infty}$ is an orthonormal system, i.e., if

$$\langle e_k, e_j \rangle = \delta_{k,j} = \begin{cases} 1 & \text{if } k = j, \\ 0 & \text{if } k \neq j. \end{cases}$$

An orthonormal basis leads to an expansion of the type (5) with an explicit expression for the coefficients $c_k(f)$:

Theorem 2. If $\{e_k\}_{k=1}^{\infty}$ is an orthonormal basis, then each $f \in \mathcal{H}$ has an unconditionally convergent expansion

$$f = \sum_{k=1}^{\infty} \langle f, e_k \rangle e_k. \quad (6)$$

In practice, orthonormal bases are certainly the most convenient bases to use: for other types of bases, the representation (6) has to be replaced by a more complicated expression. Unfortunately, the conditions for $\{e_k\}_{k=1}^{\infty}$ being an orthonormal basis are strong, and often it is impossible to construct orthonormal bases satisfying extra conditions. We discuss this in more detail later. Note also that it is not always a good idea to use the Gram–Schmidt orthonormalization procedure to construct an orthonormal basis from a given basis: it might destroy special properties of the basis at hand. For example, the special structure of a Gabor basis (to be discussed later) will be lost.

Frames and Their Properties

We are now ready to introduce one of the central subjects:

Definition 3. A sequence $\{f_k\}_{k=1}^{\infty}$ of elements in \mathcal{H} is a frame for \mathcal{H} if there exist constants $A, B > 0$ such that

$$A \|f\|^2 \leq \sum_{k=1}^{\infty} |\langle f, f_k \rangle|^2 \leq B \|f\|^2, \quad \forall f \in \mathcal{H}. \quad (7)$$

The numbers A and B are called *frame bounds*. A special role is played by frames for which the optimal frame bounds coincide:

Definition 4. A sequence $\{f_k\}_{k=1}^{\infty}$ in \mathcal{H} is a tight frame if there exists a number $A > 0$ such that

$$\sum_{k=1}^{\infty} |\langle f, f_k \rangle|^2 = A \|f\|^2, \quad \forall f \in \mathcal{H}.$$

The number A is called the frame bound.

Since a frame $\{f_k\}_{k=1}^{\infty}$ is a Bessel sequence, the operator

$$T : \ell^2(\mathbb{N}) \rightarrow \mathcal{H}, \quad T\{c_k\}_{k=1}^{\infty} = \sum_{k=1}^{\infty} c_k f_k \quad (8)$$

is bounded by Theorem 1. Composing T and T^* , we obtain the *frame operator*

$$S : \mathcal{H} \rightarrow \mathcal{H}, \quad Sf = TT^*f = \sum_{k=1}^{\infty} \langle f, f_k \rangle f_k. \quad (9)$$

The *frame decomposition*, stated in (10) below, is the most important frame result. It shows that if $\{f_k\}_{k=1}^{\infty}$ is a frame for \mathcal{H} , then every element in \mathcal{H} has a representation as an infinite linear combination of the frame elements. Thus, it is natural to view a frame as a “generalized basis.”

Theorem 3. *Let $\{f_k\}_{k=1}^{\infty}$ be a frame with frame operator S . Then*

$$f = \sum_{k=1}^{\infty} \langle f, S^{-1} f_k \rangle f_k, \quad \forall f \in \mathcal{H}, \quad (10)$$

and

$$f = \sum_{k=1}^{\infty} \langle f, f_k \rangle S^{-1} f_k, \quad \forall f \in \mathcal{H}. \quad (11)$$

Both series converge unconditionally for all $f \in \mathcal{H}$.

Theorem 3 shows that all information about a given vector $f \in \mathcal{H}$ is contained in the sequence $\{\langle f, S^{-1} f_k \rangle\}_{k=1}^{\infty}$. The numbers $\langle f, S^{-1} f_k \rangle$ are called *frame coefficients*. The sequence $\{S^{-1} f_k\}_{k=1}^{\infty}$ is also a frame; it is called the *canonical dual frame* of $\{f_k\}_{k=1}^{\infty}$.

Theorem 3 also immediately reveals one of the main difficulties in frame theory. In fact, in order for the expansions (10) and (11) to be applicable in practice, we need to be able to find the operator S^{-1} or at least to calculate its action on all f_k , $k \in \mathbb{N}$. In general, this is a major problem. One way of circumventing the problem is to consider only tight frames:

Corollary 2. *If $\{f_k\}_{k=1}^{\infty}$ is a tight frame with frame bound A , then the canonical dual frame is $\{A^{-1} f_k\}_{k=1}^{\infty}$, and*

$$f = \frac{1}{A} \sum_{k=1}^{\infty} \langle f, f_k \rangle f_k, \quad \forall f \in \mathcal{H}. \quad (12)$$

By a suitable scaling of the vectors $\{f_k\}_{k=1}^{\infty}$ in a tight frame, we can always obtain that $A = 1$; in that case, (12) has exactly the same form as the representation via an orthonormal basis; see (6). Thus, such frames can be used without any additional computational effort compared with the use of orthonormal bases; however, the family does not have to be linearly independent now.

Tight frames have other advantages. For the design of frames with prescribed properties, it is essential to control the behavior of the canonical dual frame, but the complicated structure of the frame operator and its inverse makes this difficult. If, e.g., we consider a frame $\{f_k\}_{k=1}^{\infty}$ for $L^2(\mathbb{R})$ consisting of functions with exponential decay, nothing guarantees that the functions in the canonical dual frame $\{S^{-1}f_k\}_{k=1}^{\infty}$ have exponential decay. However, for tight frames, questions of this type trivially have satisfactory answers, because the dual frame equals the original one. Also, for a tight frame, the canonical dual frame automatically has the same structure as the frame itself: if the frame has Gabor structure (to be described in Sect. 4), the same is the case for the canonical dual frame.

There is another way to avoid the problem of inverting the frame operator S . A frame that is *not* a basis is said to be *overcomplete*; in the literature, the term *redundant frame* is also used. For frames $\{f_k\}_{k=1}^{\infty}$ that are *not* bases, one can replace the canonical dual $\{S^{-1}f_k\}_{k=1}^{\infty}$ by other frames:

Theorem 4. *Assume that $\{f_k\}_{k=1}^{\infty}$ is an overcomplete frame. Then there exist frames $\{g_k\}_{k=1}^{\infty} \neq \{S^{-1}f_k\}_{k=1}^{\infty}$ for which*

$$f = \sum_{k=1}^{\infty} \langle f, g_k \rangle f_k, \quad \forall f \in \mathcal{H}. \quad (13)$$

A frame $\{g_k\}_{k=1}^{\infty}$ satisfying (13) is called a *dual frame* of $\{f_k\}_{k=1}^{\infty}$. The hope is to find dual frames that are easier to calculate or have better properties than the canonical dual. Examples of this type can be found in [17].

3 Operators

In this section, we introduce several operators that play key roles in Gabor analysis. In particular, we will need the basic properties of the *localized Fourier transform*, which is called the STFT (short-time Fourier transform). It is natural for us to start with the *Fourier transform*, which is defined as an integral transform on the space of all (Lebesgue) integrable functions, denoted by $L^1(\mathbb{R}^d)$.

The Fourier Transform

Definition 5. For $f \in L^1(\mathbb{R}^d)$, the *Fourier transform* is defined as

$$\hat{f}(\omega) := (\mathcal{F}f)(\omega) := \int_{\mathbb{R}^d} f(x) e^{-2\pi i x \cdot \omega} dx, \quad (14)$$

where $x \cdot \omega = \sum_{k=1}^d x_k \omega_k$ is the usual scalar product of vectors in \mathbb{R}^d .

Lemma 3 (Riemann–Lebesgue). *If $f \in L^1(\mathbb{R}^d)$, then \hat{f} is uniformly continuous and $\lim_{|\omega| \rightarrow \infty} |\hat{f}(\omega)| = 0$.*

The Fourier transform yields a continuous bijection from the Schwartz space $\mathcal{S}(\mathbb{R}^d)$ to $\mathcal{S}(\mathbb{R}^d)$. This follows from the fact that it turns analytic operations (differentiation) into multiplication with polynomials and vice versa:

$$\mathcal{F}(D^\alpha f) = (2\pi i)^{|\alpha|} X^\alpha (\mathcal{F}f) \quad (15)$$

and

$$D^\alpha (\mathcal{F}f) = (-2\pi i)^{|\alpha|} \mathcal{F}(X^\alpha f), \quad (16)$$

with a multi-index $\alpha = (\alpha_1, \dots, \alpha_d) \in \mathbb{N}_0^d$, $|\alpha| := \sum_{i=1}^d \alpha_i$, D^α as differential operator

$$D^\alpha f(x) := \frac{\partial^{\alpha_1} \cdots \partial^{\alpha_d}}{\partial x_1^{\alpha_1} \cdots \partial x_d^{\alpha_d}} f(x_1, \dots, x_d)$$

and X^α as multiplication operator $(X^\alpha f)(x) := x_1^{\alpha_1} \cdots x_d^{\alpha_d} f(x_1, \dots, x_d)$. It follows from the definition that $\mathcal{S}(\mathbb{R}^d)$ is invariant under these operations, i.e.,

$$X^\alpha f \in \mathcal{S}(\mathbb{R}^d) \quad \text{and} \quad D^\alpha f \in \mathcal{S}(\mathbb{R}^d) \quad \forall \alpha \in \mathbb{N}_0^d \quad \forall f \in \mathcal{S}(\mathbb{R}^d).$$

Using the reflection operator $(\mathcal{I}f)(x) := f(-x)$, one can show that $\mathcal{F}^2 = \mathcal{I}$ and so $\mathcal{F}^4 = \text{Id}_{\mathcal{S}(\mathbb{R}^d)}$. This yields

$$\mathcal{F}^{-1} = \mathcal{I}\mathcal{F} \quad (17)$$

and we can give an inversion formula explicitly:

Theorem 5 (Inversion Formula). *The Fourier transform is a bijection from $\mathcal{S}(\mathbb{R}^d)$ to $\mathcal{S}(\mathbb{R}^d)$, and the inverse operator is given by*

$$(\mathcal{F}^{-1} f)(x) = \int_{\mathbb{R}^d} f(\omega) e^{2\pi i x \cdot \omega} d\omega \quad \forall x \in \mathbb{R}^d. \quad (18)$$

Furthermore,

$$\langle \mathcal{F}f, \mathcal{F}g \rangle_{L^2} = \langle f, g \rangle_{L^2} \quad \forall f, g \in \mathcal{S}(\mathbb{R}^d).$$

We can extend the Fourier transform to an isometric operator on all of $L^2(\mathbb{R}^d)$. We will use the same symbol \mathcal{F} although the Fourier transform on $L^2(\mathbb{R}^d)$ is not defined by a Lebesgue integral (14) anymore if $f \in L^2 \setminus L^1(\mathbb{R}^d)$, but rather by

means of summability methods. Moreover, $\mathcal{F}f$ should be viewed as an equivalence class of functions, rather than a pointwise given function.

Theorem 6 (Plancherel). *If $f \in L^1 \cap L^2(\mathbb{R}^d)$, then*

$$\|f\|_{L^2} = \|\mathcal{F}f\|_{L^2}. \quad (19)$$

As a consequence, \mathcal{F} extends in a unique way to a unitary operator on $L^2(\mathbb{R}^d)$ that satisfies Parseval's formula

$$\langle f, g \rangle_{L^2} = \langle \mathcal{F}f, \mathcal{F}g \rangle_{L^2} \quad \forall f, g \in L^2(\mathbb{R}^d). \quad (20)$$

In signal analysis, the isometry of the Fourier transform has the interpretation that it preserves the energy of a signal. For more details on the role of the Schwartz class for the Fourier transform, see [78, V].

Translation and Modulation

Definition 6. For $x, \omega \in \mathbb{R}^d$, we define the *translation operator* T_x by

$$(T_x f)(t) := f(t - x) \quad (21)$$

and the *modulation operator* M_ω by

$$(M_\omega f)(t) := e^{2\pi i \omega \cdot t} f(t). \quad (22)$$

One has $T_x^{-1} = T_{-x}$ and $M_\omega^{-1} = M_{-\omega}$. The operator T_x is called a *time shift* and M_ω a *frequency shift*. Operators of the form $T_x M_\omega$ or $M_\omega T_x$ are called *time-frequency shifts* (TF-shifts). They satisfy the *commutation relations*

$$T_x M_\omega = e^{-2\pi i x \cdot \omega} M_\omega T_x. \quad (23)$$

Time-frequency shifts are isometries on L^p for all $1 \leq p \leq \infty$, i.e.,

$$\|T_x M_\omega f\|_{L^p} = \|f\|_{L^p}.$$

The interplay of TF-shifts with the Fourier transform is as follows:

$$\widehat{T_x f} = M_{-x} \hat{f} \quad \text{or} \quad \mathcal{F} T_x = M_{-x} \mathcal{F} \quad (24)$$

and

$$\widehat{M_\omega f} = T_\omega \hat{f} \quad \text{or} \quad \mathcal{F} M_\omega = T_\omega \mathcal{F}. \quad (25)$$

Equation (25) explains why modulations are also called *frequency shifts*: modulations become translations on the Fourier transform side. Altogether, we have

$$\widehat{T_x M_\omega f} = M_{-x} T_\omega \hat{f} = e^{-2\pi i x \cdot \omega} T_\omega M_{-x} \hat{f}.$$

Convolution, Involution, and Reflection

Definition 7. The *convolution* of two functions $f, g \in L^1(\mathbb{R}^d)$ is the function $f * g$ defined by

$$(f * g)(x) := \int_{\mathbb{R}^d} f(y) g(x - y) dy. \quad (26)$$

It satisfies

$$\|f * g\|_{L^1} \leq \|f\|_{L^1} \|g\|_{L^1} \quad \text{and} \quad \widehat{f * g} = \hat{f} \cdot \hat{g}.$$

One may view $f * g$ as f being “smeared” by g and vice versa. One can thus smoothen a function by convolving it with a narrow bump function.

Definition 8. The *involution* of a function is defined by

$$f^*(x) := \overline{f(-x)}. \quad (27)$$

It follows that

$$\widehat{f^*} = \bar{\hat{f}} \quad \text{and} \quad \widehat{\mathcal{I}f} = \mathcal{I}\hat{f}.$$

Finally, let us mention that convolution corresponds to pointwise multiplication (and conversely), i.e., the so-called *convolution theorem* is valid:

$$\widehat{g * f} = \hat{f} \cdot \hat{g}. \quad (28)$$

The Short-Time Fourier Transform

The Fourier transform as described in section “The Fourier Transform” provides only global frequency information of a signal f . This is useful for signals that do not vary during the time, e.g., for analyzing the spectrum of a violin tone. However, dynamic signals such as a melody have to be split into short time intervals over which it can be well approximated by a linear combination of few pure frequencies. Since sharp cutoffs would introduce discontinuities in the localized signal and

therefore leaking of the frequency spectrum, a smooth window function g is usually used in the definition of the short-time Fourier transform.

In image processing, one has plane waves instead of pure frequencies; thus, the global Fourier transform is only well suited to stripe-like patterns. Again, a localized version of the Fourier transform allows to determine dominant plane waves locally, and one can reconstruct an image from such a redundant transform. Gabor analysis deals with the question of how one can reconstruct an image from only somewhat overlapping local pieces, which are stored only in the form of a sampled (local) 2D Fourier transform (Fig. 1).

Definition 9. Fix a *window function* $g \in L^2(\mathbb{R}^d) \setminus \{0\}$. The *short-time Fourier transform* (STFT), also called (*continuous*) *Gabor transform* of a function $f \in L^2(\mathbb{R}^d)$ with respect to g , is defined as

$$(\mathcal{V}_g f)(x, \omega) := \int_{\mathbb{R}^d} f(t) \overline{g(t-x)} e^{-2\pi i t \cdot \omega} dt \quad \text{for } x, \omega \in \mathbb{R}^d. \quad (29)$$

For $f, g \in L^2(\mathbb{R}^d)$, the STFT $\mathcal{V}_g f$ is uniformly continuous (by Riemann–Lebesgue) on \mathbb{R}^{2d} and can be written as

$$(\mathcal{V}_g f)(x, \omega) = \widehat{f \cdot T_x \bar{g}}(\omega) \quad (30)$$

$$= \langle f, M_\omega T_x g \rangle_{L^2} \quad (31)$$

$$= e^{-2\pi i x \cdot \omega} (f * M_\omega g^*)(x). \quad (32)$$

The STFT as a function in x and ω seems to provide the possibility to obtain information about the occurrence of arbitrary frequencies ω at arbitrary locations x as desired. However, the *uncertainty principle* (cf. [51]) implies that there is a limitation concerning the joint resolution. In fact, the STFT has limitations in its time–frequency resolution capability: Low frequencies can hardly be located with narrow windows, and similarly, short pulses remain invisible for wide windows. The choice of the analyzing window is therefore crucial.

Just like the Fourier transform, the STFT is a kind of time–frequency representation of a signal. This again raises the question of how to reconstruct the signal from its time–frequency representation. To approach this, we need the orthogonality relations of the STFT, which corresponds to Parseval’s formula (20) for the Fourier transform:

Theorem 7 (Orthogonality relations for STFT). Let $f_1, f_2, g_1, g_2 \in L^2(\mathbb{R}^d)$. Then $\mathcal{V}_{g_j} f_j \in L^2(\mathbb{R}^{2d})$ for $j \in \{1, 2\}$, and

$$\langle \mathcal{V}_{g_1} f_1, \mathcal{V}_{g_2} f_2 \rangle_{L^2(\mathbb{R}^{2d})} = \langle f_1, f_2 \rangle_{L^2} \overline{\langle g_1, g_2 \rangle_{L^2}}.$$

Corollary 3. If $f, g \in L^2(\mathbb{R}^d)$, then

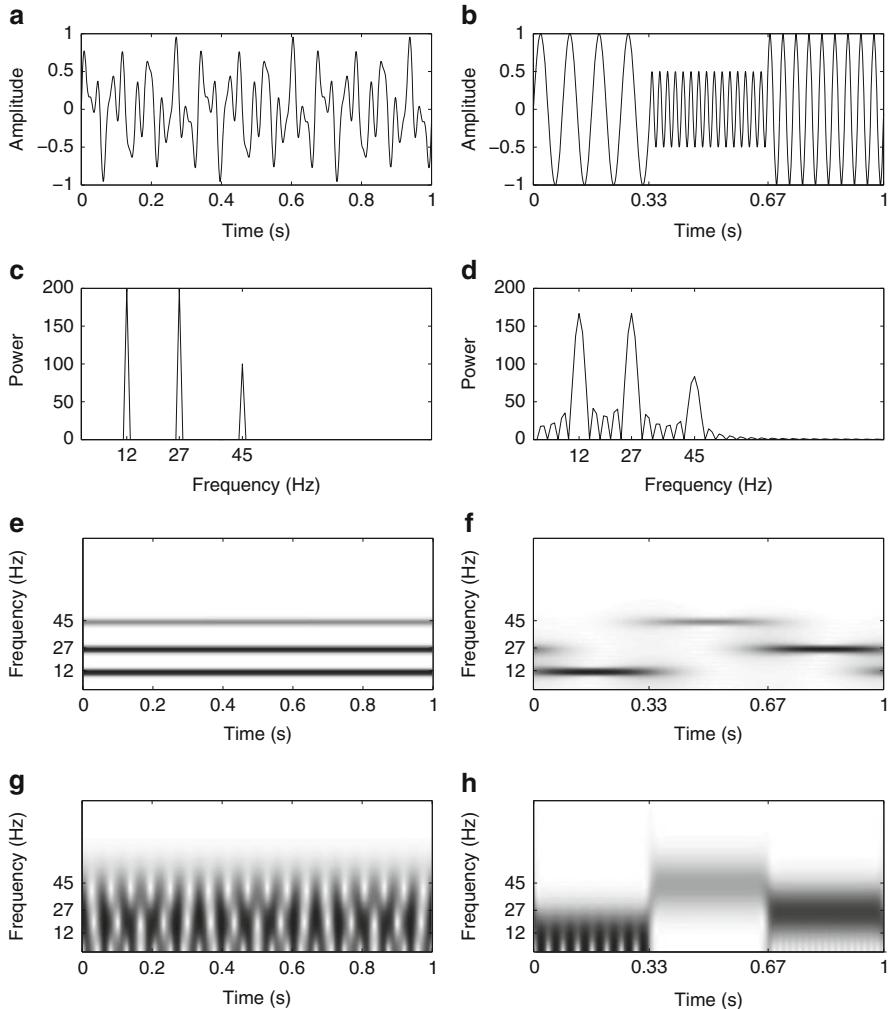

Fig. 1 Two signals and their (short-time) Fourier transforms. (a) Signal 1: Concurrent frequencies. (b) Signal 2: Consecutive frequencies. (c) Fourier power spectrum 1. (d) Fourier power spectrum 2. (e) STFT 1 with wide window. (f) STFT 2 with wide window. (g) STFT 1 with narrow window. (h) STFT 2 with narrow window

$$\|\mathcal{V}_g f\|_{L^2(\mathbb{R}^{2d})} = \|f\|_{L^2} \|g\|_{L^2}.$$

In the case of $\|g\|_{L^2} = 1$, we have

$$\|f\|_{L^2} = \|\mathcal{V}_g f\|_{L^2(\mathbb{R}^{2d})} \quad \forall f \in L^2(\mathbb{R}^d), \quad (33)$$

i.e., the STFT as an isometry from $L^2(\mathbb{R}^d)$ into $L^2(\mathbb{R}^{2d})$.

Formula (33) shows that the STFT preserves the energy of a signal; it corresponds to (19) which shows the same property for the Fourier transform. Therefore, f is completely determined by $\mathcal{V}_g f$, and the inversion is given by a vector-valued integral (for good functions valid in the pointwise sense):

Corollary 4 (Inversion formula for the STFT). *Let $g, \gamma \in L^2(\mathbb{R}^d)$ and $\langle g, \gamma \rangle \neq 0$. Then*

$$f(x) = \frac{1}{\langle \gamma, g \rangle_{L^2}} \iint_{\mathbb{R}^{2d}} \mathcal{V}_g f(x, \omega) M_\omega T_x \gamma(x) d\omega dx \quad \forall f \in L^2(\mathbb{R}^d). \quad (34)$$

Obviously, $\gamma = g$ is a natural choice here. The time–frequency analysis of signals is usually done by three subsequent steps:

- (i) *Analysis:* Using the STFT, the signal is transformed into a joint time–frequency representation.
- (ii) *Processing:* The obtained signal representation is then manipulated in a certain way, e.g., by restriction to a part of the signal yielding the relevant information.
- (iii) *Synthesis:* The inverse STFT is applied to the processed representation, thus creating a new signal.

A function is completely represented by its STFT but in a highly redundant way. To minimize the influence of the uncertainty principle, the analyzing window g should be chosen such that g and its Fourier transform \hat{g} both decay rapidly, e.g., as Schwartz functions. A computational implementation can only be obtained by a discretization of both the functions and the STFT. Therefore, only sampled versions of the STFT are possible, and only certain locations and frequencies are used for analyzing a given signal. The challenge is to find the appropriate lattice constants in time and frequency and to obtain good time–frequency resolution.

4 Gabor Frames in $L^2(\mathbb{R}^d)$

By formula (31), the STFT analyzes a function $f \in L^2(\mathbb{R}^d)$ into coefficients $\langle f, M_\omega T_x g \rangle_{L^2}$ using modulations and translations of a single window function $g \in L^2(\mathbb{R}^d) \setminus \{0\}$. One problem we noticed was that these TF-shifts are infinitesimal and overlap largely, making the STFT a highly redundant time–frequency representation. An idea to overcome this is to restrict to discrete choices of time positions x and frequencies ω such that this redundancy is decreased while leaving enough information in the coefficients about the time–frequency behavior of f . This is the very essence of Gabor analysis: It is sought to expand functions in $L^2(\mathbb{R}^d)$ into an absolutely convergent series of modulations and translations of a window function g . Therefore, it is interesting to find necessary and sufficient conditions on g and a discrete set $\Lambda \subseteq \mathbb{R}^d \times \mathbb{R}^d$ such that

$$\{g_{x,\omega}\}_{(x,\omega) \in \Lambda} := \{M_\omega T_x g\}_{(x,\omega) \in \Lambda}$$

forms a frame for $L^2(\mathbb{R}^d)$. The question arises how the sampling set Λ should be structured. It turns out to be very convenient to have this set closed under the addition operation, urging Λ to be a subgroup of the time–frequency plane, i.e., $\Lambda \trianglelefteq \mathbb{R}^d \times \mathbb{R}^d$. Dennis Gabor (actually *Dénes Gábor*) suggested in his *Theory of Communication* [45], 1946, to use fixed step sizes $\alpha, \beta > 0$ for time and frequency and use the set $\{\alpha k\}_{k \in \mathbb{Z}^d}$ for the time positions and $\{\beta n\}_{n \in \mathbb{Z}^d}$ for the frequencies, yielding the functions

$$g_{k,n}(x) := M_{\beta n} T_{\alpha k} g(x) = e^{2\pi i \beta n \cdot x} g(x - \alpha k)$$

as analyzing elements. This is the approach that is usually presented in the literature, although there is also a more general group theoretical setting possible where Λ is an arbitrary (discrete) subgroup. This subgroup is also called a *time–frequency lattice*, although it does not have to be of such a “rectangular” shape in general.

Definition 10. A *lattice* $\Lambda \subseteq \mathbb{R}^d$ is a (discrete) subgroup of \mathbb{R}^d of the form $\Lambda = \mathfrak{A} \mathbb{Z}^d$, where \mathfrak{A} is an invertible $d \times d$ -matrix over \mathbb{R} . Lattices in \mathbb{R}^{2d} can be described as

$$\Lambda = \{(x, y) \in \mathbb{R}^{2d} \mid (x, y) = (Ak + B\ell, Ck + D\ell), (k, \ell) \in \mathbb{Z}^{2d}\}$$

with $A, B, C, D \in \mathbb{C}^{d \times d}$ and

$$\mathfrak{A} = \begin{pmatrix} A & B \\ C & D \end{pmatrix}.$$

A lattice $\Lambda = \alpha \mathbb{Z}^d \times \beta \mathbb{Z}^d \trianglelefteq \mathbb{R}^{2d}$ for $\alpha, \beta > 0$ is called a *separable lattice*, a *product lattice*, or a *grid*.

In the following, our lattice will be of the separable type for fixed lattice parameters $\alpha, \beta > 0$.

Definition 11. For a nonzero window function $g \in L^2(\mathbb{R}^d)$ and lattice parameters $\alpha, \beta > 0$, the set of time–frequency shifts

$$\mathcal{G}(g, \alpha, \beta) := \{M_{\beta n} T_{\alpha k} g\}_{k,n \in \mathbb{Z}^d}$$

is called a *Gabor system*. If $\mathcal{G}(g, \alpha, \beta)$ is a frame for $L^2(\mathbb{R}^d)$, it is called a *Gabor frame* or *Weyl–Heisenberg frame*. The associated frame operator is the *Gabor frame operator* and takes the form

$$Sf = \sum_{k,n \in \mathbb{Z}^d} \langle f, M_{\beta n} T_{\alpha k} g \rangle_{L^2} M_{\beta n} T_{\alpha k} g \quad (35)$$

$$= \sum_{k,n \in \mathbb{Z}^d} \mathcal{V}_g f(\alpha k, \beta n) M_{\beta n} T_{\alpha k} g$$

for all $f \in L^2(\mathbb{R}^d)$. The window g is also called the *Gabor atom*.

According to the general frame theory, $\{S^{-1}g_{k,n}\}_{k,n \in \mathbb{Z}^d}$ yields the *canonical dual frame*. So we would have to compute S^{-1} and apply it to *all* modulated and translated versions of the Gabor atom g . A direct computation shows that for arbitrary fixed indices $\ell, m \in \mathbb{Z}^d$,

$$S M_{\beta m} T_{\alpha \ell} = M_{\beta m} T_{\alpha \ell} S. \quad (36)$$

Consequently, also S^{-1} commutes with time–frequency shifts, which gives the following fundamental result for (regular) Gabor analysis:

Theorem 8. *If the given Gabor system $\mathcal{G}(g, \alpha, \beta)$ is a frame for $L^2(\mathbb{R}^d)$, then all of the following hold:*

- (a) *There exists a dual window $\gamma \in L^2(\mathbb{R}^d)$ such that the dual frame is given by the Gabor frame $\mathcal{G}(\gamma, \alpha, \beta)$.*
- (b) *Every $f \in L^2(\mathbb{R}^d)$ has an expansion of the form*

$$\begin{aligned} f &= \sum_{k,n \in \mathbb{Z}^d} \langle f, M_{\beta n} T_{\alpha k} g \rangle_{L^2} M_{\beta n} T_{\alpha k} \gamma \\ &= \sum_{k,n \in \mathbb{Z}^d} \langle f, M_{\beta n} T_{\alpha k} \gamma \rangle_{L^2} M_{\beta n} T_{\alpha k} g \end{aligned} \quad (37)$$

with unconditional convergence in $L^2(\mathbb{R}^d)$.

- (c) *The canonical dual frame is given by the Gabor frame $\{M_{\beta n} T_{\alpha k} S^{-1} g\}_{k,n \in \mathbb{Z}^d}$ built from the canonical dual window $\gamma^\circ := S^{-1} g$.*
- (d) *The inverse frame operator S^{-1} is just the frame operator for the Gabor system $\mathcal{G}(\gamma^\circ, \alpha, \beta)$ and*

$$S^{-1} f = \sum_{k,n \in \mathbb{Z}^d} \langle f, M_{\beta n} T_{\alpha k} \gamma^\circ \rangle_{L^2} M_{\beta n} T_{\alpha k} \gamma^\circ. \quad (38)$$

We note that if the function g is compactly supported and the modulation parameter β is sufficiently small, it is easy to verify whether $\mathcal{G}(g, \alpha, \beta)$ is a frame and to find the canonical dual window in the affirmative case; see [51, 6.4] or [17, 9.1].

One can show [51, 7.6.1] that all dual windows γ of a Gabor frame $\mathcal{G}(g, \alpha, \beta)$ are within an affine subspace of $L^2(\mathbb{R}^d)$, namely, $\gamma \in \gamma^\circ + \mathcal{K}^\perp$, where \mathcal{K} is the closed linear span of $\mathcal{G}\left(g, \frac{1}{\beta}, \frac{1}{\alpha}\right)$ and therefore

$$\mathcal{K}^\perp = \{h \in L^2(\mathbb{R}^d) : \langle h, M_{n/\alpha} T_{k/\beta} g \rangle_{L^2} = 0 \quad \forall k, n \in \mathbb{Z}^d\}. \quad (39)$$

Hence, we have $\gamma = \gamma^\circ + h$ for a certain $h \in \mathcal{K}^\perp$, and as $\gamma^\circ \in \mathcal{K}$, the canonical dual window possesses the smallest L^2 -norm among all dual windows and is most similar to the original window g . However, there might be reasons not to choose the canonical dual window, but one of the others in $\gamma^\circ + \mathcal{K}^\perp$, if, e.g., one wants the dual window to have a smaller essential support or if the window should be as smooth as possible. Explicit constructions of alternative dual windows can be found in [17].

A key result in Gabor analysis states a necessary condition for a Gabor system to form a frame:

Theorem 9. *Let $g \in L^2(\mathbb{R}^d) \setminus \{0\}$ and $\alpha, \beta > 0$. If $\mathcal{G}(g, \alpha, \beta)$ is a frame, then:*

- (a) $\alpha\beta \leq 1$.
- (b) $\mathcal{G}(g, \alpha, \beta)$ is a basis if and only if $\alpha\beta = 1$.

Unfortunately, having $\alpha\beta \leq 1$ is not sufficient for a Gabor system to form a frame. Sufficient conditions are presented, e.g., in [16, 8.4]. A special result is known for the Gaussian function:

Theorem 10. *Consider the normalized Gaussian $\varphi(x) := 2^{d/4} e^{-\pi x^2}$. Then $\mathcal{G}(\varphi, \alpha, \beta)$ is a frame for $L^2(\mathbb{R}^d)$ if and only if $\alpha\beta < 1$.*

In signal analysis, it is customary to call the case

$$\begin{aligned} \alpha\beta &< 1 \text{ oversampling} \\ \alpha\beta &= 1 \text{ critical sampling} \\ \alpha\beta &> 1 \text{ undersampling} \end{aligned}$$

In the case of the Gaussian window, oversampling guarantees an excellent time-frequency localization. But for Gabor frame theory in $L^2(\mathbb{R}^d)$, it is quite delicate to find appropriate windows for given $\alpha\beta \leq 1$. The case $\alpha\beta = 1$ is problematic from the point of view of time-frequency analysis, as the Balian–Low theorem demonstrates:

Theorem 11 (Balian–Low). *Let $g \in L^2(\mathbb{R}^d)$ be a nonzero window and $\alpha, \beta > 0$ with $\alpha\beta = 1$. If g has good TF-concentration in the sense of*

$$\|Xg\|_{L^2} \|X\hat{g}\|_{L^2} < \infty,$$

then $\mathcal{G}(g, \alpha, \beta)$ cannot constitute a frame.

Combining Theorems 9 and 10 shows that it is impossible for a Gabor basis to be well localized in both the time domain and the frequency domain. This motivates the study of redundant Gabor systems: As demonstrated by Theorem 10, redundant Gabor frames exist for any $\alpha\beta < 1$.

5 Discrete Gabor Systems

For practical implementations of Gabor analysis, it is essential to develop discrete versions of the theory for Gabor frames.

Gabor Frames in $\ell^2(\mathbb{Z})$

Classically, most signals were considered as “continuous waves.” Indeed, the technology for signal processing originally was of the continuous-time analog type before digital computers came into our everyday life. Nowadays, digital signal processing is used almost exclusively, forcing us to change our function model to a time-discrete one. It is therefore natural to switch from $L^2(\mathbb{R})$ to $\ell^2(\mathbb{Z})$.

Gabor frame theory in $\ell^2(\mathbb{Z})$ is very similar to that in $L^2(\mathbb{R})$ and will therefore only be discussed briefly in this section. The main differences concern the time shifts and frequency shifts. Time shifts are given as multiples of integer translates, i.e.,

$$T_k f(j) = f(j - k) \quad (40)$$

for $k \in \mathbb{Z}$ and $f \in \ell^2(\mathbb{Z})$. A shift parameter $\alpha > 0$ for Gabor frames in $\ell^2(\mathbb{Z})$ can only be given as $\alpha = N \in \mathbb{N}$.

For fixed $L \in \mathbb{N}$ and corresponding to the modulation parameter $1/L$, we define the modulation operator M_ℓ by

$$M_\ell f(j) = e^{2\pi i j \ell / L} f(j) \quad (41)$$

for $\ell \in \mathbb{Z}$. Modulations are now periodic with period L , i.e., $M_{\ell+nL} = M_\ell \quad \forall n \in \mathbb{Z}$, implying that one needs only the modulations M_0, \dots, M_{L-1} .

The *discrete Gabor system* generated by the sequence $g \in \ell^2(\mathbb{Z})$, shift parameters N , and modulation parameter $1/L$ is now the family of sequences $\{g_{k,\ell}\}_{k \in \mathbb{Z}, \ell \in \{L\}}$ where

$$g_{k,\ell}(j) := M_\ell T_{kN} g(j) = e^{2\pi i j \ell / L} g(j - kN)$$

and $\langle L \rangle := \{0, \dots, L-1\} \subseteq \mathbb{Z}$.

If a Gabor system satisfies the frame inequalities for $f \in \ell^2(\mathbb{Z})$, the dual frame is again a Gabor frame built from a dual window $\gamma \in \ell^2(\mathbb{Z})$. The frame expansion takes the form

$$f = \sum_{k=-\infty}^{\infty} \sum_{\ell=0}^{L-1} \langle f, M_{\ell} T_{kN} \gamma \rangle_2 M_{\ell} T_{kN} g \quad \text{for } f \in \ell^2(\mathbb{Z}).$$

Many results and conditions for Gabor systems in $\ell^2(\mathbb{Z})$ can *mutatis mutandis* be taken over from $L^2(\mathbb{R})$, e.g., a necessary condition for the mentioned Gabor system to be a frame for $\ell^2(\mathbb{Z})$ is that $\alpha\beta = N/L \leq 1$.

We note that there is a natural way of constructing Gabor frames in $\ell^2(\mathbb{Z})$ from Gabor frames in $L^2(\mathbb{R})$ through sampling; see the paper [55] by Janssen.

The step from $L^2(\mathbb{R})$ to $\ell^2(\mathbb{Z})$ is the first one toward computational realization of Gabor analysis. However, since in finite time only finitely many elements can be considered, only vectors of finite length and finite sums can be computed. Therefore, we turn to signals of finite length next.

Finite Discrete Periodic Signals

In practice, one has to resort to finite, discrete sequences. We will consider signals $f \in \mathbb{C}^L$, i.e., signals of length $L \in \mathbb{N}$, and write $f = (f(0), \dots, f(L-1))$, defined (for convenience) over the domain $\langle L \rangle := \{0, \dots, L-1\} \subseteq \mathbb{Z}$. This way of indexing suggests in a natural way to view them as functions over the group of unit roots of order L or equivalently as periodic sequences with

$$f(j + nL) := f(j) \quad \forall n \in \mathbb{Z}, j \in \langle L \rangle.$$

The discrete modulation M_{ℓ} defined in (41) can still be applied; the translation T_k defined in (40) can be taken from the range $0 \leq k \leq L-1$.

The *discrete Fourier transform* (DFT) of $f \in \mathbb{C}^L$ is defined as

$$\hat{f}(j) := (\mathcal{F}f)(j) := \sum_{k=0}^{L-1} f(k) e^{-2\pi i j k / L}, \quad j \in \mathbb{Z}_L, \quad (42)$$

which is – up to a constant – a unitary mapping on \mathbb{C}^L . Its inverse is

$$(\mathcal{F}^{-1} f)(j) := \frac{1}{L} \sum_{k=0}^{L-1} f(k) e^{2\pi i j k / L}, \quad j \in \mathbb{Z}_L. \quad (43)$$

The unitary version $\mathbb{C}^L \rightarrow \mathbb{C}^L$ has the factor $1/\sqrt{L}$ in front. A well-known and very efficient implementation of the DFT is the *fast Fourier transform* (FFT).

The discrete STFT of $f \in \mathbb{C}^L$ with respect to the discrete window $g \in \mathbb{C}^L$ is given as

$$(\mathcal{V}_g f)(k, \ell) = \langle f, M_{\ell} T_k g \rangle_{\mathbb{C}^L}.$$

The actions of time and frequency shifts are in more detail given as

$$T_k f = T_k(f(0), \dots, f(L-1)) = (f(-k), \dots, f(L-1-k))$$

and

$$\begin{aligned} M_\ell f &= M_\ell(f(0), \dots, f(L-1)) \\ &= (f(0), e^{2\pi i k \ell / L} f(1), e^{2\pi i 2\ell / L} f(2), \dots, e^{2\pi i (L-1)\ell / L} f(L-1)). \end{aligned}$$

The actions of the TF-shifts can be described as matrices that operate on the vector $f = (f(0), \dots, f(L-1))^T$. The time-shift matrix T_k is given as the permutation matrix with ones on the (periodized) k -th subdiagonal, whereas the modulation matrix has its exponential entries positioned at the main diagonal. It is obvious that the composition of arbitrary TF-shifts need not be commutative, since

$$T_k M_\ell = e^{2\pi i k \ell / L} M_\ell T_k, \quad k, \ell \in \mathbb{Z}_L$$

To get a more compact notation for TF-shifts, we write

$$\pi(\lambda) := \pi(k, \ell) := M_\ell T_k \quad \text{with} \quad \lambda = (k, \ell) \in \mathbb{Z}_L \times \mathbb{Z}_L,$$

where $\mathbb{Z}_L \times \mathbb{Z}_L$ is the discrete time–frequency plane. The commutation relations imply for $\lambda = (r, m)$ and $\mu = (s, n)$

$$\pi(\lambda) \pi(\mu) = \pi(\lambda + \mu) e^{2\pi i rn / L} \tag{44}$$

$$= \pi(\mu) \pi(\lambda) e^{2\pi i (rn - sm) / L}. \tag{45}$$

Frames and Gabor Frames in \mathbb{C}^L

The general frame definitions and results can easily be carried over to the case of finite discrete signals. The conditions for the finite sequence $\{g_0, \dots, g_{N-1}\}$ of elements $g_j \in \mathbb{C}^L$ to be a frame for the finite-dimensional Hilbert space \mathbb{C}^L are that there exist $A, B > 0$ such that

$$A \sum_{k=0}^{L-1} |f(k)|^2 \leq \sum_{j=0}^{N-1} |\langle f, g_j \rangle_{\mathbb{C}^L}|^2 \leq B \sum_{k=0}^{L-1} |f(k)|^2 \quad \forall f \in \mathbb{C}^L$$

or

$$A \|f\|_2^2 \leq \|Cf\|_2^2 \leq B \|f\|_2^2 \quad \forall f \in \mathbb{C}^L,$$

where C is the analysis operator. It is obvious that the sequence $\{g_j\}_{j=1}^{N-1}$ has to span all of \mathbb{C}^L , i.e., $\text{span}\{g_j\}_{j=0}^{N-1} = \mathbb{C}^L$; hence, $N \geq L$ in a Hilbert space with dimension L . Also the converse is true: Every spanning set in \mathbb{C}^L is a frame for \mathbb{C}^L .

The action of the linear analysis operator C on the vector f is given as the vector $Cf = (\langle f, g_j \rangle)_{j=1}^{N-1}$, indicating that its j -th entry is

$$(Cf)_j = \langle f, g_j \rangle = \sum_{k=0}^{L-1} f(k) \overline{g_j(k)}.$$

Letting $g^* = \bar{g}^T$, the matrix form of $C \in \mathbb{C}^{N \times L}$ is

$$C = \begin{pmatrix} g_0^* \\ \vdots \\ g_{N-1}^* \end{pmatrix} = \begin{pmatrix} \overline{g_0(0)} & \cdots & \overline{g_0(L-1)} \\ \vdots & \ddots & \vdots \\ \overline{g_{N-1}(0)} & \cdots & \overline{g_{N-1}(L-1)} \end{pmatrix}.$$

A family $\{g_j\}_{j \in \{N\}}$ is a frame for \mathbb{C}^L if and only if the corresponding analysis operator C has full rank, and every matrix with full rank uniquely represents a frame.

The frame operator $S = C^*C$ becomes an $L \times L$ matrix that also has full rank, and it is therefore invertible. Its condition number equals the ratio between its largest and smallest eigenvalue; letting A denote the largest lower frame bound and B the smallest upper frame bound, this is equal to the ratio B/A .

If we translate the discrete frame expansion

$$f = C^*c = (g_0, \dots, g_{N-1}) \begin{pmatrix} c(0) \\ \vdots \\ c(N-1) \end{pmatrix} = \begin{pmatrix} \sum_{j=0}^{N-1} c(j) g_j(0) \\ \vdots \\ \sum_{j=0}^{N-1} c(j) g_j(L-1) \end{pmatrix}$$

for a given $f \in \mathbb{C}^L$, we see from a linear algebra point of view that we are looking for N unknown coordinates of $c \in \mathbb{C}^N$, using $L \leq N$ equations. Clearly, the solution cannot be unique if $L < N$. Considering that

$$f = SS^{-1}f = C^*C(C^*C)^{-1}f,$$

we see that one solution for c could be given as

$$c = C(C^*C)^{-1}f = (C^*)^\dagger f$$

in terms of the pseudo-inverse of the synthesis operator C^* . This also provides the matrix form of the canonical dual frame that is given by

$$(S^{-1}g_0, \dots, S^{-1}g_{N-1})^* = (S^{-1}C^*)^* = CS^{-1} = (C^*)^\dagger.$$

We will now proceed to the special case of Gabor frames. They are given as a sequence of TF-shifts of a single window function $g \in \mathbb{C}^L$, i.e., a Gabor frame for \mathbb{C}^L is a sequence $\{g_\lambda\}_{\lambda \in \Lambda} := \{\pi(\lambda)g\}_{\lambda \in \Lambda}$ for a certain discrete subset $\Lambda \subseteq \mathbb{Z}_L \times \mathbb{Z}_L$. We write C_g for the Gabor analysis operator to indicate the dependence on g and use it synonymously for the Gabor frame itself. It is clear that it is necessary to have $N \geq L$ elements to span all of \mathbb{C}^L , but this is of course not sufficient for validating a frame. The ratio between N and L is also called the *redundancy* of the frame,

$$\text{red}_C := \frac{N}{L}.$$

For any subgroup $\Lambda \trianglelefteq \mathbb{Z}_L \times \mathbb{Z}_L$, the Gabor frame operator $S_g = C_g^* C_g$ commutes with all TF-shifts $\pi(\lambda)$ for $\lambda \in \Lambda$. This can be shown in a similar way as in Sect. 4. Therefore, the dual frame is once again a Gabor frame, built by the same TF-shifts of a single dual window $\gamma \in \mathbb{C}^L$. The canonical dual frame consists of elements

$$S_g^{-1} \pi(\lambda)g = \pi(\lambda)S_g^{-1}g = \pi(\lambda)\gamma^\circ,$$

and the computation of the canonical dual window reduces to finding a solution for the linear equation

$$S_g \gamma^\circ = g. \quad (46)$$

Therefore, the discrete Gabor expansion of an $f \in \mathbb{C}^L$ is given as

$$f = \sum_{\lambda \in \Lambda} \langle f, \pi(\lambda)g \rangle_{\mathbb{C}^L} \pi(\lambda)\gamma^\circ = \sum_{\lambda \in \Lambda} \langle f, \pi(\lambda)\gamma^\circ \rangle_{\mathbb{C}^L} \pi(\lambda)g,$$

where the Gabor coefficients belong to $\ell^2(\Lambda) \cong \mathbb{C}^N$.

A special case for a lattice is a so-called separable lattice $\Lambda = \alpha\mathbb{Z}_L \times \beta\mathbb{Z}_L$ with $\alpha, \beta \in \mathbb{N}$ being divisors of L . The elements of such a Gabor frame take the form

$$M_{\beta\ell} T_{\alpha k} g(j) = e^{2\pi i \beta\ell j/L} g(j - \alpha k)$$

with $k \in \left\langle \frac{L}{\alpha} \right\rangle$ and $\ell \in \left\langle \frac{L}{\beta} \right\rangle$. The number of elements is $N = \frac{L}{\alpha} \cdot \frac{L}{\beta} = \frac{L^2}{\alpha\beta}$, and it is necessary to have $\frac{L^2}{\alpha\beta} \geq L$ elements to have a frame. The oversampled case is therefore given for $\alpha\beta < L$, and the undersampled case for $\alpha\beta > L$. Critical sampling is given for $\alpha\beta = L$.

6 Image Representation by Gabor Expansion

We have seen that Gabor analysis can be considered as a localized Fourier analysis, where the main design freedom is the choice of (a) the time–frequency lattice and (b) the window function. The type of sampling lattice can be distinguished into a separable or non-separable case, where the first one can be described by the choice of lattice constants $\alpha, \beta > 0$.

It turns out that in the twofold-separable case, i.e., where the d -dimensional analysis window is a tensor product of d one-dimensional functions

$$\mathbf{g} = g_1 \otimes \cdots \otimes g_d, \quad \text{with} \quad g_1 \otimes \cdots \otimes g_d(x_1, \dots, x_d) = g_1(x_1) \dots g_d(x_d),$$

and the sampling lattice Λ is a product $\Lambda = \prod_{i=1}^d \alpha_i \mathbb{Z}_{L_i} \times \prod_{i=1}^d \beta_i \mathbb{Z}_{L_i}$, the dual Gabor window $\boldsymbol{\gamma}$ is given as a product $\boldsymbol{\gamma} = \gamma_1 \otimes \cdots \otimes \gamma_d$ as well. Thus, the computation is reduced to finding the 1D duals γ_i of the 1D atoms g_i with respect to the corresponding 2D time–frequency lattices $\Lambda_i = \alpha_i \mathbb{Z}_{L_i} \times \beta_i \mathbb{Z}_{L_i}$.

Our aim here is to show how the results can be applied to the case of image signals. Gabor expansions of finite discrete 2D signals (i.e., digital images) are similar to those of finite discrete 1D signals, and in a more general notation, there is no difference at all. We are going to describe it next (Fig. 2).

2D Gabor Expansions

The key point for the development of efficient algorithms is to interpret an image of size $L_1 \times L_2$ as a real- or complex-valued function on the additive Abelian group $\mathcal{G} = \mathbb{Z}_{L_1} \times \mathbb{Z}_{L_2}$. The position–frequency space is

$$\mathcal{G} \times \widehat{\mathcal{G}} = \mathbb{Z}_{L_1} \times \mathbb{Z}_{L_2} \times \widehat{\mathbb{Z}_{L_1} \times \mathbb{Z}_{L_2}}.$$

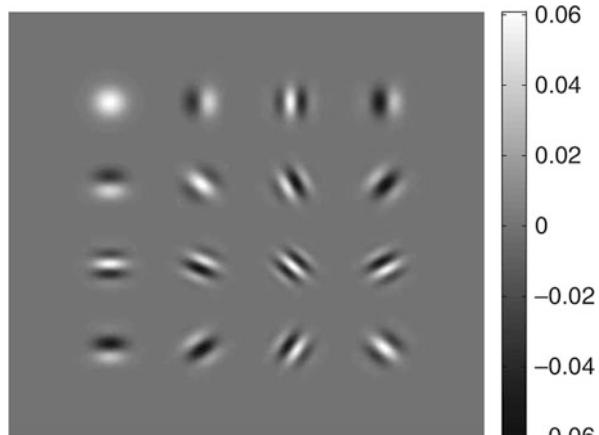

Fig. 2 Typical 2D Gabor atoms

A Gabor system $\mathcal{G}(\mathbf{g}, \Lambda)$ consists of TF-shifts $M_l T_k \mathbf{g}$ of a window $\mathbf{g} \in \mathbb{C}^{L_1 \times L_2}$, where (k, l) are elements of a sampling subgroup $\Lambda \trianglelefteq \mathbb{Z}_{L_1} \times \mathbb{Z}_{L_2} \times \widehat{\mathbb{Z}_{L_1} \times \mathbb{Z}_{L_2}}$. The Gabor coefficients of the image $f \in \mathbb{C}^{L_1 \times L_2}$ are defined as

$$c_{k,l} := \langle f, M_l T_k \mathbf{g} \rangle_F, \quad (k, l) \in \Lambda. \quad (47)$$

Here, we use the subscript F in order to recall that for matrices (this is how images are usually stored), one takes the scalar product and the corresponding norm just as the Euclidian one in \mathbb{C}^N , with $N = L_1 L_2$, usually denoted as Frobenius norm.

The Gabor system is a frame if for $0 < A \leq B < \infty$ one has

$$A \|f\|_F^2 \leq \sum_{(k,l) \in \Lambda} |\langle f, M_l T_k \mathbf{g} \rangle_F|^2 \leq B \|f\|_F^2 \quad \forall f \in \mathbb{C}^{L_1 \times L_2}.$$

For dimensionality reasons, it is clear that the frame condition is only possible if the number of elements in Λ has to be at least equal to the dimension of the signal space, and, therefore, we need $L_1 L_2 \leq |\Lambda| \leq (L_1 L_2)^2$. The redundancy of the Gabor frame is

$$\text{red}_\Lambda := \frac{|\Lambda|}{L_1 L_2} \geq 1.$$

As in the one-dimensional case, the Gabor frame operator

$$S_g f := \sum_{(k,l) \in \Lambda} \langle f, M_l T_k \mathbf{g} \rangle_F M_l T_k \mathbf{g}$$

commutes with TF-shifts determined by Λ , and the minimal resp. maximal eigenvalue are equal to the maximal lower frame bound A and minimal upper frame bound B , respectively.

Again, the dual Gabor frame has a similar structure as the Gabor frame itself: using the same TF-shifts, now applied to a dual window $\gamma \in \mathbb{C}^{L_1 \times L_2}$, one has the expansion

$$f = \sum_{(k,l) \in \Lambda} \langle f, M_l T_k \mathbf{g} \rangle_F M_l T_k \gamma = \sum_{(k,l) \in \Lambda} \langle f, M_l T_k \gamma \rangle_F M_l T_k \mathbf{g}$$

for all $f \in \mathbb{C}^{L_1 \times L_2}$. The existence of the dual atom is guaranteed by the theory of frames, and the calculation of the dual Gabor frame is done by the methods developed there. Recent results guarantee that good TF-concentration of the atom \mathbf{g} implies a similar quality for the dual Gabor atom. Typically, the condition number of the frame operator depends on the geometric density (hence, to some extent, on the redundancy) of the lattice. However it is worth mentioning that even for low redundancy factors, relatively good condition numbers can be expected for

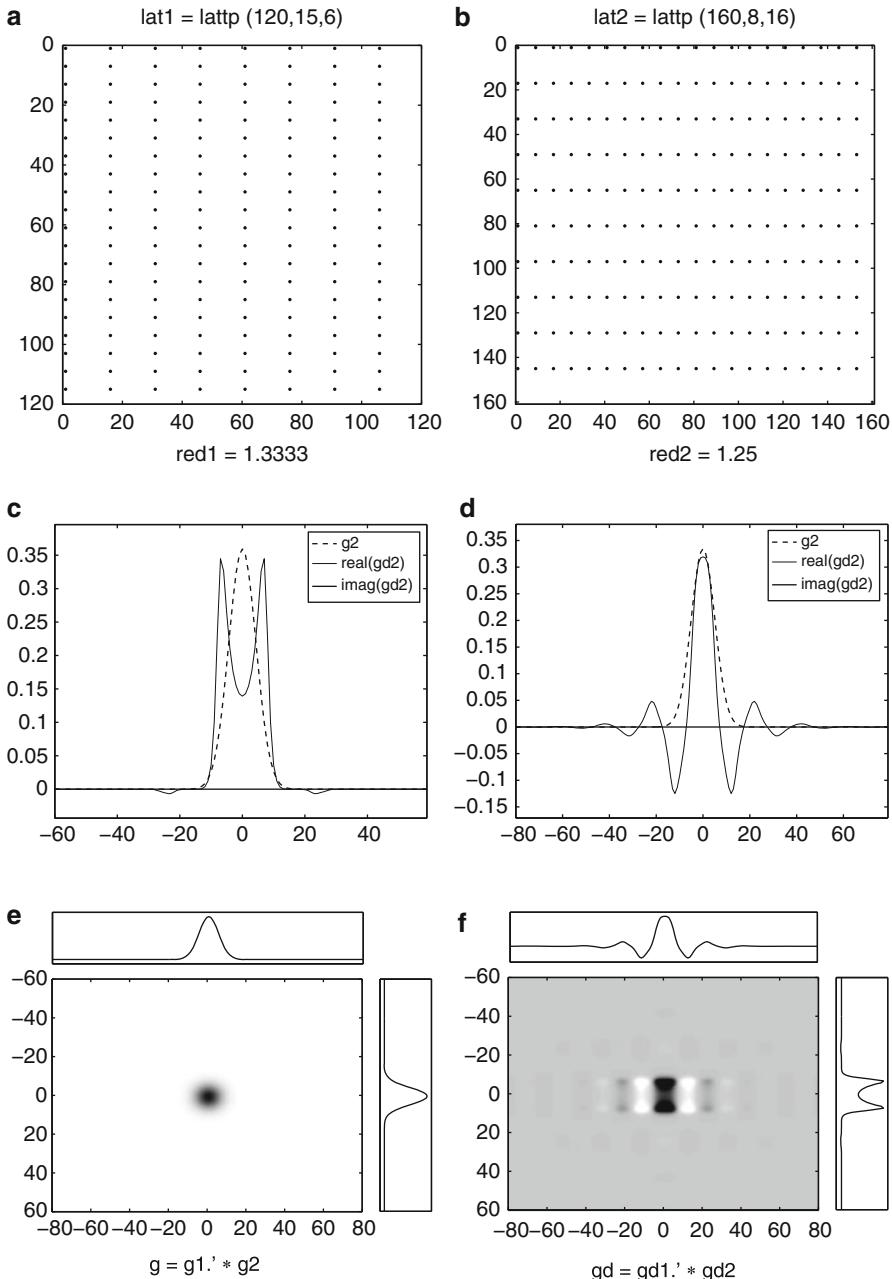

Fig. 3 2D separable window and its dual on a fully separable lattice. (a) Lattice $\Lambda_1 = 15\mathbb{Z}_{120} \times 6\mathbb{Z}_{120}$. (b) Lattice $\Lambda_2 = 8\mathbb{Z}_{160} \times 16\mathbb{Z}_{160}$. (c) Guassian g_1 and its dual γ_1° on Λ_1 . (d) Guassian g_2 and its dual γ_2° on Λ_2 . (e) 2D window $g = g_1 \otimes g_2$. (f) 2D dual window $gd = \gamma_1^\circ \otimes \gamma_2^\circ$ on $\Lambda_1 \times \Lambda_2$

suitably chosen atoms and that perfect reconstruction can be achieved in a stable way in a computationally efficient way even if the discretization of the continuous representation formula is far from satisfactory. Expressed differently, the frame operator may be far away from the identity operator but still stably invertible.

The optimal method and effective computational cost for obtaining Gabor expansions of an image depend on the structure of the 4D sampling lattice. A (fully) separable position–frequency lattice (PF-lattice) can be described by parameters $\alpha_1, \alpha_2, \beta_1, \beta_2 > 0$ such that the constants α_i and β_i describing the position and frequency shift parameters are divisors of L_i , respectively. The set Λ itself is given as

$$\Lambda = \left\{ (\mathbf{k}, \mathbf{l}) = (k_1, k_2, \ell_1, \ell_2) = (\alpha_1 u_1, \alpha_2 u_2, \beta_1 v_1, \beta_2 v_2) \mid u_i \in \left\langle \frac{L_i}{\alpha_i} \right\rangle, v_i \in \left\langle \frac{L_i}{\beta_i} \right\rangle \right\},$$

i.e., it is a product group: $\Lambda = \Lambda_1 \times \Lambda_2$ with $\Lambda_i = \alpha_i \mathbb{Z}_{L_i} \times \beta_i \widehat{\mathbb{Z}_{L_i}}$.

Full separability may be violated in different ways. Assume that $\Lambda = \Lambda_1 \times \Lambda_2$ but with non-separable 2D lattices Λ_i . There are at least two natural choices, whose usefulness may depend on the concrete application. The first and probably more relevant choice is a lattice Λ_1 in position space and Λ_2 , another lattice, in the wave-number domain. For the case of radial symmetric windows, g , one may choose a hexagonal packing in both the spatial and the wave-number domain.

Another flavor of separability comes in by choosing lattices within $\mathbb{C}^{L_1^2}$ and $\mathbb{C}^{L_2^2}$, respectively, describing the first and the second pair of phase space variables.

In passing, we note that there are also fully non-separable subgroups. They will not be discussed here, because it is not clear whether the increased level of technicality is worth the effort.

Separable Atoms on Fully Separable Lattices

In this section, we will show why the case of a 2D separable window $\mathbf{g} = g_1 \otimes g_2$ and a fully separable PF-lattice

$$\Lambda = \Lambda_1 \times \Lambda_2 = \alpha_1 \mathbb{Z}_{L_1} \times \beta_1 \widehat{\mathbb{Z}_{L_1}} \times \alpha_2 \mathbb{Z}_{L_2} \times \beta_2 \widehat{\mathbb{Z}_{L_2}}$$

allows for very efficient Gabor expansions at decent redundancy. It is crucial to observe that in this case, it is enough to find a dual 1D window γ_1 for the 1D window g_1 on the TF-lattice $\Lambda_1 \trianglelefteq \mathbb{Z}_{L_1} \times \widehat{\mathbb{Z}_{L_1}}$ and a dual 1D window γ_2 for the 1D window g_2 on the TF-lattice $\Lambda_2 \trianglelefteq \mathbb{Z}_{L_2} \times \widehat{\mathbb{Z}_{L_2}}$ in order to obtain a dual 2D window $\boldsymbol{\gamma}$ for \mathbf{g} for the lattice Λ , simply as $\boldsymbol{\gamma} := \gamma_1 \otimes \gamma_2$. In short, the 2D Gabor frame on the product space $\mathbb{C}^{L_1} \otimes \mathbb{C}^{L_2}$ is obtained by combining via tensorization the Gabor frames for the signal spaces \mathbb{C}^{L_1} and \mathbb{C}^{L_2} . The abstract result in the background can be summarized as follows:

Lemma 4. If $\{e_m\}_{m \in \langle N_1 \rangle} \subseteq \mathbb{C}^{L_1}$ and $\{f_n\}_{n \in \langle N_2 \rangle} \subseteq \mathbb{C}^{L_2}$ are frames for \mathbb{C}^{L_1} and \mathbb{C}^{L_2} , respectively, then the sequence $\{e_m \otimes f_n\}_{(m,n) \in \langle N_1 \rangle \times \langle N_2 \rangle}$ is a frame for $\mathbb{C}^{L_1} \otimes \mathbb{C}^{L_2}$, where $(g \otimes h)(j, k) := g(j)h(k)$ for $g \in \mathbb{C}^{L_1}$ and $h \in \mathbb{C}^{L_2}$. The joint redundancy is $\frac{N_1 N_2}{L_1 L_2} \geq 1$.

As our image space is a tensor product, we define 2D Gabor windows $\mathbf{g} \in \mathbb{C}^{L_1 \times L_2}$ by $\mathbf{g} = g_1 \otimes g_2$ for $g_i \in \mathbb{C}^{L_i}$. As we are looking at the case where $\Lambda = \Lambda_1 \times \Lambda_2$, we take two Gabor frames $\{g_{k_i, \ell_i}^{(i)}\}_{(k_i, \ell_i) \in \Lambda_i} := \{M_{\ell_i} T_{k_i} g_i\}_{(k_i, \ell_i) \in \Lambda_i} \subseteq \mathbb{C}^{L_i}$ with frame operators S_i and use the set of products $\{g_{k_1, \ell_1}^{(1)} \otimes g_{k_2, \ell_2}^{(2)}\}_{(k, l) \in \Lambda} \subseteq \mathbb{C}^{L_1} \otimes \mathbb{C}^{L_2}$ as frame for the image space with frame operator $S_1 \otimes S_2$.

In order to ensure the fact that this is a 2D Gabor family, one just has to verify that the translation by some element in a product group, applied to a tensor product, can be split into the action of each component to the corresponding factor. Finally, the exponential law implies that a similar splitting is valid for the modulation operators; in fact, plane waves are themselves tensor products of pure frequencies. We thus have altogether

$$M_{\ell_1} T_{k_1} g_1 \otimes M_{\ell_2} T_{k_2} g_2 = M_{(\ell_1, \ell_2)} T_{(k_1, k_2)}(g_1 \otimes g_2) \quad \forall (k_1, k_2), (\ell_1, \ell_2) \in \mathbb{Z}_{L_1} \times \mathbb{Z}_{L_2}$$

as building blocks for our 2D Gabor frame.

The canonical dual of \mathbf{g} with respect to that frame is given as

$$\boldsymbol{\gamma}^\circ = S^{-1} \mathbf{g} = S_1^{-1} g_1 \otimes S_2^{-1} g_2 = \boldsymbol{\gamma}_1^\circ \otimes \boldsymbol{\gamma}_2^\circ.$$

The calculation of 1D dual windows for separable TF-lattices has been efficiently implemented in MATLAB available from the NuHAG webpage (<http://www.univie.ac.at/nuhag-php/mmodule/resp>. by Peter Søndergaard LTFAT (linked with the above page)).

Next, let us check out how we can efficiently obtain the Gabor coefficients of an image $f \in \mathbb{C}^{L_1 \times L_2}$ as given by (47). How does the Gabor matrix C_g look like if it is to be applied to an image $f \in \mathbb{C}^{L_1 \times L_2}$ stored as an $L_1 \times L_2$ -matrix? For sure, f must be seen as a vector in $\mathbb{C}^{L_1 L_2}$ and C_g as an $N_1 N_2 \times L_1 L_2$ -matrix if the number of elements in the 2D frame is $N_1 N_2$ and the coefficient vector is $c \in \mathbb{C}^{N_1 N_2}$. In general, f cannot be assumed to be separable; thus, the only thing simplifying our computation is the structure

$$c_{k,l} = \langle f, M_{\ell_1} T_{k_1} g_1 \otimes M_{\ell_2} T_{k_2} g_2 \rangle_F.$$

If we think of the 1D case with some $f \in \mathbb{C}^L$ and a general frame $\{g_j\}_{j \in \langle N \rangle} \subseteq \mathbb{C}^L$, the coefficients are obtained by

$$c = Cf = (\langle f, g_j \rangle)_{j \in \langle N \rangle} = (c_j)_{j \in \langle N \rangle},$$

and for Gabor frames, $c = (c_{k,\ell})_{(k,\ell) \in \Lambda}$ with $\Lambda \trianglelefteq \mathbb{Z}_L \times \widehat{\mathbb{Z}}_L$ is actually a coefficient matrix in $\mathbb{C}^{L \times L}$ with $|\Lambda| = N \leq L^2$ nonzero entries. But due to simply stacking the vectors $\{g_{k,\ell}\}_{(k,\ell) \in \Lambda} = \{g_j\}_{j \in \{N\}} \subseteq \mathbb{C}^L$ in the coefficient matrix

$$C = \begin{pmatrix} g_0^* \\ \vdots \\ g_{N-1}^* \end{pmatrix} \in \mathbb{C}^{N \times L}, \quad (48)$$

one just gets a “flat” $c \in \mathbb{C}^N$. In our 2D case, the Gabor coefficient even consists of entries $c_{k,l} = c_{k_1,k_2,\ell_1,\ell_2}$. We also want to take the approach by using general frames $\{g_m\}_{m \in \{N_1\}} \subseteq \mathbb{C}^{L_1}$ and $\{h_n\}_{n \in \{N_2\}} \subseteq \mathbb{C}^{L_2}$ and look at the product frame $\{g_m \otimes h_n\}_{m,n}$ for $\mathbb{C}^{L_1} \otimes \mathbb{C}^{L_2}$. We also reduce the coefficient $c = (c(m,n))_{m,n} \in \mathbb{C}^{N_1 N_2}$ to a vector of the form

$$\begin{aligned} c = & (c(0,0), c(0,1), \dots, c(0, N_2 - 1), c(1,0), \dots, c(1, N_2 - 1), \dots \\ & \dots, c(N_1 - 1,0), \dots, c(N_1 - 1, N_2 - 1))^T \end{aligned}$$

such that we can try to find the corresponding coefficient matrix $C \in \mathbb{C}^{N_1 N_2 \times L_1 L_2}$ that can be applied to $f \in \mathbb{C}^{L_1 L_2}$, where

$$f = (f(0,0), \dots, f(0, L_2 - 1), f(1,0), \dots, f(L_1 - 1, L_2 - 1))^T. \quad (49)$$

Now, we can look at the (m,n) -th or, rather, $(mN_2 + n)$ -th entry of the coefficient:

$$\begin{aligned} (Cf)_{m,n} &= c(m,n) = \langle f, g_m \otimes h_n \rangle_{\mathbb{C}^{L_1 L_2}} \\ &= \sum_{u=0}^{L_1-1} \sum_{v=0}^{L_2-1} f(u,v) \overline{(g_m \otimes h_n)(u,v)} \\ &= \sum_{u=0}^{L_1-1} \sum_{v=0}^{L_2-1} f(u,v) \overline{g_m(u) h_n(v)}. \end{aligned} \quad (50)$$

Since we are now able to split the indices u and v for the frame elements, we can consider the order in (49) and get

$$(Cf)_{m,n} = (\overline{g_m(0)} h_n^* \overline{g_m(1)} h_n^* \cdots \overline{g_m(L_1 - 1)} h_n^*) f = (C)_{m,n} f,$$

where $(C)_{m,n}$ is the (m,n) -th or $(mN_2 + n)$ -th line of C and contains $L_1 L_2$ entries. The line vectors $\{h_n^*\}_{n \in \{N_2\}}$ form the frame matrix $C_2 \in \mathbb{C}^{N_2 \times L_2}$ like in (48). If we look at the range of N_2 lines $\{(m,0), \dots, (m, N_2 - 1)\}$, we are able to express the corresponding segment of C as

$$(C)_{m;n \in \{N_2\}} = (\overline{g_m(0)} C_2 \overline{g_m(1)} C_2 \cdots \overline{g_m(L_1 - 1)} C_2).$$

This shows that the frame matrix of the product frame is the Kronecker product of the partial frame operators $C_i \in \mathbb{C}^{N_i \times L_i}$, $i = 1, 2$:

$$C = C_1 \otimes C_2 \in \mathbb{C}^{N_1 N_2 \times L_1 L_2}.$$

Nevertheless, we want to see whether we can compute $c = (C_1 \otimes C_2)f$ in a cheaper way by applying the frame matrices C_i without computing their Kronecker product. As images are not stored as vectors $f \in \mathbb{C}^{L_1 L_2}$ but rather as matrices $f \in \mathbb{C}^{L_1 \times L_2}$ in numerical software like MATLAB or Octave, we could try to get the coefficient $c = (c(m, n))_{m,n} \in \mathbb{C}^{N_1 \times N_2}$ more directly.

Proposition 1. *Given two frames $\{g_m\}_{m \in \{N_1\}} \subseteq \mathbb{C}^{L_1}$ and $\{h_n\}_{n \in \{N_2\}} \subseteq \mathbb{C}^{L_2}$ with frame matrices $C_i \in \mathbb{C}^{N_i \times L_i}$, then the frame coefficient $c \in \mathbb{C}^{N_1 \times N_2}$ for the image $f \in \mathbb{C}^{L_1 \times L_2}$ with respect to the product frame $\{g_m \otimes h_n\}_{(m,n)}$ is given by matrix multiplication as follows:*

$$\begin{aligned} c &= C_1 * f * C_2^T = \\ &\left(\begin{array}{ccc} \overline{g_0(0)} & \cdots & \overline{g_0(L_1-1)} \\ \vdots & \vdots & \vdots \\ \overline{g_{N_1-1}(0)} & \cdots & \overline{g_{N_1-1}(L_1-1)} \end{array} \right) \left(\begin{array}{ccc} f(0,0) & \cdots & f(0,L_2-1) \\ \vdots & \ddots & \vdots \\ f(L_1-1,0) & \cdots & f(L_1-1,L_2-1) \end{array} \right) \left(\begin{array}{ccc} \overline{h_0(0)} & \cdots & \overline{h_{N_2-1}(0)} \\ \vdots & \ddots & \vdots \\ \overline{h_0(L_2-1)} & \cdots & \overline{h_{N_2-1}(L_2-1)} \end{array} \right) \end{aligned} \quad (51)$$

Note that similar thoughts reveal the fact that the 2D DFT of an image $f \in \mathbb{C}^{L_1 \times L_2}$ can be obtained by the matrix multiplication

$$\mathcal{F}f = F_{L_1} * f * F_{L_2} \in \mathbb{C}^{L_1 \times L_2}, \quad (52)$$

where $F_{L_i} \in \mathbb{C}^{L_i \times L_i}$ are the (symmetric) Fourier matrices of order L_i .

If the synthesis operation is to be done by $f = C^*c$ for given $f \in \mathbb{C}^L$ and a frame $C \in \mathbb{C}^{N \times L}$, one solution is obtained by $c = (C^*)^\dagger f$ with a right inverse for C^* such that $I_L = SS^{-1} = C^*C(C^*C)^{-1} = C^*(C^*)^\dagger$, making the pseudo-inverse of the synthesis operator the matching analysis operator. $C^*(C^*)^\dagger$ is the orthogonal projection onto the range of the desired synthesis operator. One notices that due to $(C^*)^\dagger = (C^\dagger)^*$, we already have $I_L = (C^\dagger C)^* = C^\dagger C$, the orthogonal projection onto the range of $\text{ran } C^\dagger$. Thus, the role of the operators can be interchanged, meaning that C^\dagger is the matching synthesis operator for the analysis operator C .

If we again interpret signals $f \in \mathbb{C}^{L_1} \otimes \mathbb{C}^{L_2}$ as $f \in \mathbb{C}^{L_1 L_2}$ and take a product frame $\{g_m \otimes h_n\}_{m,n}$ with analysis operator $C_1 \otimes C_2$, we get $I_{L_1 L_2} = C^\dagger(C_1 \otimes C_2)$ and $I_{L_1 L_2} = I_{L_1} \otimes I_{L_2} = (C_1^\dagger C_1) \otimes (C_2^\dagger C_2)$, yielding that the matching synthesis operator is $C^\dagger = C_1^\dagger \otimes C_2^\dagger$. Due to Proposition 1, we can thus reconstruct $f \in \mathbb{C}^{L_1 \times L_2}$ by

$$\mathbf{f} = \left(C_1^\dagger C_1 \right) \mathbf{f} \left(C_2^\dagger C_2 \right)^T = C_1^\dagger \mathbf{c} \left(C_2^\dagger \right)^T \quad (53)$$

because $\mathbf{c} = C_1 \mathbf{f} C_2^T$ is in the range of the corresponding analysis operator.

These results were derived for products of general frames and therefore also hold for products of Gabor frames. Given two Gabor frames $\{M_{\ell_i} T_{k_i} g_i\}$ on subgroups $\Lambda_i \trianglelefteq \mathbb{Z}_{L_i} \times \widehat{\mathbb{Z}_{L_i}}$ and with analysis operators C_{g_i} , we get their synthesis operators by $C_{g_i}^\dagger = C_{\gamma_i^\circ}^*$ with $\gamma_i^\circ := S_{g_i}^{-1} g_i$. The product of those two frames is the Gabor frame $\{M_l T_k \mathbf{g}\}_{(k,l) \in \Lambda_1 \times \Lambda_2}$ consisting of PF-shifts of the window $\mathbf{g} = g_1 \otimes g_2 \in \mathbb{C}^{L_1 \times L_2}$ on the lattice $\Lambda = \Lambda_1 \times \Lambda_2$. The dual window to \mathbf{g} is given by $\boldsymbol{\gamma}^\circ := \gamma_1^\circ \otimes \gamma_2^\circ$. Due to (51) and (53), the 2D Gabor analysis operation for the image $\mathbf{f} \in \mathbb{C}^{L_1 \times L_2}$ is obtained by

$$\mathbf{c} = C_{g_1} \mathbf{f} C_{g_2}^T \quad (54)$$

and a possible reconstructing synthesis operation by

$$\mathbf{f} = C_{\gamma_1^\circ}^* \mathbf{c} \left(C_{\gamma_2^\circ}^* \right)^T = \overline{C_{\gamma_1^\circ}}^T \mathbf{c} \overline{C_{\gamma_2^\circ}}, \quad (55)$$

yielding that it is enough to obtain the two duals γ_i° . Figure 3 shows the construction and look of the separable dual 2D window of a 2D Gaussian window on a fully separable PF-lattice.

Efficient Gabor Expansion by Sampled STFT

In the case of a separable 2D atom and a fully separable PF-lattice, we can make use of any fast 1D STFT implementation (cf. the NuHAG software page or the LTFAT by Peter Søndergaard) to obtain the Gabor analysis coefficient $\mathbf{c} = C_{g_1} \mathbf{f} C_{g_2}^T$ and the Gabor reconstruction $\mathbf{f} = C_{\gamma_1^\circ}^* \mathbf{c} \left(C_{\gamma_2^\circ}^* \right)^T$ for a given image $\mathbf{f} \in \mathbb{C}^{L_1 \times L_2}$. These matrix multiplications from the left and right could still be rather expensive, so one can obtain the set of Gabor coefficients \mathbf{c} by calculating a finite number of sampled 1D STFTs, with the sampling points determined by shift parameters α_1, α_2 and modulation parameters β_1, β_2 .

If we remember the 1D case, the Gabor frame C_g for \mathbb{C}^L by a window $g \in \mathbb{C}^L$ involves a separable lattice $\Lambda = \alpha \mathbb{Z}_L \times \beta \mathbb{Z}_L$ with $|\Lambda| = N = \frac{L^2}{\alpha\beta}$, and for arbitrary $f \in \mathbb{C}^L$, we have

$$(C_g f)_{k,\ell} = c_{k,\ell} = \langle f, M_{\beta\ell} T_{\alpha k} g \rangle_{\mathbb{C}^L} = \sum_{u=0}^{L-1} f(u) \overline{M_{\beta\ell} T_{\alpha k} g(u)} = \mathcal{V}_g f(\alpha k, \beta \ell)$$

for $k \in \left\langle \frac{L}{\alpha} \right\rangle$ and $\ell \in \left\langle \frac{L}{\beta} \right\rangle$, which can be viewed as a vector of length N if the frame is seen as a matrix $C_g \in \mathbb{C}^{N \times L}$. In the 2D case, if we consider $f = (f_0, \dots, f_{L_2-1})^T$, then $b_j = C_{g_1} f_j$ acts as the Gabor analysis operation for all $f_j \in \mathbb{C}^{L_1}$ with coefficients $b_j \in \mathbb{C}^{N_1}$ for all $j \in \langle L_2 \rangle$. The operation $\mathbf{b} = C_{g_1} f$ collects these in a matrix $\mathbf{b} = (b_0, \dots, b_{L_2-1})$. If we express its k -th line as a line vector $q_k^T := (\mathbf{b})_k = (b_0(k), \dots, b_{L_2-1}(k))$, we get

$$C_{g_1} f = \mathbf{b} = \mathbf{q}^T = \begin{pmatrix} q_0^T \\ \vdots \\ q_{N_1-1}^T \end{pmatrix} \in \mathbb{C}^{N_1 \times L_2}.$$

The complete 2D Gabor analysis operation is thus $\mathbf{c} = \mathbf{q}^T C_{g_2}^T = (C_{g_2} \mathbf{q})^T$, and this is just the Gabor analysis operation of the vectors $q_k \in \mathbb{C}^{L_2}$ for $k \in \langle N_1 \rangle$ with respect to the Gabor frame C_{g_2} .

All in all, the 2D Gabor analysis operation in the twofold-separable case can be obtained by first computing L_2 1D STFT-operations of output length N_1 using the parameters α_1, β_1 followed by N_1 1D STFT-operations of output length N_2 using the parameters α_2, β_2 .

As the reconstruction (2D Gabor expansion) is just a multiplication of the dual Gabor matrices $C_{g_i}^*$ from the left and right of \mathbf{c} , this task can be seen as a sequence of 1D Gabor expansions and can thus be obtained by a sequence of inverse 1D STFT-operations as well. There are again two ways: The first one is to do N_1 inverse operations with output length L_2 using the parameters α_2, β_2 followed by N_2 operations with output length L_1 using α_1, β_1 . The second way exchanges L_i and N_i correspondingly.

Visualizing a Sampled STFT of an Image

So far, we have visualized the full STFT of an image as a large block image, where either each block fully represents the frequency domain and the position of the blocks the position domain, or vice versa. As such an image would become rather huge, we prefer to visualize only a sampled STFT instead. In the case of a separable atom, this can be realized by obtaining the discrete 2D Gabor transform by (54), where the two involved matrices C_{g_i} consider a special order of their Gabor frame elements $M_{\ell_i} T_{k_i} g_i$.

For a Gabor frame $\{M_\ell T_k g\}_{(k,\ell) \in \Lambda} \subseteq \mathbb{C}^L$ given by a 1D window $g \in \mathbb{C}^L$ on a separable lattice $\Lambda = \alpha \mathbb{Z}_L \times \beta \mathbb{Z}_L$ with $N = |\Lambda| = \frac{L^2}{\alpha\beta}$ elements, we say that the Gabor frame elements are ordered by *modulation priority* if the frame matrix $C_g \in \mathbb{C}^{N \times L}$ is of the form

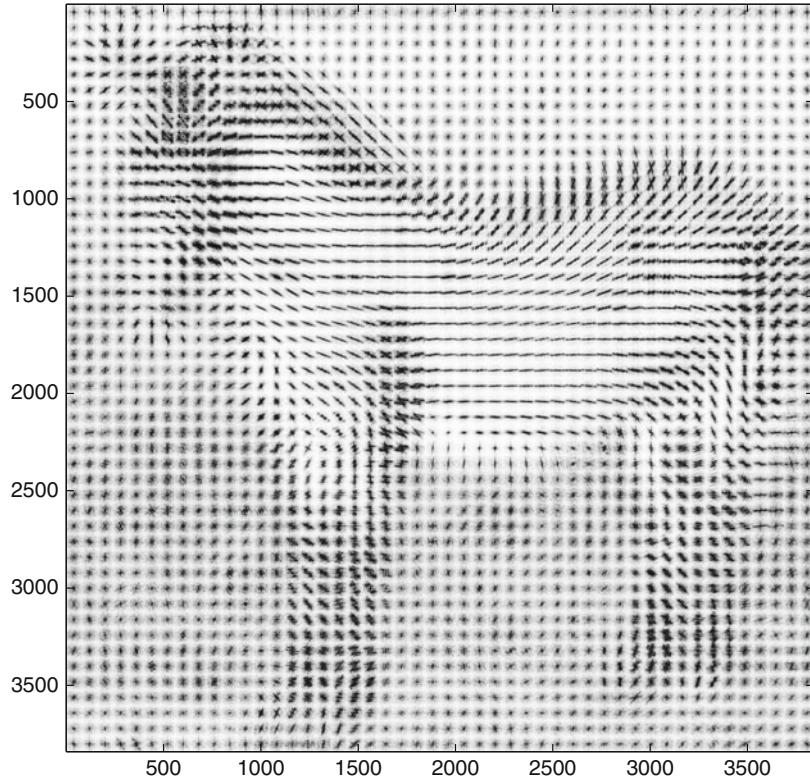

Fig. 4 Discrete 2D Gabor transform of a zebra, modulation priority. The picture shows the absolute values of $c = C_g f C_g^T$, where g is the 1D Gaussian of length 480 and C_g is the Gabor matrix for the lattice $\Lambda = 10\mathbb{Z}_{480} \times 6\mathbb{Z}_{480}$, whose entries were ordered with modulation priority

$$C_g = \begin{pmatrix} M_0 T_0 g^* \\ M_\beta T_0 g^* \\ \vdots \\ M_{L/\beta-1} T_0 g^* \\ M_0 T_1 g^* \\ \vdots \\ M_{L/\beta-1} T_1 g^* \\ \vdots \\ M_{L/\beta-1} T_{L/\alpha-1} g^* \end{pmatrix}$$

We call it ordered by *translation priority* if it is of the form

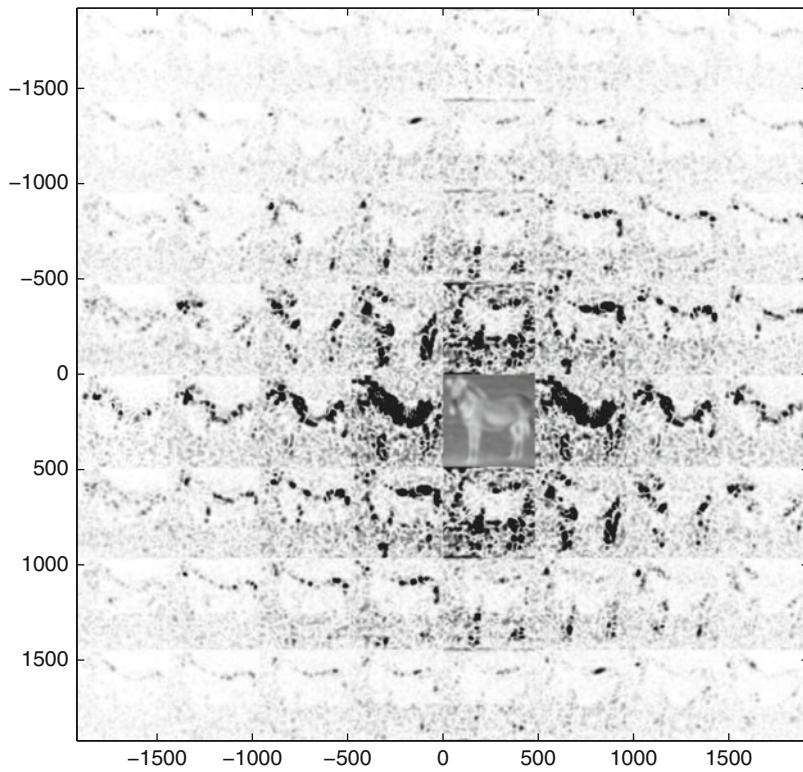

Fig. 5 Discrete 2D Gabor transform of a zebra, translation priority. The picture shows the absolute values of $\tilde{c} = \tilde{C}_g f \tilde{C}_g^T$, where g is the 1D Gaussian of length 480 and \tilde{C}_g is the Gabor matrix for the lattice $\Lambda = \mathbb{Z}_{480} \times 60\mathbb{Z}_{480}$, whose entries were ordered with translation priority. The Gaussian blurred image in the middle has been scaled into the colormap individually

$$\tilde{C}_g = \begin{pmatrix} M_0 T_0 g^* \\ M_0 T_\alpha g^* \\ \vdots \\ M_0 T_{L/\alpha-1} g^* \\ M_1 T_0 g^* \\ \vdots \\ M_1 T_{L/\alpha-1} g^* \\ \vdots \\ M_{L/\beta-1} T_{L/\alpha-1} g^* \end{pmatrix}$$

Obviously, $\tilde{C}_g = P C_g$ for a suitable permutation matrix $P \in \mathbb{C}^{N \times N}$.

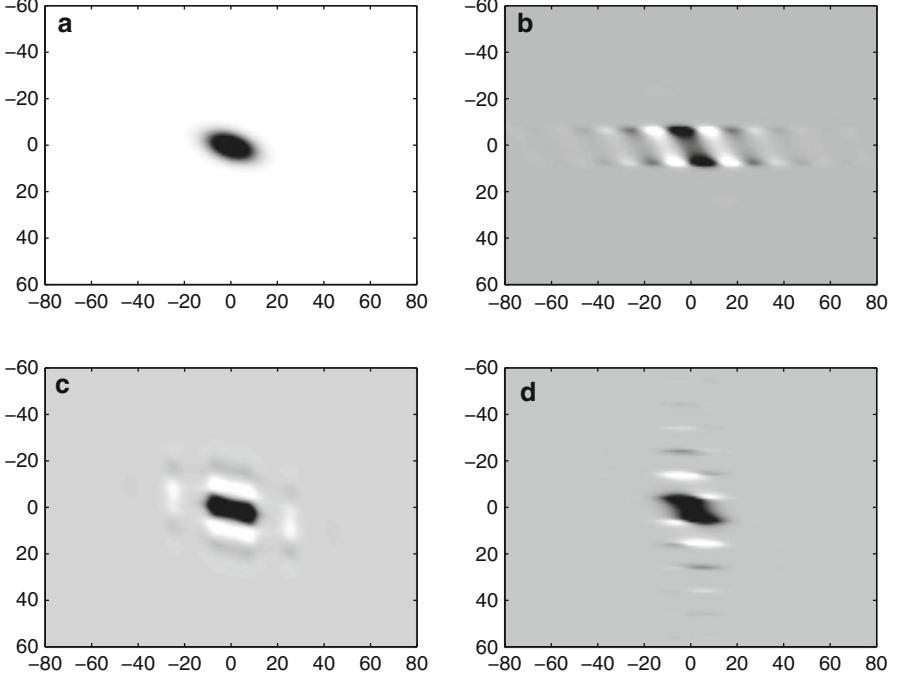

Fig. 6 A non-separable window and some duals on fully separable lattices. The lattices Λ_i are that of Fig. 3. The lattices Λ'_i exchange α_i with β_i . The last lattice has vertical redundancy 1 and horizontal redundancy 6.4. (a) Non-separable window g . (b) Dual γ° on $\Lambda_1 \times \Lambda_2$. (c) Dual on $\Lambda'_1 \times \Lambda'_2$ with exchange parameters (d) Dual at vertically critical redundancy

If we take an image $f \in \mathbb{C}^{L_1 \times L_2}$ and two Gabor frames $\{M_{\ell_i} T_{k_i} g_i\}, (k_i, \ell_i) \in \Lambda_i$, on separable lattices $\Lambda_i = \alpha_i \mathbb{Z}_{L_i} \times \beta_i \mathbb{Z}_{L_i}$, we can take their product Gabor frame for $\mathbb{C}^{L_1 \times L_2}$ and obtain the mentioned two possibilities for an STFT block image by either considering the frame matrices C_{g_i} or \tilde{C}_{g_i} . The matrices C_{g_i} are ordered by modulation priority, and if $c = C_{g_1} f C_{g_2}^T$, then c consists of $\frac{L_1}{\beta_1} \times \frac{L_2}{\beta_2}$ -blocks

$$X_{k_1, k_2} := (\langle f, M_{(\ell_1, \ell_2)} T_{(k_1, k_2)} g \rangle)_{\ell_1, \ell_2}$$

such that

$$c = \begin{pmatrix} X_{0,0} & \cdots & X_{0, L_2/\alpha_2 - 1} \\ \vdots & \cdots & \vdots \\ X_{L_1/\alpha_1 - 1, 0} & \cdots & X_{L_1/\alpha_1 - 1, L_2/\alpha_2 - 1} \end{pmatrix}.$$

The blocks X_{k_1, k_2} equal the part $(\mathcal{V}_g f(k_1, k_2, \ell_1, \ell_2))_{\ell_1, \ell_2}$ of the sampled STFT and thus contain the whole (sampled) set of frequency shifts for a certain position shift

of the window $\mathbf{g} = g_1 \otimes g_2$. The (sampled) frequency domain is therefore spanned in each of the blocks X_{k_1, k_2} , and their positions in \mathbf{c} span the (sampled) position domain. Each X_{k_1, k_2} could be seen as a sampled “Fourier image” of the discrete Fourier transform $\widehat{\mathbf{f}} \cdot T_{(k_1, k_2)} \bar{\mathbf{g}}$.

In the other case, where we have $\tilde{\mathbf{c}} = \tilde{C}_{g_1} \mathbf{f} \tilde{C}_{g_2}^T$, the Gabor coefficient consists of $\frac{L_1}{\alpha_1} \times \frac{L_2}{\alpha_2}$ -blocks

$$Y_{\ell_1, \ell_2} := (\langle \mathbf{f}, M_{(\ell_1, \ell_2)} T_{(k_1, k_2)} \mathbf{g} \rangle)_{k_1, k_2}$$

such that

$$\tilde{\mathbf{c}} = \begin{pmatrix} Y_{0,0} & \cdots & Y_{0, L_2/\beta_2 - 1} \\ \vdots & \cdots & \cdots \\ Y_{L_1/\beta_1 - 1, 0} & \cdots & Y_{L_1/\beta_1 - 1, L_2/\beta_2 - 1} \end{pmatrix}.$$

Here, the blocks Y_{ℓ_1, ℓ_2} equal the part $(\mathcal{V}_g f(k_1, k_2, \ell_1, \ell_2))_{k_1, k_2}$ of the sampled STFT and contain the corresponding set of position shifts for a certain frequency shift of \mathbf{g} . The position domain is spanned in each of the blocks Y_{ℓ_1, ℓ_2} , and their positions in $\tilde{\mathbf{c}}$ span the frequency domain.

Figures 4 and 5 show examples for both cases using the zebra test image. As it is a square image, we can take $g_1 = g_2$ and thus $C_{g_1} = C_{g_2}$. The first figure composes the Gabor transform coefficient matrix as blocks of Fourier images. Clearly, the overall image reflects the shape of the zebra. The “pixels” of that image contain “Fourier jets” that are orthogonal to the edges at the corresponding position in the original zebra image. Thus, the “jets” are oriented horizontally where, e.g., the body of the animal shows vertical line patterns. The second figure shows blocks of zebra images that have been convolved with modulated Gaussians. The absolute values show the peaks as black spots within the respective image blocks.

Non-separable Atoms on Fully Separable Lattices

Non-separable windows are those that can only be defined considering the complete image domain $\mathbb{Z}_{L_1} \times \mathbb{Z}_{L_2}$, and not \mathbb{Z}_{L_1} and \mathbb{Z}_{L_2} separately. These cannot be described as a tensor product $g_1 \otimes g_2$ with $g_i \in \mathbb{C}^{L_i}$ anymore, but only generally as $\mathbf{g} \in \mathbb{C}^{L_1 \times L_2}$. With this case, we lose the ability to consider two (1D) frames independently for each dimension, and we cannot apply two frame matrices independently to an image. It appears that we have to stick to the known factorizations of Gabor matrices on (fully) separable lattices with parameters α_i, β_i , and we thus cannot make use of the equidistantly sampled 1D STFT. However, under certain conditions, this case can be completely referred to a 1D case, as we will see below.

Figure 6 indicates an important thing about the redundancy. Sure, a redundancy of $\frac{|\Lambda|}{L_1 L_2} \geq 1$ is only a necessary condition, but it seems to be important to consider

the redundancy in each dimension. The involved window is a 2D Gaussian window $\mathbf{g} \in \mathbb{C}^{120 \times 160}$, stretched vertically by $\frac{4}{3}$, shrunken horizontally by $\frac{3}{4}$, then rotated (counter-clockwise) by $\frac{3}{8}\pi$. Figure 6d shows its dual on a fully separable 4D PF-lattice with overall redundancy 6.4. It was computed in the work of P. Prinz which makes use of the Gabor matrix factorizations [66]. But although the redundancy value gives the impression to be safe, it hides the fact that the involved lattice is actually $\Lambda = 10\mathbb{Z}_{120} \times 12\mathbb{Z}_{120} \times 5\mathbb{Z}_{160} \times 5\mathbb{Z}_{160}$, yielding the redundancy as $\frac{120}{10 \cdot 12} \cdot \frac{160}{5 \cdot 5} = 1 \cdot 6.4$. This shows that the vertical redundancy is critical, and the dual has a bad localization in the vertical dimension. It is therefore necessary to make sure that the redundancy is reasonably distributed among the dimensions. In this sense, fully separable 4D lattices can always be considered as a product of two 2D TF-lattices with independent redundancies, no matter what structure the 2D window possesses.

7 Historical Notes and Hint to the Literature

Nonorthogonal expansions as proposed by D. Gabor in his seminal work [45] of 1946 were ignored for a long time by the mathematical community. The question to which extent the claims made by D. Gabor could be realized in the context of generalized functions, was carefully analyzed by A.J.E.M. Janssen in 1981 [53]. Around the same time, M. Bastiaans explored the connections between Gabor theory and optics [3–7]. In the critically sampled case, he suggested to use the biorthogonal function γ in order to calculate Gabor coefficients. The connection to the biorthogonality relations for dual Gabor windows was pointed out in two papers in 1995 [26, 54] and brought to the multidimensional case in [39, 40, 69].

Two early papers in the field, authored by J. Daugman and Y.Y. Zeevi and his coauthors, established a connection between a 2D version of Gabor analysis and early vision [27, 46, 64, 83, 84]. Various subsequent papers emphasized that a Gabor family is not an orthogonal system and that, therefore, computation of coefficients has to be computationally expensive. We know by now that while linear independence is indeed lost, the rich covariance structure of the Gabor problems actually leads to efficient algorithms.

The mathematical theory of Gabor expansions was promoted in various directions in the last two decades. Although a lot of Gabor analysis is naturally valid in the context of general locally compact Abelian groups, a substantial body of references only covers the standard case, for 1D signals and separable lattices.

Of course, the theory underlying image processing is formally covered by the theory of Gabor analysis over finite Abelian groups as described in [40]. Some basic facts in the general LCA context are given in [50], and some further results generalize to this setting, applying standard facts from abstract harmonic analysis [44].

Multidimensional, non-separable lattices are discussed in [41], and [38] deals with situations where the isomorphism of 2D groups with certain 1D groups helps to use 1D Gabor code to calculate 2D dual Gabor windows.

Numerical methods for Gabor representations have been discussed since the first and pioneering papers (see, e.g., [2, 46, 84]). There are also hints on how to perform parallel versions of the Gabor transform [30]. A partial comparison of algorithms is in [67] and in the toolbox of P. Søndergaard. It can be expected to provide further implementations and more details concerning numerical issues in the near future.

One of the most natural applications (based on the interpretation of Gabor coefficients) are *space-variant filters*. Given the Gabor transform, one can multiply them with a 0/1 function over the coefficient domain, passing through, e.g., higher frequencies within regions of interest, whereas otherwise, only low frequencies are stored, thus representing foveated images (with somewhat blurred parts outside the region of interest).

Since different textures in different regions of an image might also be detected using Gabor coefficients, natural applications are texture segmentation (see e.g., [31, 77]), image restoration [19, 82], and image fusion [68]. The extraction of directional features in images has been considered recently in [48]. Other contributions to texture analysis are found in [49]. Other applications are pattern recognition [76], face identification as described in [70], and face detection [52].

Some of the material presented in this paper can be found in an extended form in the master thesis of the last named author [63].

Abstract

This chapter describes a selection of models that have been used to build Riemannian spaces of shapes. It starts with a discussion of the finite-dimensional

space of point sets (or landmarks) and then provides an introduction to the more challenging issue of building spaces of shapes represented as plane curves. A special attention is devoted to constructions involving quotient spaces, since they are involved in the definition of shape spaces via the action of groups of diffeomorphisms and in the process of identifying shapes that can be related by a Euclidean transformation. The resulting structure is first described via the geometric concept of a Riemannian submersion and then reinterpreted in a Hamiltonian and optimal control framework, via momentum maps. These developments are followed by the description of algorithms and illustrated by numerical experiments.

1 Introduction

The analysis of shapes as mathematical objects has constituted a significant area of interest in the past few decades motivated by the development of image acquisition methods and segmentation algorithms, in which shapes could be extracted as isolated objects. Shape analysis is a framework, in which a given shape is considered as a single (typically infinite dimensional) variable, requiring the development of new techniques for their representation and statistical interpretation. This framework has found applications in several fields, including object recognition in computer vision and computational anatomy.

The example in Fig. 1 can help in framing the kind of problems that are being addressed and serve as a motivation. These shapes are fairly easily recognizable for the human eye. They do however exhibit large variations, and a description in simple terms of how they vary and of how they can be compared is a much harder task. It is clear that a naive representation, like a list of points, cannot be used directly, because the discretized curves may have different numbers of points, and no correspondence is available between them. Coming up with quantitative and reliable descriptors that can be, for example, analyzed in a rigorous statistical study is, however, of main importance for the many applications, and the goal of this chapter is to provide a framework in which such a task can be performed in a reliable well-posed way.

2 Background

During the past decades, several essential contributions have been made, using rigorous mathematical concepts and methods, to address this problem and others of similar nature. This collection of efforts has progressively defined a new discipline that can be called *mathematical shape theory*.

Probably, the first milestone in the development of the theory is Kendall's construction of a space of shapes, defined as a quotient of the space of disjoint points in \mathbb{R}^d by the action of translation, rotation, and scaling [40]. Kendall's theory has been the starting point of a huge literature [15, 41, 64] and allowed for new approaches for studying datasets in which the group of similitudes was a nuisance

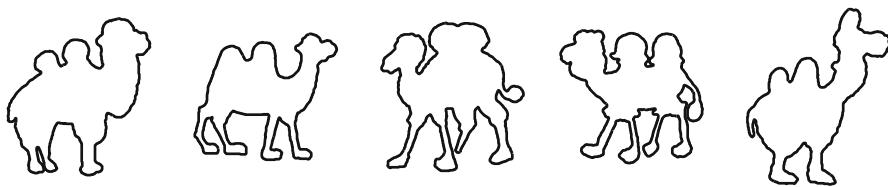

Fig. 1 Examples of shapes (Taken from the MPEG-7 shape database)

factor (for such data as human skulls, prehistoric jewelry, etc.). One can argue that, as a candidate for a shape space, Kendall's model suffers from two main limitations. First, it relies on the representation of a shape by a finite number of labeled points, or *landmarks*. These landmarks need to have been identified on each shape, and shapes with different numbers of landmarks belong to different spaces. From a practical point of view, landmarks are most of the time manually selected, the indexation of large datasets being time consuming and prone to user-dependent errors. The second limitation is that the metric on shapes is obtained by quotienting out the standard Euclidean metric on point sets, using a standard “Riemannian submersion” process that we will discuss later in this chapter. The Euclidean metric ignores a desirable property of shape comparison, which states that shapes that are smooth deformations of one another should be considered more similar than those for which the points in correspondence are randomly displaced, even if the total point displacement is the same.

This important issue, related to smoothness, was partially addressed by another important contribution to the theory, which is Bookstein's use of the thin plate splines originally developed by Duchon and Meinguet [10, 16, 51]. Splines interpolate between *landmark displacements* to obtain a smooth, dense, displacement field (or vector field). It can be addressed with the generic point of view of *reproducing kernel Hilbert spaces* [7, 77], which will also be reviewed later in this chapter.

This work had a tremendous influence on shape analysis based on landmarks, in particular for medical studies. It suffers, however, from two major drawbacks. The first one is that the interpolated displacement can be ambiguous, with several points moved to the same position. This is an important limitation, since inferring unobserved correspondences is one of the objectives of this method. The second drawback, in relation with the subject of this chapter, is that the linear construction associated to splines fails to provide a metric structure on the nonlinear space of shapes. The spline deformation energy provides in fact a first-order approximation of a nonconstant Riemannian metric on point sets, which provides an interesting version of a manifold of landmarks, as introduced in [11, 36, 72].

After point sets, plane curves are certainly the shape representation in which most significant advances have been observed over the last few years. Several important metrics have been discussed in publications like [37, 42, 43, 52, 79–81]. They have been cataloged, among many other metrics, in a quasencyclopedia effort by D. Mumford and P. Michor [55]. We will return to some of these metrics in section “Spaces of Plane Curves.”

Grenander's theory of deformable templates [27] is another seminal work for shape spaces. In a nutshell, Grenander's basic idea, which can be traced back to D'Arcy Thomson's work on biological shapes in the beginning of last century [65], is to introduce suitable group actions as generative engines for visual object models, with the natural use of the group of diffeomorphisms for shapes. While the first developments in this context use linear approximations of diffeomorphisms [2, 28, 29], a first computational breakthrough in the nonlinear estimation of diffeomorphisms was provided in [12] with the introduction of flows associated to ordinary differential equations. This idea was further developed in a fully metric approach of diffeomorphisms and shape spaces, in a framework that was introduced in [17, 66, 67] and further developed in [8, 11, 35, 36, 57, 58]. The approach also led to important developments in medical imaging, notably via the establishment of a new discipline, called computational anatomy, dedicated to the study of datasets of anatomical shapes [30, 60, 61, 78].

3 Mathematical Modeling and Analysis

Some Notation

The following notation will be used in this chapter. The Euclidean norm of vectors $a \in \mathbb{R}^d$ will be denoted using single bars and the dot product between a and b as $a \cdot b$ or explicitly as $a^T b$, where a^T is the transpose of a . So

$$|a|^2 = a \cdot a = a^T a$$

for $a \in \mathbb{R}^d$.

Other norms (either Riemannian metrics or norms on infinite-dimensional spaces) will be denoted with double bars, generally with a subscript indicating the corresponding space, or relevant point in the manifold. We will use angles for the corresponding inner product, with the same index, so that, for a Hilbert space V , the notation for the inner product between V and w in V will be $\langle v, w \rangle_V$ with

$$\|v\|_V^2 = \langle v, v \rangle_V.$$

When f is a function that depends on a variable t , its derivative with respect to t computed at some point t_0 will be denoted either $\partial_t f(t_0)$ or $\dot{f}_t(t_0)$, depending on which form gives the most readable formula. Primes are never used to denote derivative, that is, f' is not the derivative of f , but just another function. The differential at x of a function of several variables F is denoted $DF(x)$. If F is scalar valued, its gradient is denoted $\nabla F(x)$. The divergence of a vector field $v : \mathbb{R}^d \rightarrow \mathbb{R}^d$ is denoted $\nabla \cdot v$.

If M is a differential manifold, the tangent space to M at $x \in M$ will be denoted $T_x M$ and its cotangent space (dual of the former) $T_x^* M$. The tangent bundle (disjoint union of the tangent spaces) is denoted TM and the cotangent bundle $T^* M$.

When μ is a linear form on a vector space V (i.e., a scalar-valued linear transformation), the natural pairing between μ and $v \in V$ will be denoted $(\mu|v)$, that is,

$$(\mu|v) = \mu(v).$$

A Riemannian Manifold of Deformable Landmarks

Interpolating Splines and RKHSs

Let us start with some preliminary facts on Hilbert spaces of functions or vector fields and their relation with interpolating splines. A Hilbert space is a possibly infinite-dimensional vector space equipped with an inner product which induces a complete topology. Letting V be such a space, with norm and inner product, respectively, denoted $\|\cdot\|_V$ and $\langle \cdot, \cdot \rangle_V$, a linear form on V is a continuous linear transformation $\mu : V \mapsto \mathbb{R}$. The set of such transformations is called the dual space of V and denoted V^* . An element μ in V^* being continuous by definition, there exists a constant C such that

$$\forall v \in V, \mu(v) \leq C \|v\|_V.$$

The smaller number C for which this assertion is true is called the operator norm of μ and denoted $\|\mu\|_{V^*}$.

Instead of $\mu(v)$ like above, the notation $(\mu|v)$ will be used to represent the result of μ applied to V . The Riesz representation theorem implies that V^* is in one-to-one correspondence with V , so that for any μ in V^* , there exists a unique element $v = K_V \mu \in V$ such that, for any $w \in V$,

$$(\mu|w) = \langle K_V \mu, w \rangle_V;$$

K_V and its inverse $L_V = K_V^{-1}$ are called the duality operators of V . They provide an isometric identification between V and V^* , with, in particular, $\|\mu\|_{V^*}^2 = (\mu|K_V \mu) = \|K_V \mu\|_V^2$.

Of particular interest is the case when V is a space of vector fields in d dimensions, that is, of functions $v : \mathbb{R}^d \rightarrow \mathbb{R}^d$ (or from $\Omega \rightarrow \mathbb{R}^d$ where Ω is an open subset of \mathbb{R}^d), and when the norm in V is such that the evaluation functionals $a \otimes \delta_x$ belong to V^* for any $a, x \in \mathbb{R}^d$, where

$$(a \otimes \delta_x|v) = a^T v(x), v \in V. \quad (1)$$

In this case, the vector field $K_V(a \otimes \delta_x)$ is well defined and linear in a . One can define the matrix-valued function $(y, x) \mapsto \tilde{K}_V(y, x)$ by

$$\tilde{K}_V(y, x)a = (K_V(a \otimes \delta_x))(y);$$

\tilde{K}_V is the kernel of the space V . In the following, we will write $K_V(x, y)$ instead of $\tilde{K}_V(x, y)$, with the customary abuse of notation of identifying the kernel and the operator that it defines.

One can easily deduce from its definition that K_V satisfies the reproducing property

$$\forall a, b \in \mathbb{R}^d, \langle K_V(\cdot, x)a, K_V(\cdot, y)b \rangle_V = a^T K_V(x, y)b,$$

which also implies the symmetry property $K_V(x, y) = K_V(y, x)^T$. Unless otherwise specified, it will always be assumed that V is a space of vector fields that vanish at infinity, which implies the same property for the kernel (one variable tending to infinity and the other remaining fixed).

A space V as considered above is called a reproducing kernel Hilbert space (RKHS) of vector fields. Fixing such a space, one can consider the *spline interpolation problem*, which is to find $v \in V$ with minimal norm such that $v(x_i) = c_i$, where x_1, \dots, x_N are points in \mathbb{R}^d and c_1, \dots, c_N are d -dimensional vectors. It is quite easy to prove that the solution takes the form

$$v(y) = \sum_{i=1}^N K_V(y, x_i) \alpha_i, \quad (2)$$

where $\alpha_1, \dots, \alpha_N$ are identified by solving the dN -dimensional system

$$\sum_{i=1}^N K_V(x_j, x_i) \alpha_i = c_j, \text{ for } j = 1, \dots, N. \quad (3)$$

Let $S_V(\mathbf{x})$ (where $\mathbf{x} = (x_1, \dots, x_N)$) denote the dN by dN block matrix

$$S_V(\mathbf{x}) = (K_V(x_i, x_j))_{i,j=1,\dots,N}.$$

Stacking c_1, \dots, c_N and $\alpha_1, \dots, \alpha_N$ in dN -dimensional column vectors \mathbf{c} and $\boldsymbol{\alpha}$, one can show that, for the optimal V ,

$$\|v\|_V^2 = \boldsymbol{\alpha}^T S_V(\mathbf{x}) \boldsymbol{\alpha} = \mathbf{c}^T S(\mathbf{x})_V^{-1} \mathbf{c}, \quad (4)$$

each term representing this spline deformation energy for the considered interpolation problem.

How one uses this interpolation method now depends on how one interprets the vector field V . One possibility is to consider it as a *displacement field*, in the sense that a particle at position x in space is moved to position $x + v(x)$, therefore involving the space transformation $\varphi^v := \text{id} + v$. In this view, the interpolation problem can be rephrased as finding the smoothest (in the V -norm sense) full space interpolation of given landmark displacements. The deformation energy in

(4) can then be interpreted as some kind of “elastic” energy that evaluates the total stress involved in the transformation φ^v . This (with some variants, including allowing for some no-cost affine, or polynomial, transformations) is the framework of interpolation based on thin plates, or radial basis functions, as introduced in [3, 4, 9, 10, 18], for example. As discussed in the introduction, this approach does not lead to a nice mathematical notion of a shape space of landmarks; moreover, in the presence of large displacements, the interpolated transformation φ^v may fail to be one to one and therefore to provide a well-defined dense correspondence.

The other way to interpret V is as a velocity field, so that $v(x)$ is the speed of a particle at x at a given time. The interpolation problem is then to obtain a smooth velocity field given the speeds c_1, \dots, c_N of particles x_1, \dots, x_N . This point of view has the double advantage of providing a diffeomorphic displacement when the velocity field is integrated over time and allowing for the interpretation of the deformation energy as a kinetic energy, directly related to a Riemannian metric on the space of landmarks.

Riemannian Structure

Let Lmk_N denote the submanifold of \mathbb{R}^{dN} consisting of all ordered collections of N distinct points in \mathbb{R}^d :

$$Lmk_N = \{\mathbf{x} = (x_1, \dots, x_N) \in (\mathbb{R}^d)^N, x_i \neq x_j \text{ if } i \neq j\}.$$

The tangent space to Lmk_N at \mathbf{x} can be identified to the space of all families of d -dimensional vectors $\mathbf{c} = (c_1, \dots, c_N)$, and one defines (with the same notation as in the previous section) the Riemannian metric on Lmk_N

$$\|\mathbf{c}\|_{\mathbf{x}}^2 = \mathbf{c}^T S_V(\mathbf{x})^{-1} \mathbf{c}.$$

As already pointed out, $\|\mathbf{c}\|_{\mathbf{x}}^2$ is the minimum of $\|v\|_V^2$ among all V in V such that $v(x_i) = c_i$, $i = 1, \dots, N$. This minimum is attained at

$$v^{\mathbf{c}}(\cdot) = \sum_{i=1}^N K(\cdot, x_i) \alpha_i$$

with $\alpha = S_V(\mathbf{x})^{-1} \mathbf{c}$.

Now, given any differentiable curve $t \mapsto \mathbf{x}(t)$ in Lmk_N , one can build an optimal time-dependent velocity field

$$v(t, \cdot) = v^{\mathbf{c}(t)}(\cdot)$$

with $\mathbf{c} = \partial_t \mathbf{x}$. One can then define the flow associated to this time-dependent velocity, namely, the time-dependent diffeomorphism φ^v , such that $\varphi^v(0, x) = x$ and

$$\partial_t \varphi^v(t, x) = v(t, \varphi^v(t, x))$$

which is, by construction, such that $\varphi^v(t, x_i(0)) = x_i(t)$ for $i = 1, \dots, N$. So, this construction provides a diffeomorphic extrapolation of any curve in Lmk_N , which is optimal in the sense that its velocity has minimal V norms, given the induced constraints. The metric that has been defined on Lmk_N is the projection of the V norm via the infinitesimal action of velocity fields on Lmk_N , which is defined by

$$v \cdot (x_1, \dots, x_N) = (v(x_1), \dots, v(x_N)).$$

This concept will be extensively discussed later on in this chapter.

Geodesic Equation

Geodesics on Lmk_N are curves that locally minimize the energy, that is, they are curves $t \mapsto \mathbf{x}(t)$ such that, for any t , there exists $h > 0$ such that

$$\int_{t-h}^{t+h} \|\dot{\mathbf{x}}_u(u)\|_{\mathbf{x}(u)}^2 du$$

is minimal over all possible curves in Lmk_N that connect $\mathbf{x}(t-h)$ and $\mathbf{x}(t+h)$. The geodesic, or Riemannian, distance between \mathbf{x}_0 and \mathbf{x}_1 is defined as the minimizer of the square root of the geodesic energy

$$\int_0^1 \|\dot{\mathbf{x}}_u\|_{\mathbf{x}(u)}^2 du$$

over all curves in Lmk_N that connect \mathbf{x}_0 and \mathbf{x}_1 .

Geodesics are characterized by a second-order equation, called the geodesic equation. If one denotes $G_V(\mathbf{x}) = S_V(\mathbf{x})^{-1}$, with coefficients $g_{(k,i),(l,j)}$ for $k, l = 1, \dots, N$ and $i, j = 1, \dots, d$, the classical expression of this equation is

$$\ddot{x}_{k,i} + \sum_{l,l'=1'}^N \sum_{j,j'=1}^d \Gamma_{(l,j),(l',j')}^{(k,i)} \dot{x}_{l,j} \dot{x}_{l',j'} = 0,$$

where $\Gamma_{(l,j),(l',j')}^{(k,i)}$ are the Christoffel symbols, given by

$$\Gamma_{(l,j),(l',j')}^{(k,i)} = \frac{1}{2} \left(\partial_{x_{l',j'}} g_{(k,i),(l,j)} + \partial_{x_{l,j}} g_{(k,i),(l',j')} - \partial_{x_{k,i}} g_{(l,j),(l',j')} \right).$$

In these formulae, the two indices that describe the coordinates in Lmk_N , $x_{k,i}$ were made explicit, representing the i th coordinate of the k th landmark. Solutions of this equation are unique as soon as $\mathbf{x}(0)$ and $\dot{\mathbf{x}}(0)$ are specified.

Equations put in this form become rapidly intractable when the number of landmarks becomes large. The inversion of the matrix $S_V(\mathbf{x})$ or even simply its storage can be computationally impossible when N gets larger than a few thousands.

It is much more efficient, and analytically simpler as well, to use the *Hamiltonian form* of the geodesic equation, which is (see [38])

$$\begin{cases} \partial_t \mathbf{x} = S_V(\mathbf{x})\boldsymbol{\alpha} \\ \partial_t \boldsymbol{\alpha} = -\frac{1}{2}\partial_{\mathbf{x}}(\boldsymbol{\alpha}^T S_V(\mathbf{x})\boldsymbol{\alpha}) \end{cases} \quad (5)$$

This equation will be justified in section ‘‘General Principles,’’ in which the optimality conditions for geodesics will be retrieved as a particular case of general problems in calculus of variations and optimal control. Its solution is uniquely defined as soon as $\mathbf{x}(0)$ and $\boldsymbol{\alpha}(0)$ are specified. The time-dependent collection of vectors $t \mapsto \boldsymbol{\alpha}(t)$ is called the *momentum* of the motion. It is related to the velocity $\mathbf{c}(t) = \dot{\mathbf{x}}(t)$ by the identity $\mathbf{c} = S_V(\mathbf{x})\boldsymbol{\alpha}$.

Introducing K_V and letting $K_V^{ij}(x, y)$ denote the i, j entry of $K_V(x, y)$, this geodesic equation can be rewritten in the following even more explicit form:

$$\begin{cases} \partial_t x_k = \sum_{l=1}^N K_V(x_k, x_l)\alpha_l, & k = 1, \dots, N, \\ \partial_t \alpha_k = -\sum_{l=1}^N \sum_{i,j=1}^d \nabla_1 K_V^{ij}(x_k, x_l)\alpha_{k,i}\alpha_{l,j}, & k = 1, \dots, N, \end{cases} \quad (6)$$

where $\nabla_1 K_V^{ij}$ denotes the gradient of the i, j entry of K_V with respect to its first variable.

The geodesic equation defines the Riemannian exponential map as follows. Fix $\mathbf{x}_0 \in Lmk_N$. The exponential map at \mathbf{x}_0 is the transformation $\mathbf{c} \mapsto \exp_{\mathbf{x}_0}(\mathbf{c})$ defined over all tangent vectors \mathbf{c} to Lmk_N at \mathbf{x}_0 (which are identified to all families of d -dimensional vectors, $\mathbf{c} = (c_1, \dots, c_N)$), such that $\exp_{\mathbf{x}_0}(\mathbf{c})$ is the solution at time $t = 1$ of the geodesic equation initialized at $\mathbf{x}(0) = \mathbf{x}_0$ and $\dot{\mathbf{x}}(0) = \mathbf{c}$. Alternatively, one can define the exponential chart in Hamiltonian form that will also be called the *momentum representation* in Lmk_N by the transformation

$$\boldsymbol{\alpha}_0 \mapsto \exp_{\mathbf{x}_0}^\flat(\boldsymbol{\alpha}_0),$$

where $\exp_{\mathbf{x}_0}^\flat(\boldsymbol{\alpha}_0)$ is the solution at time 1 of system (6) initialized at $(\mathbf{x}_0, \boldsymbol{\alpha}_0)$.

For the metric that is considered here, one can prove that the exponential map at \mathbf{x}_0 (resp. the momentum representation) is defined for any vector \mathbf{c} (resp. $\boldsymbol{\alpha}_0$); this also implies that they both are onto, so that any landmark configuration \mathbf{y} can be written as $\mathbf{y} = \exp_{\mathbf{x}_0}^\flat(\boldsymbol{\alpha}_0)$ for some $\boldsymbol{\alpha}_0 \in (\mathbb{R}^d)^N$. The representation is not one to one, because geodesics may intersect, but it is so if restricted to a small-enough neighborhood of 0. More precisely, there exists an open subset $U \subset T_{\mathbf{x}_0}Lmk_N$ over which $\exp_{\mathbf{x}_0}$ is a diffeomorphism. This provides the so-called *exponential chart* at \mathbf{x} on the manifold.

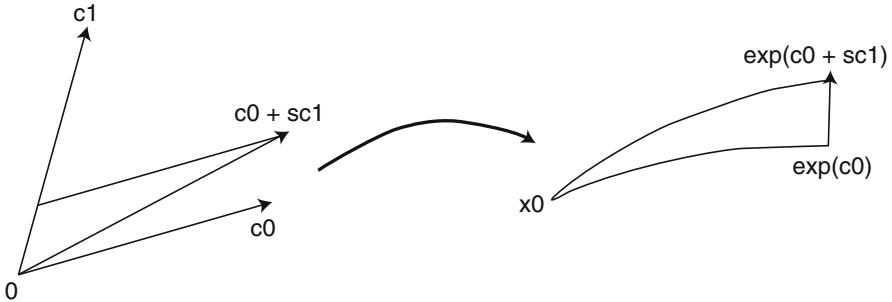

Fig. 2 Metric distortion for the exponential chart

Metric Distortion and Curvature

Exponential charts are often used for data analysis on a manifold, because they provide, in a neighborhood of a reference point x_0 , a vector-space representation which has no radial metric distortion, in the sense that, in the chart, the geodesic distance between x_0 and $\exp_{x_0}(\mathbf{c})$ is equal to $\|\mathbf{c}\|_{x_0}$. The representation does distort the metric in the other directions. One way to measure this is by comparing (see Fig. 2), for given \mathbf{c}_0 and \mathbf{c}_1 with $\|\mathbf{c}_0\|_{x_0} = \|\mathbf{c}_1\|_{x_0} = 1$, the points $\exp_{x_0}(t\mathbf{c}_0)$ and $\exp_{x_0}(t(\mathbf{c}_0 + s\mathbf{c}_1))$. Let $F(t, s)$ denote the last term (so that the first one is $F(t, 0)$). One can write

$$\text{dist}(F(t, s), F(t, 0)) = s \|\partial_s F(t, 0)\|_{F(t, 0)} + o(s).$$

Without metric distortion, this distance would be given by $st \|\mathbf{c}_1\|_{x_0} = st$. However, it turns out that [14]

$$\|\partial_s F(t, 0)\|_{F(t, 0)} = t - \rho_x(\mathbf{c}_0, \mathbf{c}_1) \frac{t^3}{6} + o(t^3),$$

where $\rho_x(\mathbf{c}_0, \mathbf{c}_1)$ is the *sectional curvature* of the plane generated by \mathbf{c}_0 and \mathbf{c}_1 in $T_{x_0} Lm_N$. So, this sectional curvature directly measures (among many other things) the first order of metric distortion in the manifold and is therefore an important indication of this distortion of the exponential charts.

The usual explicit formula for the computation of the curvature involves the second derivatives of the metric tensor matrix $G_V(\mathbf{x})$, which, as we have seen, is intractable for large values of N . In a recent work, Micheli [53] introduced an interesting new formula for the computation of the curvature in terms of the inverse tensor, $S_V(\mathbf{x}_0)$.

Invariance

The previous landmark space ignored the important facts that two shapes are usually considered as identical when one can be deduced from the other by a Euclidean transformation, which is a combination of a rotation and a translation

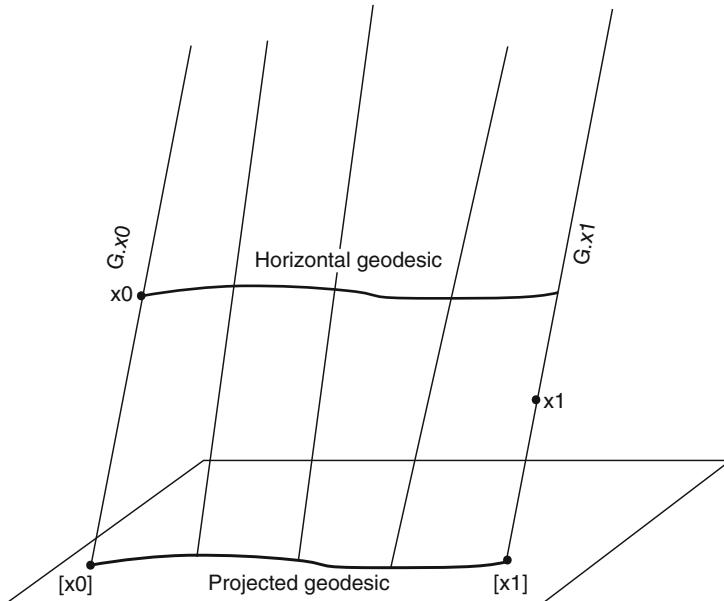

Fig. 3 Riemannian submersion (geodesics in the quotient space)

(scale invariance is another important aspect that will not be discussed in this section). To take this into account, we need to “mod out” these transformations, that is, to consider the quotient space of Lmk_N by the Euclidean group.

One can pass from the metric discussed in the previous section to a metric on the quotient space via the mechanism of Riemannian submersion (Fig. 3). The scheme is relatively simple, and we describe it and set up notation in a generic framework before taking the special case of the landmark manifold. So, let Q be a Riemannian manifold and $\pi : Q \rightarrow M$ be a submersion, that is, a smooth surjection from Q to another manifold M such that its differential $D\pi$ has full rank everywhere. This implies that, for $m \in M$, the set $\pi^{-1}(m)$ is a submanifold of Q , called the fiber at m . If $q \in Q$ and $m = \pi(q)$, the tangent space $T_q Q$ can be decomposed into the direct sum of the tangent space to $\pi^{-1}(m)$ and the space perpendicular to it. We will refer to the former as the space of vertical vectors at q , and denote it \mathcal{V}_q , and to the latter as the space of horizontal vectors, denoted \mathcal{H}_q . We therefore have

$$T_q Q = \mathcal{V}_q \perp \mathcal{H}_q.$$

The differential of π at q , $D\pi(q)$, vanishes on \mathcal{V}_q (since π is constant on $\pi^{-1}(m)$) and is an isomorphism between \mathcal{H}_q and $T_m M$. Let us make the abuse of notation of still denoting $D\pi(q)$ the restriction of $D\pi(q)$ to \mathcal{H}_q . Then, if $q, q' \in \pi^{-1}(m)$, the map $p_{q',q} := D\pi(q)^{-1} \circ D\pi(q')$ is an isomorphism between $\mathcal{H}_{q'}$ and \mathcal{H}_q . One says that π is a Riemannian submersion if and only if the maps $p_{q',q}$ are in fact isometries between $\mathcal{H}_{q'}$ and \mathcal{H}_q whenever q and q' belong in the same fiber, that is, if one has, for all $v' \in \mathcal{H}_{q'}$,

$$\|P_{q',q}v'\|_q = \|v'\|_{q'}.$$

Another way to phrase this property is

$$\pi(q) = \pi(q'), v \in \mathcal{H}_q, v' \in \mathcal{H}_{q'}, D\pi(q)v = D\pi(q')v' \Rightarrow \|v\|_q = \|v'\|_{q'}.$$

A Riemannian submersion naturally induces a Riemannian metric on M , simply defining, for $m \in M$ and $h \in T_m M$,

$$\|h\|_m = \|D\pi(q)^{-1}h\|_q$$

for any $q \in \pi^{-1}(m)$, the definition being independent of q by assumption. This is the Riemannian projection of the metric on Q via the Riemannian submersion π .

Let us now return to the landmark case, and consider the action of rotations and translations, that is of the special Euclidean group of \mathbb{R}^d , which is traditionally denoted $SE(\mathbb{R}^d)$. The action of a transformation $g \in SE(\mathbb{R}^d)$ on a landmark configuration $\mathbf{x} = (x_1, \dots, x_N) \in Lmk_N$ is

$$g \cdot \mathbf{x} = (g(x_1), \dots, g(x_N)).$$

We want to use a Riemannian projection to deduce a metric on the quotient space $M = Lmk_N / SE(\mathbb{R}^d)$ from the metric that has been defined on Lmk_N , the surjection π being the projection $\pi : Lmk_N \rightarrow M$, which assigns to a landmark configuration \mathbf{x} its equivalence class, or orbit under the action of $SE(\mathbb{R}^d)$, defined by

$$[\mathbf{x}] = \{g \cdot \mathbf{x}, g \in SE(\mathbb{R}^d)\} \in M.$$

To make sure that M is a manifold, one needs to restrict to affinely independent landmark configurations, which form an open subset of Lmk_N and therefore let Q be this space and restrict π to Q . In this context, one can show that a sufficient condition for π to be a Riemannian submersion is that the action of $SE(\mathbb{R}^d)$ is isometric, that is, for all $g \in SE(\mathbb{R}^d)$, the operation $a_g : \mathbf{x} \mapsto g \cdot \mathbf{x}$ is such that, for all $u, v \in T_{\mathbf{x}} Q$,

$$\langle Da_g(\mathbf{x})u, Da_g(\mathbf{x})v \rangle_{g \cdot \mathbf{x}} = \langle u, v \rangle_{\mathbf{x}}.$$

This property can be translated into equivalent properties on the metric. For translations, for example, it says that, for every $\mathbf{x} \in Q$ and $\tau \in \mathbb{R}^d$, one must have

$$S_V(\mathbf{x} + \tau) = S_V(\mathbf{x})$$

which is in turn equivalent to the requirement that, for all $x, y, \tau \in \mathbb{R}^d$, $K_V(x + \tau, y + \tau) = K_V(x, y)$, so that K_V only depends on $x - y$. With rotations, one needs

$$\text{diag}(R)^T S_V(R\mathbf{x})\text{diag}(R) = S_V(\mathbf{x}),$$

which again translates into a similar property for the kernel, namely,

$$R^T K_V(Rx, Ry)R = K_V(x, y).$$

Here, R is an arbitrary d dimensional rotation, and $\text{diag}(R)$ is the dN by dN block-diagonal matrix with R repeated N times.

Kernels that satisfy these properties can be characterized in explicit forms. These kernels include all positive radial kernels, that is, all kernels taking the form

$$K_V(x, y) = \gamma(|x - y|^2)\text{Id}_{\mathbb{R}^d},$$

where $\gamma : [0, +\infty) \rightarrow \mathbb{R}$ is the Laplace transform of some positive measure μ , that is,

$$\gamma(t) = \int_0^\infty e^{-ty} d\mu(y).$$

Such functions include Gaussians,

$$\gamma(t^2) = \exp(-t^2/2\sigma^2), \quad (7)$$

Cauchy,

$$\gamma(t^2) = \frac{1}{1 + t^2/\sigma^2}, \quad (8)$$

or Laplacian kernels, defined for any integer $c \geq 0$ by

$$\gamma_c(t^2) = \left(\sum_{l=1}^c \rho(c, l) \frac{t^l}{\sigma^l} \right) \exp(-t/\sigma) \quad (9)$$

with $\rho(c, l) = 2^{l-c} (2c - l) \cdots (c + 1 - l)/l!$.

One can also use non-diagonal kernels. One simple construction of such kernels is to start with a scalar kernel, for example, associated to a radial function γ as above, and, for some parameter $\lambda \geq 0$, to implicitly define K_V via the identity, valid for all pairs of smooth compactly supported vector fields V and w ,

$$\begin{aligned} \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} v(x)^T K_V(x, y) w(y) dx dy &= \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} \gamma(|x - y|^2) (v(x)^T w(y)) dx dy \\ &\quad + \frac{\lambda}{2} \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} \gamma(|x - y|^2) (\nabla \cdot v(x)) (\nabla \cdot w(y)) dx dy, \end{aligned}$$

where $(\nabla \cdot)$ denotes the divergence operator. The explicit form of the kernel can be deduced after a double application of the divergence theorem yielding

$$K_V(x, y) = (\gamma(r^2) - \lambda\dot{\gamma}(r^2))\text{Id}_{\mathbb{R}^d} - 2\lambda\ddot{\gamma}(r^2)(x - y)(x - y)^T$$

with $r = |x - y|$.

Assume that one of these choices has been made for K_V , so that one can use a Riemannian submersion to define a metric on the quotient space $Q/SE(\mathbb{R}^d)$. One of the appealing properties of this construction is that geodesics in the quotient space are given by (equivalent classes of) geodesics in the original space, provided that they are initialized with horizontal velocities. Another interesting feature is that the horizontality condition is very simply expressed in terms of the momenta, which provides another advantage of the momentum representation in Eq. (6). Take translations, for example. A vertical tangent vector for their action at any point $\mathbf{x} \in M$ is a vector of the form (τ, \dots, τ) , where τ is a d -dimensional vector repeated N times. A momentum, or covector, α is horizontal if and only if it vanishes when applied to any such vertical vector, which yields

$$\sum_{k=1}^N \alpha_k = 0. \quad (10)$$

A similar analysis for rotations yields the horizontality condition

$$\sum_{k=1}^N (\alpha_k x_k^T - x_k \alpha_k^T) = 0. \quad (11)$$

These two conditions provide the $d(d + 1)/2$ constraints that must be imposed to the momentum representation on M to obtain a momentum representation on $M/SE(\mathbb{R}^d)$.

Hamiltonian Point of View

General Principles

This section presents an alternate formulation in which the accent is made on variational principles rather than on geometric concepts. Although the results obtained using the Hamiltonian approach that is presented here will be partially redundant with the ones that were obtained using the Riemannian point of view, there is a genuine benefit in understanding and being able to connect the two of them. As will be seen below, working with the Hamiltonian formulation brings new, relatively simple concepts, especially when dealing with invariance and symmetries. It is also often the best way to handle numerical implementations.

To lighten the conceptual burden, the presentation will remain within the elementary formulation that uses a state variable q and a momentum p , rather

than the more general symplectic formulation. On a manifold, this implies that the presentation is made with variables restricted to a local chart.

An optimal control problem in Lagrangian form is associated to a real-valued cost function (or Lagrangian) $(q, u) \mapsto L(q, u)$ defined on $Q \times U$, where Q is a manifold and U is the space of controls, and to a function $(q, u) \mapsto f(q, u) \in T_q Q$. The resulting variational problem consists in the minimization of

$$\int_{t_i}^{t_f} L(q, u) dt \quad (12)$$

subject to the constraint $\dot{q}_t = f(q, u)$ and some boundary conditions for $q(t_i)$ and $q(t_f)$. The simplest situation is the classical problem in the calculus of variations for which $f(q, u) = u$, and the problem is to minimize $\int_{t_i}^{t_f} L(q, \dot{q}_t) dt$. Here, $[t_i, t_f]$ is a fixed finite interval. The values $t_i = 0$ and $t_f = 1$ will be assumed in the following.

The general situation in (12) can be formally addressed by introducing Lagrange multipliers, denoted $p(t)$, associated to the constraint $\partial_t q = f(q, u)$ at time t ; p is called the costate in the optimal control setting. One then looks for critical paths of

$$J_0(q, p, u) \doteq \int_0^1 (L(q, u) + (p| \dot{q}_t - f(q, u))) dt,$$

where the paths p , u , and q vary now freely as far as $q(0)$ and $q(1)$ remain fixed. The costate is here a linear form on Q , that is, an element of $T_q^* Q$.

Introduce the Hamiltonian

$$H(q, p, u) \doteq (p| f(q, u)) - L(q, u)$$

for which

$$J_0 = \int_0^1 ((p| \dot{q}_t) - H(q, p, u)) dt.$$

Writing the conditions for criticality, $\delta J_0 / \delta u = \delta J_0 / \delta q = \delta J_0 / \delta p = 0$, directly leads to the Hamiltonian equation:

$$\partial_t q = \partial_p H, \quad \partial_t p = -\partial_q H, \quad \partial_u H = 0. \quad (13)$$

The above derivation is only formal. A rigorous derivation in various finite-dimensional as well as infinite-dimensional situations is the central object of Pontryagin Maximum Principle (PMP) theorems which state that along a solution (q_*, p_*, u_*) , one has

$$H(q_*(t), p_*(t), u_*(t)) = \max_u H(q_*(t), p_*(t), u).$$

Introducing $\tilde{H}(q, p) \doteq \max_u H(q, p, u)$, one gets the usual Hamiltonian equation:

$$\partial_t p = -\partial_q \tilde{H}, \quad \partial_t q = \partial_p \tilde{H}. \quad (14)$$

One can notice that, in the classical case $f(q, u) = u$, $\tilde{H}(q, p)$ coincides with the Hamiltonian obtained via the Legendre transformation in which a function $u(p, q)$ is defined via the equation $p = \partial_u L$ and

$$\tilde{H}(p, q) = (p | u(q, p)) - L(q, u(q, p)).$$

Application to Geodesics in a Riemannian Manifold

Let Q be a Riemannian manifold with metric at q denoted $\langle \cdot, \cdot \rangle_q$. The computation of geodesics in Q can be seen as a particular case of the previous framework in at least two (equivalent) ways. The first one is to take

$$L(\mathbf{x}, u) = \|u\|_q^2/2 \text{ and } f(\mathbf{x}, u) = u,$$

which gives a variational problem in standard form. For the other choice, introduce the duality operator $K_q : T_q^* Q \rightarrow T_q Q$ defined by

$$(\alpha | \xi) = \langle K_q \alpha, \xi \rangle_q,$$

$\alpha \in T_q^* Q$, $\xi \in T_q Q$, and let, denoting the control by α ,

$$L(q, \alpha) = (\alpha | K_q \alpha)/2 \text{ and } f(q, \alpha) = K_q \alpha.$$

The Hamiltonian equation in this case yields $p = \alpha$ and

$$\begin{cases} \partial_t q = K_q \alpha, \\ \partial_t \alpha = -\frac{1}{2} \partial_q ((\alpha | K_q \alpha)). \end{cases} \quad (15)$$

This equation obviously reduces to (5) with $q = \mathbf{x}$, $K_q \alpha = S_V(\mathbf{x})\alpha$.

Momentum Map and Conserved Quantities

A central aspect of the Hamiltonian formulation is its ability to turn symmetries into conserved quantities. This directly relates to the Riemannian submersion discussed in section “Invariance.”

Consider a Lie group G acting on the state variable $q \in Q$, assuming, for the rest of this section and the next one, an action on the right denoted $(g, q) \rightarrow g \cdot q$. Notice that results obtained with a right action immediately translate to left actions, by transforming a left action $(g, q) \mapsto g \cdot q$ into the right action $(g, q) \mapsto g^{-1} \cdot q$. In fact, both right and left actions are encountered in this chapter. The standard notation $T_{\text{id}} G = \mathfrak{G}$ will be used in the following to represent the Lie algebra of G .

By differentiation in the q variable, the action can be extended to the tangent bundle, with notation $(g, v) \rightarrow v \cdot g$ for $v \in TQ$. By duality, this induces an action on the costate variable through the equality $(p \cdot g|v) \doteq (p|v \cdot g^{-1})$. Differentiating again in g at $g = \text{id}_G$ gives the infinitesimal actions on the tangent and cotangent bundles, defined for any $\xi \in \mathfrak{G} \doteq T_{\text{id}_G} G$ by $(\xi, v) \rightarrow v \cdot \xi$ and for any $(\xi, p) \rightarrow p \cdot \xi$ such that $(p \cdot \xi|v) + (p|v \cdot \xi) = 0$, for all $v \in TQ$ and $p \in T^*Q$.

Now, assume that H is G -invariant, that is, $H(q \cdot g, p \cdot g) = H(q, p)$ for any $g \in G$, and define the *momentum map* $(q, p) \rightarrow \mathbf{m}(q, p) \in \mathfrak{G}^*$ by

$$(\mathbf{m}(q, p)|\xi) = (p|q \cdot \xi). \quad (16)$$

Then, one has, along a Hamiltonian trajectory,

$$\partial_t \mathbf{m}(p, q) = 0, \quad (17)$$

that is, the momentum map is a conserved (vectorial) quantity along the Hamiltonian flow. This result is proved as follows. First notice that if $g(t)$ is a curve in G with $g(0) = \text{id}_G$ and $\dot{g}(0) = \xi$, then, if H is G -invariant,

$$0 = \partial_t H(q \cdot g, p \cdot g) = (\partial_q H|q \cdot \xi) + (p \cdot \xi|\partial_p H).$$

On the other hand, from the definitions of the actions, one has

$$(\partial_t \mathbf{m}(q, p)|\xi) = \partial_t (p|q \cdot \xi) = (\partial_t p|q \cdot \xi) - (p \cdot \xi|\partial_t q),$$

so that if (q, p) is a Hamiltonian trajectory,

$$(\partial_t \mathbf{m}(q, p)|\xi) = -(\partial_q H|q \cdot \xi) - (p \cdot \xi|\partial_p H) = 0$$

which gives (17).

Notice that the momentum map has an interesting equivariance property:

$$\begin{aligned} (\mathbf{m}(q \cdot g, p \cdot g)|\xi) &= (p \cdot g|(q \cdot g) \cdot \xi) \\ &= (p \cdot g|q \cdot (g\xi)) \\ &= (p|(q \cdot (g\xi)) \cdot g^{-1}) \\ &= (p|q \cdot ((g\xi)g^{-1})) \end{aligned}$$

where $g\xi$ denotes the derivative of $h \mapsto gh$ in h at $h = \text{id}_G$ along the direction ξ and $(g\xi)g^{-1}$ the derivative of $h \mapsto hg^{-1}$ in h at $h = g$ along the direction $g\xi$. The map $\xi \mapsto (g\xi)g^{-1}$ defined on \mathfrak{G} is called the *adjoint representation* and usually denoted $v \mapsto \text{Ad}_g v$. One therefore gets

$$(\mathbf{m}(q \cdot g, p \cdot g)|\xi) = (p|q \cdot \text{Ad}_g(\xi)) = (\mathbf{m}(q, p)|\text{Ad}_g(\xi)) = (\text{Ad}_g^*(\mathbf{m}(q, p))|\xi),$$

where Ad_g^* is the conjugate of Ad_g . Hence

$$\mathfrak{m}(q \cdot g, p \cdot g) = \text{Ad}_g^*(\mathfrak{m}(q, p)), \quad (18)$$

that is, \mathfrak{m} is Ad^* -equivariant.

Euler–Poincar  Equation

Consider the particular case in which $Q = G$ and G acts on itself. In this case,

$$(\mathfrak{m}(\text{id}_G, p)| v) = (p| v),$$

so that $\mathfrak{m}(\text{id}_G, p) = p$ and one gets from Eq. (18)

$$pg^{-1} = \mathfrak{m}(\text{id}_G, pg^{-1}) = \text{Ad}_{g^{-1}}^*(\mathfrak{m}(g, p)).$$

Hence, along a trajectory starting from $g(0) = \text{id}_G$ of a G -invariant Hamiltonian H , one has (denoting $\rho = pg^{-1} \in \mathfrak{G}^*$ and using the fact that the momentum map is conserved over time)

$$\begin{aligned} \rho(t) &\doteq p(t)g(t)^{-1} = \text{Ad}_{g^{-1}(t)}^*(\mathfrak{m}(g(t), p(t))) \\ &= \text{Ad}_{g^{-1}(t)}^*(\mathfrak{m}(\text{id}_G, p(0))) = \text{Ad}_{g^{-1}(t)}^*(\rho(0)). \end{aligned} \quad (19)$$

This is the integrated version of the so-called *Euler–Poincar * equation on \mathfrak{G}^* [6,50],

$$\partial_t \rho + \text{ad}_{v(\rho)}^*(\rho) = 0, \quad (20)$$

where $v(\rho) = \dot{g}g^{-1} = \partial_p H(\text{id}_G, pg^{-1}) = \partial_p H(\text{id}_G, \rho)$ and ad is the differential at location $g = \text{id}_G$ of Ad_g .

A special case of this, which will be important later, is when the Hamiltonian corresponds to a right-invariant Riemannian metric on G . There is a large literature on invariant metrics on Lie groups, which can be shown to be related to important finite and infinite-dimensional mechanical models, including the Euler equation for perfect fluids. The interested reader can refer to [5,6,33,34,49,50].

Such a metric is characterized by an inner product $\langle \cdot, \cdot \rangle_V$ on \mathfrak{G} and defined by

$$\langle v, w \rangle_g = \langle vg^{-1}, wg^{-1} \rangle_{\mathfrak{G}}. \quad (21)$$

If one lets $K_{\mathfrak{G}}$ be the duality operator on \mathfrak{G} so that

$$(\rho| v) = \langle K_{\mathfrak{G}}\rho, v \rangle_{\mathfrak{G}},$$

the issue of finding minimizing geodesics can be rephrased as an optimal control problem like in the case of landmarks, with Lagrangian $L(g, \mu) = (\mu| K_g \mu)/2$, $f(g, \mu) = K_g \mu$, and

$$K_g \mu = (K_{\mathfrak{G}}(\mu g^{-1}))g. \quad (22)$$

The Hamiltonian equations are then directly given by (15), namely,

$$\begin{cases} \partial_t g = K_g \mu, \\ \partial_t \mu = -\frac{1}{2} \partial_g ((\mu | K_g \mu)). \end{cases} \quad (23)$$

This equation is equivalent to the one obtained from the conservation of the momentum map, which is (with $\rho = \mu g^{-1}$)

$$\begin{cases} \partial_t g = vg, \\ v = K_{\mathfrak{G}} \rho, \\ \partial_t \rho = -\text{ad}_v^* \rho. \end{cases} \quad (24)$$

A Note on Left Actions

Invariance with respect to left actions is handled in a symmetrical way to right actions. If G is acting on the left on G , define the momentum map by

$$(\mathfrak{m}(p, q) | v) = (p | v \cdot q)$$

which is conserved along Hamiltonian trajectories. Working out the equivariance property gives

$$\mathfrak{m}(g \cdot p, g \cdot q) = \text{Ad}_{g^{-1}}^* \mathfrak{m}(p, q).$$

When G acts on itself on the left, the Euler–Poincaré equation reads

$$\rho(t) = \text{Ad}_g^*(\rho(0))$$

or

$$\partial_t \rho - \text{ad}_{v(\rho)}^* \rho = 0$$

with $\rho = g^{-1} p$ and $v(\rho) = g^{-1} \dot{g}_t$.

Application to the Group of Diffeomorphisms

Let $G \subset \text{Diff}(\mathbb{R}^d)$ be a group of smooth diffeomorphisms of \mathbb{R}^d (which, say, smoothly converge to the identity at infinity). Elements of the tangent space to G , which are derivatives of curves $t \mapsto \varphi(t, \cdot)$ where $\varphi(t, \cdot) \in G$ for all t , can be identified to vector fields $x \mapsto v(x) \in \mathbb{R}^d$, $x \in \mathbb{R}^d$.

To define a right-invariant metric on G , introduce a Hilbert space V of vector fields on \mathbb{R}^d with inner product $\langle \cdot, \cdot \rangle_V$. Like in section “A Riemannian Manifold

of Deformable Landmarks," let L_V and $K_V = L_V^{-1}$ denote the duality operators on V , with $\langle v, w \rangle_V = (L_V v | w)$ and $\langle \mu, v \rangle_{V^*} = (\mu | K_V v)$; K_V is furthermore identified with a matrix-valued kernel $K_V(x, y)$ acting on vector fields.

The application of the formulae derived for Hamiltonian systems and of the Euler–Poincar  equation will remain in the following of this section at a highly formal level, just computing the expression assumed in the case of diffeomorphisms by the general quantities introduced in the previous section. There will be no attempt at proving that these formulae are indeed valid in this infinite-dimensional context, which is out of the scope of this chapter. As an example of the difficulties that can be encountered, let us mention the dilemma that is involved in the mere choice of the group G . On the first hand, G can be chosen as a group of infinitely differentiable diffeomorphisms that coincide with the identity outside a compact set. This would provide a rather nicely behaved manifold with a Lie group structure in the sense of [44, 45]. The problem with such a choice is that the structure would be much stronger than what Riemannian metrics of interest would induce and that geodesics would typically spring out of the group. One can, on the other hand, try to place the emphasis on the Riemannian and variational aspects so that the computation of geodesics in G , for example, remains well posed. This leads to a solution, introduced in Trouv  (Infinite dimensional group action and pattern recognition. Technical report. DMI, Ecole Normale Sup rieure, unpublished, 1995) (see also [70]), in which G is completed in a way which depends on the metric $\langle \cdot, \cdot \rangle_V$, so that the resulting group (denote it G_V) is complete for the geodesic distance. This extension, however, comes with the cost of losing the nice features of infinitely differentiable transformations, resulting in G_V not being a Lie group, for example.

This being acknowledged, first consider the transcription of (23) to the case of diffeomorphisms. This equation will involve a time-evolving diffeomorphism $\varphi(t, \cdot)$, and a time-evolving covector, denoted $\mu(t)$, which is a linear form over vector fields (it takes a vector field $x \mapsto v(x)$ and returns a number that has so far been denoted $(\mu(t) | v)$). It will be useful to apply $\mu(t)$ to vector-valued functions of several variables, say $v(x, y)$ defined for $x, y \in \mathbb{R}^2$, by letting one of the variables fixed and considering V as a function of the other. This will be denoted by adding a subscript representing the effective variable, so that

$$(\mu(t) | v(x, y))_x$$

is the number, dependent of y , obtained by applying $\mu(t)$ to the vector field $x \mapsto v(x, y)$.

One first needs to identify the operator K_φ in Eq. (22), defined by

$$K_\varphi \mu = (K_V(\mu \varphi^{-1})) \varphi = (K_V(\mu \varphi^{-1})) \circ \varphi$$

since right translation here coincides with composition. Now, for any vector $a \in \mathbb{R}^d$ and $y \in \mathbb{R}^d$, one has

$$\begin{aligned}
a^T(K_\varphi \mu)(y) &= a^T(K_V(\mu \varphi^{-1}))(\varphi(y)) \\
&= (a \otimes \delta_{\varphi(y)}| K_V(\mu \varphi^{-1})) \\
&= (\mu \varphi^{-1}| K_V(a \otimes \delta_{\varphi(y)})) \\
&= (\mu| K_V(a \otimes \delta_{\varphi(y)})) \circ \varphi \\
&= (\mu| K_V(\varphi(x), \varphi(y))a)_x.
\end{aligned}$$

So, letting e_1, \dots, e_d denote the canonical basis of \mathbb{R}^d , one has

$$(K_\varphi \mu)(y) = \sum_{i=1}^d e_i^T (K_\varphi \mu)(y) e_i = \sum_{i=1}^d (\mu| K_V^i(\varphi(x), \varphi(y)))_x e_i,$$

where K_V^i is the i th column of K_V . Therefore

$$(\mu| K_\varphi \mu) = \sum_{i=1}^d (\mu| (\mu| K_V^i(\varphi(x), \varphi(y)))_x e_i)_y$$

and (using the symmetry of K_V)

$$(\partial_\varphi (\mu| K_\varphi \mu)| w) = 2 \sum_{i=1}^d (\mu| (\mu| D_2 K_V^i(\varphi(x), \varphi(y))w(y))_x e_i)_y,$$

where $D_2 K_V^i$ is the derivative of K_V with respect to its second variable. These computations directly give the transcription of (23) for diffeomorphisms, namely,

$$\begin{cases} \partial_t \varphi(t, y) = \sum_{i=1}^d (\mu(t)| K_V^i(\varphi(t, x), \varphi(t, y)))_x e_i \\ \forall w : (\partial_t \mu(t)| w) = - \sum_{i=1}^d (\mu(t)| (\mu(t)| D_2 K_V^i(\varphi(t, x), \varphi(t, y))w(y))_x e_i)_y. \end{cases} \quad (25)$$

To transcribe Eq. (24) to diffeomorphisms, one only needs to work out the expressions of Ad_φ and ad_v in this context. Recall that $\text{Ad}_\varphi w$ was defined by $(\varphi w)\varphi^{-1}$; φw being the differential of the left translation (i.e., $\partial_t(\varphi \circ \psi(t))(0)$ with $\psi(0) = \text{id}$ and $\partial_t \psi(0) = w$), one finds $\varphi w = D\varphi w$, and since right translation is just composition,

$$\text{Ad}_\varphi w = (D\varphi w) \circ \varphi^{-1}.$$

Now, since $\text{ad}_v w$ is the differential of $\text{Ad}_\varphi w$ in φ (at $\varphi = \text{id}$), a quick computation shows that

$$\text{ad}_v w = Dv w - Dw v.$$

So, Eq. (24) provides

$$\begin{cases} \partial_t \varphi(t, y) = v(t, \varphi(t, y)) \\ v(t, x) = K_V \rho(t)(x) \\ \forall w \in V, (\partial_t \rho | w) = -(\rho(t) | Dv w - Dw v) \end{cases} \quad (26)$$

with the last equation being equivalent to

$$(\rho(t) | w) = (\rho(0) | D\varphi^{-1}(w \circ \varphi)).$$

Note that μ and ρ in (25) and (26) are related via $\mu = \rho \varphi$ or

$$(\mu | w) = (\rho | w \circ \varphi^{-1}).$$

Solving Eq. (25) (or (26)) between times 0 and 1 provides the momentum representation in G , denoted

$$\varphi(1, \cdot) = \exp_{\varphi(0, \cdot)}^\flat(\mu(0)).$$

Equivalently, the initial velocity being $K_V \mu(0)$, this is, in the exponential chart,

$$\varphi(1, \cdot) = \exp_{\varphi(0, \cdot)}(K_V \mu(0)).$$

Reduction via a Submersion

This section, which can be put in parallel with the discussion on Riemannian submersions in section ‘‘Invariance,’’ discusses how submersions from a manifold Q onto another manifold M allow for the transfer of a Hamiltonian system on Q to a Hamiltonian system on M , given some invariance properties satisfied by the Hamiltonian.

Let π be a submersion from a manifold Q onto a manifold M so that for any $q \in Q$, $D\pi_q : T_q Q \rightarrow T_{\pi(q)} M$ is a surjective mapping. For any $q \in Q$, $\mathcal{V}_q \doteq D\pi(q)^{-1}(0)$ is the previously mentioned vertical space so that $\mathcal{V} \doteq \cup_{q \in Q} \mathcal{V}_q$ will be called the vertical bundle. In the previous Riemannian setting, a metric on TQ induces the definition of a horizontal space \mathcal{H}_q at any location $q \in Q$ such that $T_q Q = \mathcal{V}_q + \mathcal{H}_q$. In the Hamiltonian approach, the horizontal space is defined in the cotangent space $T_q^* Q$ without any reference to a particular metric as the set of conormal covectors to the vertical space, that is,

$$\mathcal{H}_q^* \doteq \left\{ p \in T_q^* Q \mid (p | v) = 0 \ \forall v \in \mathcal{V}_q \right\}. \quad (27)$$

An elementary argument in linear algebra (which is left to the reader) shows that if one introduces the one-to-one adjoint mapping $D\pi^*(q) : T_{\pi(q)}^* M \rightarrow T_q^* Q$, one has

$\mathcal{H}_q^* = D\pi(\pi(q))^*(T_{\pi(q)}^*M)$. In other terms, a covector p is horizontal at q if and only if there exists a covector $\alpha \in T_{\pi(q)}^*M$ such that $D\pi(\pi(q))^*\alpha = p$. Therefore, $\mathcal{H}^* \doteq \cup_{q \in Q} \mathcal{H}_q^*$ can be seen as a sub-bundle of the cotangent bundle T^*Q for which there exists a surjective mapping

$$\tilde{\pi} : \mathcal{H}^* \rightarrow T^*M$$

defined by $\tilde{\pi}(q, p) = (\pi(q), (D\pi^*(q))^{-1}(p))$.

The main idea of this Hamiltonian (one should say symplectic or better Poisson) point of view is that \mathcal{H}^* is the natural image in T^*Q of the dynamic space (phase space) T^*M on M . Now, assume that a Hamiltonian H_Q is given on Q . One says that H_Q is π -reducible if there exists a Hamiltonian H_M on T^*M such that

$$H_{Q|_{\mathcal{H}^*}} = H_M \circ \tilde{\pi} \quad (28)$$

or equivalently

$$H_M(m, \alpha) = H_Q(q, D\pi(q)^*\alpha) \quad (29)$$

for $q \in \pi^{-1}(m)$.

Hamiltonian trajectories in both spaces are related as follows. Assume that (q, p) is H_Q -Hamiltonian (i.e., $\partial_t q = \partial_p H_Q$ and $\partial_t p = -\partial_q H_Q$) with $(q(0), p(0)) \in \mathcal{H}^*$, and consider in a similar way a H_M -Hamiltonian trajectory (m, α) such that $(m(0), \alpha(0)) = \tilde{\pi}(q(0), p(0))$; then for any $t \geq 0$, one has $(q(t), p(t)) \in \mathcal{H}^*$ and $(m(t), \alpha(t)) = \tilde{\pi}(q(t), p(t))$. Equivalently, one has the commutative diagram

$$\begin{array}{ccc} \mathcal{H}^* & \xrightarrow{\Phi_Q(\dots, t)} & \mathcal{H}^* \\ \downarrow \tilde{\pi} & & \downarrow \tilde{\pi} \\ T^*M & \xrightarrow{\Phi_M(\dots, t)} & T^*M, \end{array} \quad (30)$$

where Φ_H and Φ_Q are the associated Hamiltonian flows (in particular \mathcal{H}^* is Φ_Q invariant). To prove this fact, first, notice that from the definition of H_M , which can be rewritten as

$$H_M(\pi(q), \alpha) = H_Q(q, D\pi(q)^*\alpha),$$

one gets

$$(\rho | \partial_\alpha H_M) = (D\pi(q)^* \rho | \partial_p H_Q) \quad (31)$$

$$\text{and } (\partial_m H_M | D\pi(q)\xi) = (\partial_q H_Q | \xi) + (\alpha | D^2\pi(q)(\xi, \partial_p H_Q)) \quad (32)$$

(as usual, computations are assumed to be done within a chart, and the second derivative of π is defined according to this chart).

Define $x(t) \doteq (m(t), \alpha(t))$, $y(t) \doteq (q(t), p(t)))$, $z = (x, y)$ and the transformation

$$\psi(z) = (\psi_M(z), \psi^Q(z)) = (m - \pi(q), p - D\pi^*(q)\alpha).$$

One needs to prove that $\psi(z(t)) \equiv 0$.

If $Z(z) \doteq (\partial_\alpha H_M, -\partial_m H_M, \partial_p H_Q, -\partial_q H_Q)$ is the vector field governing the joint Hamiltonian flows (by construction $\partial_t z = Z(z)$), one has

$$D\psi(z)Z = 0 \text{ if } \psi(z) = 0. \quad (33)$$

Notice that this fact implies that Z is everywhere tangent to the set $\psi = 0$, which is locally a submanifold because $D\psi(z)$ has full rank, as can easily be seen. This implies that $\psi = 0$ is invariant by the flow associated to Z .

To prove (33), assume $\psi(z) = 0$ and notice that the statement is equivalent to $(\xi^M | D\psi_M(z)Z(z)) + (D\psi^Q(z)Z(z)|\zeta_Q) = 0$ for any $\zeta = (\xi^M, \zeta_Q)$. One has

$$(\xi^M | D\psi_M(z)Z(z)) = (\xi^M | \partial_\alpha H_M - D\pi(q)\partial_p H_Q)$$

and

$$\begin{aligned} (D\psi^Q(z)Z(z)|\zeta_Q) &= (-\partial_q H_Q + D\pi^*(q)\partial_m H_M|\zeta_Q) - (\alpha| D^2\pi(q)(\zeta_Q, \partial_p H)) \\ &= (\partial_m H_M | D\pi(q)\zeta_Q) - (\partial_q H_Q |\zeta_Q) - (\alpha| D^2\pi(q)(\partial_p H, \zeta_Q)), \end{aligned}$$

and the result is a direct consequence of (31) and (32).

Let us review how this concept of reduction via a submersion property generalizes the Riemannian submersion idea. When Q and M are Riemannian with M equipped with the projected metric, one has by construction

$$\langle \xi, \eta \rangle_q = \langle D\pi(q)\xi, D\pi(q)\eta \rangle_{\pi(q)} \quad (34)$$

for any $q \in M$ and $\xi \in \mathcal{H}_q$ horizontal at q . Let $K_q : T_q^* Q \rightarrow T_q Q$ be the duality operator for the metric at q (such that $(p|\xi) = \langle K_q p, \xi \rangle_q$) and K_m be the same operator for the metric on M . From (27), one gets

$$\mathcal{H}_q = K_q \mathcal{H}_q^*.$$

If one expresses (34) for $\xi = K_q D\pi(q)^*\alpha$ and $\eta = K_q D\pi(q)^*\beta$ and identifies the terms, one gets an equivalent version of (34) in terms of the duality operators, namely,

$$K_m = D\pi(q)K_q D\pi(q)^*, \quad (35)$$

the invariance assumption being that the right-hand term does not depend on $q \in \pi^{-1}(m)$. Now, the Hamiltonians associated to the metrics, respectively, are $H_Q(q, p) = (p|K_q p)/2$ and $H_M(m, \alpha) = (\alpha|K_m \alpha)/2$, and it is now straightforward to see that the condition $H_M(m, \alpha) = H_Q(q, D\pi(q)^*\alpha)$ if $\pi(q) = m$, that is, condition (28), is also equivalent to (35).

Reduction: Quotient Spaces

A fundamental special case of the previous situation is when π is the projection onto a quotient space $M = Q/G_s$ where G_s is a group of symmetries, acting on Q . A left action is assumed in the following, a right action being handled in a symmetrical way. Introduce the canonical projection $\pi : Q \rightarrow M$ which associates the orbit $G_s \cdot q$ to an element q of Q . Let us first work out conditions that ensure that a Hamiltonian H_Q is π -reducible. One needs

$$H_Q(q, p) = H_Q(q', p')$$

whenever $\pi(q) = \pi(q')$, and there exists $\alpha \in T_{\pi(q)}^*M$ such that $p = D\pi(q)^*\alpha$ and $p' = D\pi(q')^*\alpha$. Notice that $\pi(q) = \pi(q')$ implies that there exists a $g \in G$ such that $q' = g \cdot q$. From the relation $D\pi(q')(g \cdot \xi) = D\pi(q)\xi$ which derives from $\pi(g \cdot q) = \pi(q)$, one gets

$$(p|\xi) = (\alpha|D\pi(q)\xi) = (\alpha|D\pi(q')(g \cdot \xi)) = (p'|g \cdot \xi)$$

which implies that $p' = g \cdot p$ (this condition obviously implying that they correspond to the same α if they both are horizontal). So H_Q is π -reducible if and only if H_Q is G -invariant, namely,

$$H_Q(g \cdot q, g \cdot p) = H_Q(q, p) \tag{36}$$

For the construction made in the previous section to be useful in practice, one needs to provide a simple description of the cotangent bundle to M , T^*M . This will be done using the momentum map \mathfrak{m}_s for the action of G_s , and in particular the set

$$\mathfrak{m}_s^{-1}(0) = \{(q, p) \in T^*Q : \forall \xi \in \mathfrak{G}_s, (p|\xi \cdot q) = 0\} = \mathcal{H}^*.$$

Given this notation, one has the identification

$$\mathfrak{m}_s^{-1}(0)/G_s \cong T^*M. \tag{37}$$

First, notice that the right-hand term is meaningful, since, by the equivariance of the momentum map, $\mathfrak{m}_s^{-1}(0)$ is invariant by G_s . To prove (37), recall the transformation $\tilde{\pi} : \mathcal{H}^* = \mathfrak{m}_s^{-1}(0) \rightarrow T^*M$ by $\tilde{\pi}(q, p) = (m, \alpha)$ with $m = \pi(\alpha)$ and $p = D\pi(q)^*\alpha$. The last identity means that

$$(\alpha| D\pi(q)v) = (p| v),$$

and the condition $\mathfrak{m}_s(q, p) = 0$ implies that this definition is not ambiguous, since $D\pi(q)v = 0$ implies that $v = \xi \cdot q$ for some ξ , and therefore that $(p| v) = (\mathfrak{m}_s(q, p)| \xi) = 0$. (The definition does define $(\alpha| \rho)$ for all ρ because $D\pi(q)$ has full rank, since π is a submersion.)

The next remark is that $\tilde{\pi}$ induces a map $[\tilde{\pi}]$ on the quotient space $\mathfrak{m}_s^{-1}(0)/G_s$, defined by

$$[\tilde{\pi}](G_s \cdot (q, p)) = \tilde{\pi}(q, p).$$

Again, one must make sure that the definition makes sense by proving that $\tilde{\pi}(g \cdot q, g \cdot p) = \tilde{\pi}(p, q)$, but this is an immediate consequence of the definition of the extended action of G_s on T^*Q . Finally, $[\tilde{\pi}]$ is one to one, since as shown above if $\pi(q) = \pi(q') = m$ and $p = D\pi^*(q)\alpha$ and $p' = D\pi^*(q')\alpha$, then there exists $g \in G_s$ such that $(q', p') = (g \cdot q, g \cdot p)$. This proves the identification (37).

As an example, consider the reduction of the Hamiltonian

$$H(\mathbf{x}, \boldsymbol{\alpha}) = \frac{1}{2}\boldsymbol{\alpha}^T S_V(\mathbf{x})\boldsymbol{\alpha}$$

in the landmark case ($Q = Lmk_N$) and the invariance by the group $G_s = SE(\mathbb{R}^d)$. With $(\boldsymbol{\alpha}| \xi) = \sum_{k=1}^N \boldsymbol{\alpha}_k^T \xi_k$, the momentum map for this action is

$$(\mathfrak{m}_s(\mathbf{x}, \boldsymbol{\alpha})| (A, \tau)) = \sum_{k=1}^N \boldsymbol{\alpha}_k^T (Ax_k + \tau)$$

defined for all skew-symmetric matrix A and vector $\tau \in \mathbb{R}^d$, and the conditions for $\mathfrak{m}_s(\mathbf{x}, \boldsymbol{\alpha}) = 0$ are exactly those given in (10) and (11).

Note that condition (35) on the duality operator directly corresponds to the invariance conditions associated to the kernel K_V in section “Invariance.”

Reduction: Transitive Group Action

Consider the situation of a *left* group action $G \times M \rightarrow M$ of a group G on a manifold M . The important example in this chapter is when G is a group of diffeomorphisms and M is a set of “shapes” (for instance, $M = Lmk_N$). Assume that the action is transitive, that is, $G \cdot m_0 = M$ so that $\pi : G \rightarrow M$ defined by $\pi(g) = g \cdot m_0$ is a smooth surjection, that will be assumed to be a submersion. The situation here is on how to project a Hamiltonian system on G onto a reduced one on M .

Let

$$G_0 = \{g \in G \mid g \cdot m_0 = m_0\} = \pi^{-1}(m_0)$$

be the isotropy group of m_0 . Then condition (29) for a Hamiltonian H_G on G is equivalent to the invariance of H_G to the *right* action of G_0 on G , namely, $H_G(gh, \rho h) = H_G(g, \rho)$ for $h \in G_0$.

Although it is often more convenient to apply the reduction directly to π as defined above, since the structure of T^*M is generally easily defined in this context, it is interesting to notice that this reduction also comes as an application of the previous construction on quotient spaces via the well-known identification [32] $M \cong G/G_0$. This identity extends to cotangent spaces as above, with

$$\mathfrak{m}_G^{-1}(0)/G_0 \cong T^*M, \quad (38)$$

where \mathfrak{m}_G is the momentum map associated with G_0 .

One can interpret the construction of the Riemannian metric for landmarks within this framework. Take $M = Lmk_N$, G a group of diffeomorphisms, and $m_0 = \mathbf{x}_0$. If $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_N) \in T_{\mathbf{x}}M^*$, one can identify $p = D\pi^*(\varphi)\boldsymbol{\alpha}$ as

$$p = \sum_{i=1}^N \alpha_i \otimes \delta_{x_{0,i}},$$

since for any $v \in T_\varphi G$,

$$(p|v) = \sum_{i=1}^N (\alpha_i | v(x_{0,i}))$$

and $D\pi(\varphi)v = (v(x_{0,1}), \dots, v(x_{0,N}))$. Assume that a Riemannian metric is defined on G such that $\langle v, w \rangle_\varphi$ is associated with a duality operator K_φ that can be identified with a reproducing kernel also denoted K_φ (without assuming right invariance yet). With this assumption, one has

$$H_G(\mathbf{x}, \boldsymbol{\alpha}) = H(\varphi, p) = \frac{1}{2}(p|K_\varphi p) = \frac{1}{2} \sum_{i=1}^N \boldsymbol{\alpha}_i^T K_\varphi(x_{0,i}, x_{0,j}) \boldsymbol{\alpha}_j$$

The invariance assumption is now clear: one needs that $K_\varphi(x_{0,i}, x_{0,j})$ only depends on $\mathbf{x} = \varphi \cdot \mathbf{x}_0$. This is in particular implied by the full right-invariance assumption discussed in section ‘‘Application to the Group of Diffeomorphisms’’ for which $K_\varphi(x_{0,i}, x_{0,j}) = K_V(x_i, x_j)$, yielding in this case

$$H_M(\mathbf{x}, \boldsymbol{\alpha}) = \frac{1}{2} \sum_{i=1}^N \boldsymbol{\alpha}_i^T K_V(x_i, x_j) \boldsymbol{\alpha}_j$$

in the G -invariant case. As an alternative, one could, for example, also use the less restrictive assumption $K_\varphi(x_{0,i}, x_{0,j}) = K_{\mathbf{x}}(x_i, x_j)$ where $K_{\mathbf{x}}$ is still a kernel, like

in (7), (8), or (9), in which the scale parameter σ is chosen dependent of \mathbf{x} (e.g., increasing as a function of $|\mathbf{x} - \mathbf{x}_0|^2$).

The situation of a fully G -invariant Hamiltonian H_G can be studied in the general setting. Indeed, since G acts on M , one can consider the associated momentum map \mathfrak{m}_M on T^*M defined by

$$(\mathfrak{m}_M(m, \alpha)|\xi) = (\alpha|\xi \cdot m).$$

If $p = D\pi^*(g)(\alpha)$, then $pg^{-1} = \mathfrak{m}_M(m, \alpha)$. Indeed,

$$(pg^{-1}|\xi) = (p|\xi g) = (\alpha|D\pi(g)\xi g) = (\alpha|\xi \cdot m).$$

Hence,

$$H_M(m, \alpha) = H_G(g, p) = H_G(\text{id}_G, pg^{-1}) = H_G(\text{id}_G, \mathfrak{m}_M(m, \alpha)).$$

In the case of an invariant Riemannian metric $H(\text{id}_G, p) = \frac{1}{2}(p|K_V p) = \frac{1}{2}\|p\|_{\mathfrak{G}^*}^2$ where $\|\cdot\|_{\mathfrak{G}^*}$ denotes the dual norm, this gives

$$H_M(m, \alpha) = \frac{1}{2}\|\mathfrak{m}_M(m, \alpha)\|_{\mathfrak{G}^*}^2. \quad (39)$$

Spaces of Plane Curves

Introduction and Notation

We now consider two-dimensional shapes represented by their contours and address the case of spaces of plane curves. Compared to the space of landmarks, two new issues significantly complicate the theory. The first one is that curves are infinite-dimensional objects, which will place us in the framework of infinite-dimensional Riemannian manifolds. The second one is that curves are rarely labeled, which will require the analysis to be invariant by a change of parameterization.

Let us first start with a few definitions regarding plane curves. Parameterized plane curves can be seen as functions $\mathbf{x} : S^1 \rightarrow \mathbb{R}^2$, where S^1 is the unit circle in \mathbb{R}^2 . For simplicity, they will be assumed to be smooth (infinitely differentiable), unless specified otherwise. Smooth curves over the unit circle can equivalently be seen as infinitely differentiable 2π -periodic functions with periodic derivatives defined on the real line. It will be convenient to use both representations in the following.

One says that $\mathbf{x} : S^1 \rightarrow \mathbb{R}^2$ is an immersion (or an immersed curve) if its first differential never vanishes (one often also says that \mathbf{x} is a regular curve). We let \mathcal{I} denote the space of immersed curves. Immersed curves, which are easily characterized by their non-vanishing first derivative, are a convenient but a relatively imperfect representation of two-dimensional shapes, since they may include curves that self-intersect. A more restrictive class is the space of embedded curves, that contains immersed curves that coincide, in the neighborhood of any point, and

after a suitable rotation, with the graph of a smooth function. But because being embedded is a global statement about the curve, and therefore harder to handle than being immersed which is just local, this discussion will primarily focus on the space \mathcal{I} .

We let $\tau(u) = \dot{\mathbf{x}}(u)/|\dot{\mathbf{x}}(u)|$ be the unit tangent at u (or $\mathbf{x}(u)$) to \mathbf{x} ; $\nu(u)$ be the unit normal, obtained by rotating $\tau(u)$ of $\pi/2$; and $\kappa(u)$ be the curvature, given by

$$\kappa = (\partial_s \tau)^T \nu = \dot{\tau}_u^T \nu / |\dot{\mathbf{x}}_u|$$

where, following [55], we let ∂_s denote the operator $\partial_u/|\dot{\mathbf{x}}_u|$.

A change of parameter (or reparameterization) for a curve is a smooth diffeomorphism $u \mapsto \psi(u)$ of S^1 or, alternatively, a smooth increasing diffeomorphism of the real line such that for all $u \in \mathbb{R}$,

$$\psi(u + 2\pi) = \psi(u) + 2\pi.$$

Changes of parameter act on parameterized curves on the right via

$$(\psi, \mathbf{x}) \mapsto \mathbf{x} \circ \psi.$$

A normalized arc-length parameterization of \mathbf{x} is a change of parameter taking the form

$$s(u) = s_0 + \frac{2\pi}{L} \int_0^u |\dot{\mathbf{x}}_u(\tilde{u})| d\tilde{u} \quad (40)$$

and L is the length of \mathbf{x} with

$$\text{length}(\mathbf{x}) = \int_0^{2\pi} |\dot{\mathbf{x}}_u(\tilde{u})| d\tilde{u}.$$

The scalar number s_0 intervening in the arc-length parameterization can be assumed to be between 0 and 2π without loss of generality and will be referred to as the offset of the parameterization.

The quotient space of immersed curves by reparameterization is the space of geometric curves, denoted \mathcal{B} . This space can in turn be quotiented out by the actions of rotations, translations, and scaling, which act on the left and commute with changes of parameter, in the sense that the result of applying a similitude and a change of parameters does not depend on the order with which these operations are performed.

The goal in this section is to discuss shape spaces of curves obtained by putting a Riemannian structure on \mathcal{B} , possibly quotiented by Euclidean transformations and/or scaling. But before this discussion, it will be interesting to list a few of the basic distances that can be defined on this set without using a Riemannian construction.

Some Simple Distances

We here consider some simple parameterization-free distances between curves based on the images of the curves (the set $\mathbf{x}(\mathbb{R})$).

A very simple example is to use standard norms (like L^p or Sobolev norms) computed on the difference between two curves parameterized with their normalized arc length. Take, for example, the L^2 norm, and define for two curves \mathbf{x} and $\tilde{\mathbf{x}}$ parameterized with normalized arc length

$$d_{L^2}(\mathbf{x}, \tilde{\mathbf{x}}) = \inf_{s_0} \left(\int_0^{2\pi} |\mathbf{x}(s + s_0) - \tilde{\mathbf{x}}(s)|^2 ds \right) \quad (41)$$

the infimum being taken over all possible offsets as defined in Eq. (40).

One must apply some care when defining distances like (41) which involves some optimization over some parameters that affect the curves. The following statement (the proof of which is left to the reader) is a key for this to be a valid way of building distances on quotient spaces.

Lemma 1. *Let M be a metric space, with distance $d : (\mathbf{x}, \mathbf{x}') \mapsto d(\mathbf{x}, \mathbf{x}')$. Let G be a group acting on M (with, say, a left action). Assume that d is G -invariant, which means that, for all $\mathbf{x}, \mathbf{x}' \in M$ and all $g \in G$,*

$$d(g \cdot \mathbf{x}, g \cdot \mathbf{x}') = d(\mathbf{x}, \mathbf{x}').$$

Then the distance \bar{d} defined on the quotient space M/G by

$$\bar{d}([\mathbf{x}], [\mathbf{x}']) = \inf_{g, g' \in G} d(g \cdot \mathbf{x}, g' \cdot \mathbf{x}') \quad (42)$$

is symmetric and satisfies the triangle inequality.

Notice that, because of the G -invariance, \bar{d} is also given by

$$\bar{d}([\mathbf{x}], [\mathbf{x}']) = \inf_{g \in G} d(g \cdot \mathbf{x}, \mathbf{x}'). \quad (43)$$

A sufficient condition ensuring that \bar{d} is a distance (the missing property being $d([\mathbf{x}], [\mathbf{x}']) = 0 \Rightarrow [\mathbf{x}] = [\mathbf{x}']$) is that the orbits $[\mathbf{x}] = G \cdot \mathbf{x}$ are closed subsets of M for all $\mathbf{x} \in M$. The invariance condition can be placed in parallel with the invariance condition that arose in our discussion of the Riemannian submersion, the latter being an infinitesimal version of the former in the case of Riemannian metrics.

Returning to (41), it is easy to see that a change of offset provides a group action on the left on curves and that the L^2 distance is invariant to this action. It is not too hard to prove that the action has closed orbits so that (41) does provide a valid distance in \mathcal{B} . Since the L^2 distance is also invariant by the left action of rotations and translations, one can also define

$$\bar{d}_{L^2}(\mathbf{x}, \tilde{\mathbf{x}}) = \inf_{s_0, \theta, b} \left(\int_0^{2\pi} |g_\theta \mathbf{x}(s + s_0) + b - \tilde{\mathbf{x}}(s)|^2 ds \right), \quad (44)$$

where g_θ is the rotation of angle θ and $b \in \mathbb{R}^2$.

A variant of this distance directly compares the derivative of the curves, which provides a translation-invariant representation, defining

$$\bar{d}_{H^1}(\mathbf{x}, \tilde{\mathbf{x}}) = \inf_{s_0, \theta} \left(\int_0^{2\pi} |g_\theta \partial_s \mathbf{x}(s + s_0) - \partial_s \tilde{\mathbf{x}}(s)|^2 ds \right). \quad (45)$$

This distance has been introduced for curve comparison in [48], with a very efficient computation algorithm based on Fourier transforms.

When a curve \mathbf{x} is simple (i.e., without self-intersection), it can be considered as the boundary of a bounded set (its interior) that will be denoted $\Omega_{\mathbf{x}}$. A simple distance comparing two such curves, say \mathbf{x} and \mathbf{x}' , is the area of the symmetric difference between $\Omega_{\mathbf{x}}$ and $\Omega_{\mathbf{x}'}$, that is,

$$d_{\text{sym}}(\mathbf{x}, \mathbf{x}') = \text{area}(\Omega_{\mathbf{x}} \cup \Omega_{\mathbf{x}'}) - \text{area}(\Omega_{\mathbf{x}} \cap \Omega_{\mathbf{x}'}).$$

A more advanced notion, the Hausdorff distance, is defined by

$$d_H(\mathbf{x}, \mathbf{x}') = \inf\{\varepsilon > 0, \mathbf{x} \subset B_\varepsilon(\mathbf{x}') \text{ and } \mathbf{x}' \subset B_\varepsilon(\mathbf{x})\},$$

where $B_\varepsilon(\mathbf{x})$ is the set of points at distance less than ε from \mathbf{x} (and similarly for $B_\varepsilon(\mathbf{x}')$). The same distance can be used with $\overline{\Omega}_{\mathbf{x}}$ and $\overline{\Omega}_{\mathbf{x}'}$ instead of \mathbf{x} and \mathbf{x}' for simple closed curves, the Hausdorff distance being in fact a distance between closed subsets of \mathbb{R}^2 .

Instead of comparing curves that are already parameterized with arc length, one can start with distances that are invariant by reparameterization and quotient out this action as described in Lemma 1. It is not easy to come up with explicit formulae for such invariant distances, but here is an important example.

Start with the supremum norm between the curves, namely,

$$d_\infty(\mathbf{x}, \mathbf{x}') = \sup_u |\mathbf{x}(u) - \mathbf{x}'(u)|,$$

which is obviously invariant by changes of parameter. The distance obtained after reduction is called the *Fréchet distance* and is therefore defined by

$$d_F(\mathbf{x}, \mathbf{x}') = \inf_\psi d_\infty(\mathbf{x} \circ \psi, \mathbf{x}').$$

Note that, if, for some reparameterization ψ , one has $d_\infty(\mathbf{x} \circ \psi, \mathbf{x}') \leq \varepsilon$, then $\mathbf{x} \subset B_\varepsilon(\mathbf{x}')$ and $\mathbf{x}' \subset B_\varepsilon(\mathbf{x})$. This implies the relation

$$\varepsilon > d_F(\mathbf{x}, \mathbf{x}') \Rightarrow \varepsilon > d_H(\mathbf{x}, \mathbf{x}')$$

which implies $d_H \leq d_F$. As a consequence, $d_F(\mathbf{x}, \mathbf{x}') = 0$ is only possible when $\mathbf{x} = \mathbf{x}'$ up to reparameterization, which completes Lemma 1 in ensuring that d_F is a distance.

Another interesting point of view that leads to parameterization-invariant distances is to include plane curves in a suitable Hilbert space. We have already seen an example of this with the L^2 distance based on the arc-length parameterization, although this one required an extra one-dimensional optimization to get rid of the offset. An interesting alternate option (two of them, in fact) can be obtained by considering curves as linear forms instead of functions.

One can first identify a curve to a measure, which is a linear form on continuous functions, defined by, for a curve, \mathbf{x} and for a function $f : \mathbb{R}^2 \rightarrow \mathbb{R}$:

$$(\mu_{\mathbf{x}} | f) = \int_0^{2\pi} f(\mathbf{x}(u)) |\dot{\mathbf{x}}_u(u)| du.$$

This is clearly parameterization independent, and more precisely, $\mu_{\mathbf{x}} = \mu_{\mathbf{y}}$ if and only if $\mathbf{x} = \mathbf{y}$ up to reparameterization or change of orientation.

Another point of view is to identify a curve to a current [19] or, equivalently in this case, to a vector measure which is a linear form on vector fields. For this, simply define, for $f : \mathbb{R}^2 \rightarrow \mathbb{R}^2$,

$$(v_{\mathbf{x}} | f) = \int_0^{2\pi} \dot{\mathbf{x}}_u(u)^T f(\mathbf{x}(u)) du.$$

This is also parameterization independent, with $v_{\mathbf{x}} = v_{\mathbf{y}}$ if and only if $\mathbf{x} = \mathbf{y}$ up to reparameterization.

Both (signed) measures and vector measures form linear spaces, even if not all of them correspond to curves. Nonetheless any norm on these spaces directly induces a parameterization-invariant distance between curves. Hilbert norms are specially attracting for this purpose because of the numerical convenience of being associated to a dot product. One way to build such norms is to start with a Hilbert space of functions on \mathbb{R}^2 (resp. vector fields) for which $\mu_{\mathbf{x}}$ (resp. $v_{\mathbf{x}}$) is continuous and then use the corresponding norm on the dual space [22–25, 73].

Start with the case of scalar functions and consider a Hilbert space W of functions $f : \mathbb{R}^2 \rightarrow \mathbb{R}$ such that the evaluation functionals $x \mapsto f(x)$ are continuous (so that W is a reproducing kernel Hilbert space of scalar functions). Denote by $L_W : W \rightarrow W^*$ and $K_W : W^* \rightarrow W$ the duality operators on W , similarly to what has been introduced in section “A Riemannian Manifold of Deformable Landmarks” with L_V and K_V , so that for $f \in W$ and $\mu \in W^*$,

$$\|f\|_W^2 = (L_W f | f) \text{ and } \|\mu\|_{W^*}^2 = (\mu | K_W \mu).$$

Like in section “A Riemannian Manifold of Deformable Landmarks,” K_W is a kernel operator, and there exists a scalar-valued function $(x, y) \mapsto K_W(x, y)$ such that for a measure μ ,

$$(K_W \mu)(x) = \int_{\mathbb{R}^2} K_W(x, y) d\mu(y).$$

This implies

$$\|\mu\|_{W^*}^2 = \int_{\mathbb{R}^2 \times \mathbb{R}^2} K_W(x, y) d\mu(x) d\mu(y)$$

and directly leads to a distance between curves, namely,

$$\begin{aligned} d(\mathbf{x}, \mathbf{x}')^2 &= \|\mu_{\mathbf{x}} - \mu_{\mathbf{x}'}\|_{W^*}^2 \\ &= \int_0^{2\pi} \int_0^{2\pi} K_W(\mathbf{x}(u), \mathbf{x}(u')) |\dot{\mathbf{x}}(u)| |\dot{\mathbf{x}}(u')| du du' \\ &\quad - 2 \int_0^{2\pi} \int_0^{2\pi} K_W(\mathbf{x}(u), \mathbf{x}'(u')) |\dot{\mathbf{x}}(u)| |\dot{\mathbf{x}}'(u')| du du' \\ &\quad + \int_0^{2\pi} \int_0^{2\pi} K_W(\mathbf{x}'(u), \mathbf{x}'(u')) |\dot{\mathbf{x}}'(u)| |\dot{\mathbf{x}}'(u')| du du'. \end{aligned} \tag{46}$$

The construction associated to vector measures is similar. The space W being this time a space of vector fields, the discussion is identical to the one holding for V in section “A Riemannian Manifold of Deformable Landmarks,” with a kernel K_W which is matrix valued. Other than this, the resulting norm in the dual space is formally the same, yielding

$$\begin{aligned} d(\mathbf{x}, \mathbf{x}')^2 &= \|v_{\mathbf{x}} - v_{\mathbf{x}'}\|_{W^*}^2 \\ &= \int_0^{2\pi} \int_0^{2\pi} \dot{\mathbf{x}}_u^T K_W(\mathbf{x}(u), \mathbf{x}(u')) \dot{\mathbf{x}}_u(u') du du' \\ &\quad - 2 \int_0^{2\pi} \int_0^{2\pi} \dot{\mathbf{x}}_u^T K_W(\mathbf{x}(u), \mathbf{x}'(u')) \dot{\mathbf{x}}_u(u') du du' \\ &\quad + \int_0^{2\pi} \int_0^{2\pi} \dot{\mathbf{x}}_u'^T K_W(\mathbf{x}'(u), \mathbf{x}'(u')) \dot{\mathbf{x}}_u'(u') du du'. \end{aligned} \tag{47}$$

Riemannian Metrics on Curves

We now pass to the specific problem of designing Riemannian metrics on spaces of curves. The first issue we have to deal with is that we are now handling infinite-dimensional manifolds, which is significantly more complex than the finite-dimensional space of landmarks. Since there is more than one type of infinite-dimensional vector spaces, there is more than one type of infinite-dimensional manifolds, and the one which is appropriate when dealing with spaces of infinitely

differentiable curves is the class of *Fr  chet manifolds* [31]. It is not our intent, here, to handle the related issues with the appropriate scrutiny, the reader being invited to refer to [54, 55] for a more rigorous presentation. We will here simply state intuitively plausible facts on the structures that are defined.

The space \mathcal{I} of immersed curves is open in the Fr  chet space $C^\infty(S^1, \mathbb{R}^2)$ of infinitely differentiable functions from S^1 to \mathbb{R}^2 (in which a sequence of curves \mathbf{x}_n converges to \mathbf{x} if all its derivatives converge for the supremum norm). If $\mathbf{x} \in \mathcal{I}$, a tangent vector $\xi \in T_m \mathcal{I}$ is an element of $C^\infty(S^1, \mathbb{R}^2)$ that can also be considered as a smooth vector field along \mathbf{x} . A Riemannian metric on \mathcal{I} will therefore be a norm on this space, namely,

$$\xi \mapsto \|\xi\|_{\mathbf{x}}$$

associated to an inner product $\langle \cdot, \cdot \rangle_{\mathbf{x}}$ that depends on $\mathbf{x} \in \mathcal{I}$.

We will consider norms that allow for Riemannian projections when quotienting out the action of changes of parameters, as well as the action of the usual transformation groups, $SE(\mathbb{R}^2)$ possibly combined with scaling. Starting with changes of parameters, the differential of the map $\mathbf{x} \mapsto \mathbf{x} \circ \psi$ simply is $\xi \mapsto \xi \circ \psi$, which yields the first requirement

$$\|\xi \circ \psi\|_{\mathbf{x} \circ \psi} = \|\xi\|_{\mathbf{x}} \quad (48)$$

for all $\mathbf{x} \in \mathcal{I}$, $\xi \in C^\infty(S^1, \mathbb{R}^2)$ and smooth reparameterization ψ . A simple way to ensure parameterization invariance is to define the norm for curves that are parameterized with normalized arc length, simply ensuring that the norm is invariant by a change of offset.

Invariance with respect to translations, rotations, and scaling, respectively, requires

$$\|\xi\|_{\mathbf{x}+b} = \|\xi\|_{\mathbf{x}}, \quad b \in \mathbb{R}^2 \quad (49)$$

$$\|g\xi\|_{g\mathbf{x}} = \|\xi\|_{\mathbf{x}}, \quad g \in SO(\mathbb{R}^2) \quad (50)$$

$$\lambda \|\xi\|_{\lambda\mathbf{x}} = \|\xi\|_{\mathbf{x}}, \quad \lambda \in (0, +\infty). \quad (51)$$

A very simple norm, which satisfies (48)–(50), is the L^2 norm of ξ relative to the curve arc length, which is

$$\|\xi\|_{\mathbf{x}}^2 = \int_0^{2\pi} |\xi(u)|^2 |\dot{\mathbf{x}}_u| du. \quad (52)$$

This norm has been studied in [54, 55] and shown to provide degenerate Riemannian metrics in the sense that the projected Riemannian distance between any two curves is zero.

Before elaborating on this fact, consider vertical vectors for the projection of \mathcal{I} onto the space \mathcal{B} of curves modulo reparameterization. They are described as

follows. Tangent vectors at \mathbf{x} to the orbit of \mathbf{x} under the action of changes of parameters are obtained as $\xi = (\partial_\varepsilon(\mathbf{x} \circ \psi))(0, u)$, where $\varepsilon \mapsto \psi(\varepsilon, u)$ is a reparameterization in u which smoothly depends on ε . This yields $\xi = \partial_\varepsilon \psi(0, u) \dot{\mathbf{x}}_u \circ \psi(0, u)$, which implies that vertical vectors $\xi \in \mathcal{V}_m$ are such that all $\xi(u)$ are tangent to \mathbf{x} .

Horizontal vectors at \mathbf{x} for the metric in (52) are therefore given by vector-valued functions $\xi \mapsto \xi(u)$ that are everywhere normal to \mathbf{x} . It follows that if $[\mathbf{x}]$ and $[\mathbf{x}']$ are two equivalent classes of curves modulo reparameterization, their geodesic “distance” is given by

$$d(\mathbf{x}, \mathbf{x}')^2 = \inf \left\{ \int_0^1 \int_0^{2\pi} |\dot{\mathbf{y}}_t|^2 |\dot{\mathbf{y}}_u| du dt, \mathbf{y}(0, .) = \mathbf{x}, [\mathbf{y}(1, .)] = \mathbf{x}', \dot{\mathbf{y}}_u^T \dot{\mathbf{y}}_t = 0 \right\}. \quad (53)$$

As written above, one has the following theorem.

Theorem 1 (Mumford–Michor). *The distance defined in (53) vanishes between any pair of smooth curves \mathbf{x} and \mathbf{x}' .*

A proof of this result can be found in [54, 55]. It relies on the remark that one can grow thin protrusions (“teeth”) on a curve at a cost which is negligible compared to the size of the tooth. To get the basic idea underlying this result, one can understand how open segments can be translated at arbitrary small geodesic cost. First, consider a path that starts with a horizontal segment; progressively grow an isosceles triangle of width ε and height t (at time t) somewhere on the segment until $t = 1$. A quick computation shows that the associated geodesic length is $o(\varepsilon)$ (in fact, $O(\varepsilon^2 \ln \varepsilon)$). This implies that one can cover the horizontal segment with $O(1/\varepsilon)$ thin non-overlapping teeth at cost $O(\varepsilon \ln \varepsilon)$. With a similar construction and the same cost, one can pull up the triangles pointing downward to obtain a translated segment. The total cost of the operation being arbitrarily small when $\varepsilon \rightarrow 0$, the geodesic distance between parallel segments is zero. This can in fact be extended to any pair of close or open curves, yielding the result stated in Theorem 1.

Quite interestingly, small variations in the definition of the metric are sufficient to address this issue. Take, for example, the distance associated with

$$\|\xi\|_{\mathbf{x}}^2 = \text{length}(\mathbf{x}) \int_0^{2\pi} |\xi(u)|^2 |\dot{\mathbf{x}}_u| du, \quad (54)$$

introduced in [52, 62]. Looking back at the previous “tooth example,” the length of a teeth being approximately 2, we see that the length term penalizes the geodesic energy when growing $O(1/\varepsilon)$ teeth by an extra $(1/\varepsilon)$ factor, and the total energy is not negligible anymore. In fact, the associated distance is not degenerate, as shown in [62], in which the geodesic length is proved to correspond to the total area swept by the time-dependent curve.

Another way to control degeneracy is to penalize high curvature points, using, for example,

$$\|\xi\|_{\mathbf{x}}^2 = \int_0^{2\pi} (1 + a\kappa_{\mathbf{x}}(u)^2) |\xi(u)|^2 |\dot{\mathbf{x}}_u| du. \quad (55)$$

This metric has been studied in [55], where it is shown (among other results) that the distance between distinct curves is positive.

All the previous metrics could be put in the form

$$\|\xi\|_{\mathbf{x}}^2 = \int_0^{2\pi} \rho_{\mathbf{x}}(u) |\xi(u)|^2 |\dot{\mathbf{x}}_u| du, \quad (56)$$

where $\rho_{\mathbf{x}} > 0$ is invariant by reparameterization, in the sense that

$$\rho_{\mathbf{x} \circ \psi} \circ \psi = \rho_{\mathbf{x}}.$$

More generally, one can consider metrics associated to positive symmetric linear operators $\xi \mapsto A_{\mathbf{x}}\xi$ which associate to a smooth vector $u \mapsto \xi(u)$ along \mathbf{x} another smooth vector, $u \mapsto (A_{\mathbf{x}}\xi)(u)$, with the properties that

$$\int_0^{2\pi} (\eta)^T (A_{\mathbf{x}}\xi) |\dot{\mathbf{x}}_u| du = \int_0^{2\pi} (A_{\mathbf{x}}\eta)^T \xi |\dot{\mathbf{x}}_u| du$$

and

$$A_{\mathbf{x} \circ \psi}(\xi \circ \psi) = (A_{\mathbf{x}}\xi) \circ \psi.$$

The geodesic equation associated to such a metric can be derived by computing the first variation of the geodesic energy. The computation is straightforward if one makes the following assumption on the variations of the operator $A_{\mathbf{x}}$. Assume that there exists a bilinear operator $D'A_{\mathbf{x}}$ that takes as input two vector fields along \mathbf{x} , say $\xi(\cdot)$ and $\eta(\cdot)$, and return a new vector $D'A_{\mathbf{x}}(\xi, \eta)(\cdot)$ such that

$$\partial_{\varepsilon} \int_0^{2\pi} (A_{\mathbf{x}+\varepsilon\xi}\xi)^T \eta |\dot{\mathbf{x}}_u| du = \int_0^{2\pi} (D'A_{\mathbf{x}}(\xi, \eta))^T \xi |\dot{\mathbf{x}}_u| du,$$

where the derivative in the left-hand side is evaluated at $\varepsilon = 0$. With this notation, the geodesic equation is

$$\partial_t (A_{\mathbf{x}} \dot{\mathbf{x}}_t) + (\partial_s \dot{\mathbf{x}}_t)^T \tau A_{\mathbf{x}} \dot{\mathbf{x}}_t + \frac{1}{2} \partial_s \left((A_{\mathbf{x}} \dot{\mathbf{x}}_t)^T \dot{\mathbf{x}}_t \tau \right) = \frac{1}{2} D'A_{\mathbf{x}}(\dot{\mathbf{x}}_t, \dot{\mathbf{x}}_t) \quad (57)$$

with $\partial_s = \partial_u / |\dot{\mathbf{x}}_u|$ as above.

This class of metrics includes the so-called *Sobolev metrics* [52, 56] for which

$$\int_0^{2\pi} (A_{\mathbf{x}} \xi)^T \xi du = \sum_{k=0}^p a_k(\mathbf{x}) \int_0^{2\pi} |\partial_s^k \xi|^2 du$$

with positive coefficients $a_k(\mathbf{x})$, typically depending on the length of \mathbf{x} . Let us take one simple example that has interesting developments: define

$$\int_0^{2\pi} (A_{\mathbf{x}} \xi)^T \xi du = \text{length}(\mathbf{x})^{-1} \int_0^{2\pi} |\partial_s \xi|^2 du \quad (58)$$

or $A_{\mathbf{x}} \xi = -\text{length}(\mathbf{x})^{-1} \partial_s^2 \xi$. The metric associated to $A_{\mathbf{x}}$ is degenerate, since it vanishes over constants. But it provides a metric on curves modulo translations. It satisfies the invariance properties described above, characterized in (48), (50), and (51). This metric was first introduced in [79] and further studied in [68, 69, 81]. A direct computation shows that, in this case,

$$D' A_{\mathbf{x}}(\xi, \eta) = 2\text{length}(\mathbf{x})^{-1} \partial_s ((\partial_s \xi)^T \partial_s \eta \tau) - \text{length}(\mathbf{x})^{-1} \langle \xi, \eta \rangle_{\mathbf{x}} \kappa \nu.$$

The study of this metric is, however, much simpler than replacing the expression of $D' A_{\mathbf{x}}$ into (57) would make believe. The simplification comes after the following transformation of the curve representation. Consider the transformation, defined over pairs of real-valued functions $u \mapsto (\mathbf{a}(u), \mathbf{b}(u))$ by

$$\mathbf{x}(u) = \left(\frac{1}{2} \int_0^u (\mathbf{a}^2 - \mathbf{b}^2) d\tilde{u}, \int_0^u \mathbf{a} \mathbf{b} d\tilde{u} \right), \quad u \in [0, 2\pi], \quad (59)$$

so that

$$\dot{\mathbf{x}}_u = ((a^2 - b^2)/2, ab).$$

With the notation above, we have $|\dot{\mathbf{x}}_u| = (a^2 + b^2)/2$. This generate a curve in \mathbb{R}^2 , with length

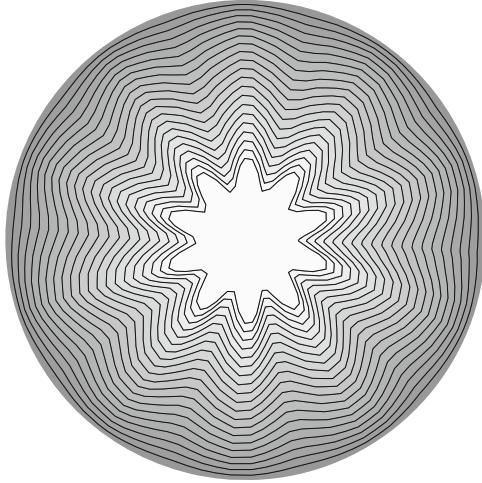

$$\text{length}(\mathbf{x}) = \frac{1}{2} \int_0^{2\pi} (\mathbf{a}^2 + \mathbf{b}^2) du = \frac{1}{2} (\|\mathbf{a}\|_2^2 + \|\mathbf{b}\|_2^2).$$

Denoting by $\mathbf{x} = T(\mathbf{a}, \mathbf{b})$ the transformation in Eq.(59), one can write the differential of T as

$$DT(\mathbf{a}, \mathbf{b})(\boldsymbol{\alpha}, \boldsymbol{\beta}) : u \mapsto \left(\int_0^u (\mathbf{a}\boldsymbol{\alpha} - \mathbf{b}\boldsymbol{\beta}) d\tilde{u}, \int_0^u (\mathbf{b}\boldsymbol{\alpha} + \mathbf{a}\boldsymbol{\beta}) d\tilde{u} \right)$$

and a direct computation yields

Fig. 4 An example of a geodesic connecting a circle to a star-shaped curve for the metric defined in (58). The evolving curves are superimposed with progressively reduced size to facilitate visualization (the compared curves having both length 1 originally)

$$\|DT(\mathbf{a}, \mathbf{b})(\boldsymbol{\alpha}, \boldsymbol{\beta})\|T(\mathbf{a}, \mathbf{b}) = 2 \frac{\sqrt{\|\boldsymbol{\alpha}\|_2^2 + \|\boldsymbol{\beta}\|_2^2}}{\sqrt{\|\mathbf{a}\|_2^2 + \|\mathbf{b}\|_2^2}}.$$

Restricting to closed curves with unit length implies the conditions

$$\|\mathbf{a}\|_2 = \|\mathbf{b}\|_2 = 1 \text{ and } \langle \mathbf{a}, \mathbf{b} \rangle_2 = 0$$

which means that (\mathbf{a}, \mathbf{b}) forms an orthonormal two-frame in the space $L^2(S^1)$, that is, an element of the Stiefel manifold $\text{St}(L^2, 2)$. Up to the factor two, the mapping T is then an isometry between $\text{St}(L^2, 2)$, equipped with its standard metric, and the subset of \mathcal{I} consisting of unit-length curves. If one furthermore makes the reduction of quotienting out rotations for curves, one finds that the isometry becomes with the Grassmannian manifold $\text{Gr}(L^2, 2)$ of two-dimensional subspaces of L^2 . This identification can be exploited to obtain explicit geodesics in the considered shape space (see [81]). It is important to notice that the restriction to curves with unit length is equivalent to making the Riemannian projection on the quotient space modulo scalings. This is because horizontal vectors for the scale action can easily be shown to satisfy $\int (\partial_s \xi)^T \tau = 0$, which, if $\xi = \dot{\mathbf{x}}_t$, directly implies that $\partial_t (\int |\dot{\mathbf{x}}_u|^2) = 0$. Therefore, length is conserved along horizontal geodesics, which justifies the choice of unit-length curves. Some numerical issues associated to this metric are studied in [68] and [69] in the simpler case in which it is applied to open curves. An example of geodesic obtained using this metric is provided in Fig. 4.

A parameterized variant of this metric, applied to closed curves with unit length, has been proposed in [43], in the form

$$\|\xi\|_{\mathbf{x}}^2 = \int_0^{2\pi} ((\partial_s)\xi^T \tau)^2 |\dot{\mathbf{x}}_u| du + c \int_0^{2\pi} ((\partial_s)\xi^T \nu)^2 |\dot{\mathbf{x}}_u| du,$$

the previous metric corresponding to $c = 1$. When $c \neq 1$, the unit length constraint is not induced by a Riemannian projection, but the metric can be studied on this space anyway.

One can analyze this metric in the following way. Let $\mathbf{x}(t, u)$ be a time-dependent curve. Define $\lambda = |\dot{\mathbf{x}}_u|$ so that

$$\partial_s \dot{\mathbf{x}}_t = \lambda^{-1} \partial_t (\lambda \tau) = \partial_t (\log \lambda) \tau + \partial_t \tau.$$

Since the two terms in the sum are perpendicular, this gives

$$\|\dot{\mathbf{x}}_t\|_{\mathbf{x}}^2 = \int_0^{2\pi} ((\partial_t \log \lambda)^2 + c |\partial_t \tau|^2) |\dot{\mathbf{x}}_u| du. \quad (60)$$

The first term measures the logarithmic variation of the arc length, and the second is the instantaneous rotation of the tangents. Interestingly, another change of variable akin to the one discussed for $c = 1$ can also simplify this metric in the case $c = 4$. Take, in this case,

$$\mathbf{x} = T(a, b) := u \mapsto \left(\int_0^u a \sqrt{a^2 + b^2} du', \int_0^u b \sqrt{a^2 + b^2} du' \right);$$

one has this time

$$\|DT(a, b)(\alpha, \beta)\|_{T(a, b)}^2 = 4 \int_0^{2\pi} (\alpha^2 + \beta^2) du$$

which provides an identification of the space of open curves with unit length with an infinite-dimensional sphere. This identification has the important property to carry over to higher-dimensional curves [37]. There is, however, no “nice” representation for closed curves in this case.

Notice that the two identifications that were just discussed apply to parameterized curves. In both cases, the geodesic distance must be optimized with respect to reparameterization to obtain a metric between geometric curves.

Another important contribution to the theory of spaces of plane curves was made in [63], in which simple closed domains in \mathbb{R}^2 are represented via the correspondence maps between the conformal mapping of their interior and of their exterior to the unit disc. This induces an almost one-to-one representation of simple curves by diffeomorphisms of the unit circle. In fact, this representation has to come modulo Möbius transformations on the circle, which are very simply accommodated by an invariant metric, called the Weil–Peterson metric, on such diffeomorphisms. The reader is referred to the cited work for more details.

Projecting the Action of 2D Diffeomorphisms

At the exception of the one just mentioned, the previously discussed metrics were all defined based on the parameterizations of the curves. This provided reasonably simple definitions, exploiting in particular the invariance property of the arc length. Because they relied on local properties of the curves, these metrics were not able to penalize singularities that occur globally, like the intersection of two remote parts.

One way to handle global constraints is to use an approach similar to the one that has been used to define the landmark manifold, based on the action of two-dimensional diffeomorphisms on curves. This will therefore be based on the projection paradigm discussed in section “Reduction: Transitive Group Action.”

So, let $G \subset \text{Diff}(\mathbb{R}^2)$ be a group of smooth diffeomorphisms of \mathbb{R}^2 (which, say, smoothly converge to the identity at infinity), and let \mathbf{x}_0 be a reference curve or template. Consider the set $M = G \cdot \mathbf{x}_0$, the orbit of \mathbf{x}_0 under the action of G , the latter being simply defined by

$$(\varphi \cdot \mathbf{x})(u) = \varphi(\mathbf{x}(u)).$$

This implies that $D\pi(\varphi)v = v \circ \mathbf{x}_0$ and a horizontal covector at $\varphi \in G$ for the projection takes the form

$$(p|v) = (\rho|v \circ \mathbf{x}_0)$$

for some $\rho \in T_{\varphi(\mathbf{x}_0)}M^*$.

Let’s make this explicit for ρ belonging to an important class of linear forms on $T_{\mathbf{x}}M$, associated to vector measures, that is,

$$(\rho|\xi) = \int_0^{2\pi} \xi^T \mathbf{a} d\mu$$

where μ is a measure on the unit circle and \mathbf{a} is a vector-valued function. The associated horizontal covector is then

$$(p|v) = \int_0^{2\pi} v(\mathbf{x}_0(u))^T \mathbf{a}(u) d\mu(u) \quad (61)$$

and the reduced Hamiltonian computed on this covector is (denoting as in section “Reduction: Transitive Group Action” K_φ the duality operator on $T_\varphi G$, still assumed to be associated to a reproducing kernel)

$$H_M(\mathbf{x}, \rho) = \frac{1}{2} \int_0^{2\pi} \int_0^{2\pi} \mathbf{a}(u)^T K_\varphi(\mathbf{x}_0(u), \mathbf{x}_0(u')) \mathbf{a}(u') d\mu(u') d\mu(u) \quad (62)$$

with $\mathbf{x} = \varphi \cdot \mathbf{x}_0$. As in section “Reduction: Transitive Group Action,” the invariance requirement boils down to $K_\varphi(\mathbf{x}_0(u), \mathbf{x}_0(u'))$ only depending on $\varphi \cdot \mathbf{x}_0$, with the simplest choice associated to a right-invariant metric on G , yielding

$$H_M(\mathbf{x}, \rho) = \frac{1}{2} \int_0^{2\pi} \int_0^{2\pi} \mathbf{a}(u)^T K_V(\mathbf{x}(u), \mathbf{x}(u')) \mathbf{a}(u') d\mu(u') d\mu(u) \quad (63)$$

for a fixed kernel K_V . An important fact is that measure covectors remain so during the evolution, the Hamiltonian (or geodesic) equations are simply written as

$$\begin{cases} \partial_t \mathbf{x}(t, u) = \int_0^{2\pi} K_V(\mathbf{x}(t, u), \mathbf{x}(t, \tilde{u})) \mathbf{a}(t, \tilde{u}) d\mu(\tilde{u}) \\ \partial_t \mathbf{a}(t, u) = - \sum_{i,j=1}^2 \int_0^{2\pi} \mathbf{a}^i(t, u) \mathbf{a}^j(t, \tilde{u}) \nabla_1 K^{ij}(\mathbf{x}(t, u), \mathbf{x}(t, \tilde{u})) d\mu(\tilde{u}) \end{cases} \quad (64)$$

Another interesting fact is that (64) exactly provides (6) in the case when μ is a weighted sum of Dirac measures. This is because these equations are, as proved in section ‘‘Reduction via a Submersion,’’ all particular instances of the Hamiltonian system (or geodesic equation) obtained on the acting group of diffeomorphisms, namely, (25).

This was the first step downward, from diffeomorphisms to parameterized plane curves. It remains to discuss the additional steps, which are the reduction for the required invariance, by reparameterization and Euclidean transformation.

Consider the action of reparameterization, which is a right action. The action of change of parameters on vector measures like in (61) is

$$(p \cdot \psi | \xi) = \int_0^{2\pi} \mathbf{a}^T \xi \circ \psi^{-1} d\mu(u) = \int_0^{2\pi} (a \circ \psi)^T \xi d(\psi^{-1} \mu)(u),$$

where $\psi \cdot \mu$ is the image of μ by ψ . Using this, the invariance requirement applied to a Hamiltonian taking the form

$$H_M(\mathbf{x}, \rho) = \frac{1}{2} \int_0^{2\pi} \int_0^{2\pi} \mathbf{a}(u)^T K_{\mathbf{x}}(u, u') \mathbf{a}(u') d\mu(u') d\mu(u) \quad (65)$$

can be seen to reduce to the constraint that

$$K_{\mathbf{x} \circ \psi}(\psi^{-1}(u), \psi^{-1}(u)) = K_{\mathbf{x}}(u, u')$$

and this property is satisfied for $K_{\mathbf{x}}(u, u) = K_V(\mathbf{x}(u), \mathbf{x}(u'))$.

The momentum map associated to changes of parameters is

$$(\mathbf{m}(\mathbf{x}, p) | v) = \int_0^{2\pi} \mathbf{a}(u)^T \dot{\mathbf{x}}_u v(u) d\mu(u),$$

so that horizontal vector measures simply are those for which \mathbf{a} is normal to the curve, that is, $\mathbf{a}(u) = \alpha(u) \mathbf{v}(u)$, where α is scalar valued and \mathbf{v} is the normal to \mathbf{x} . The evolution equations then become

$$\begin{cases} \partial_t \mathbf{x}(t, u) = \int_0^{2\pi} K_V(\mathbf{x}(t, u), \mathbf{x}(t, \tilde{u})) \boldsymbol{\alpha}(t, \tilde{u}) \mathbf{v}(t, \tilde{u}) d\tilde{u} \\ \partial_t \boldsymbol{\alpha}(t, u) = -\boldsymbol{\alpha}(t, u) \sum_{i,j=1}^2 \int_0^{2\pi} \boldsymbol{\alpha}(t, \tilde{u}) \mathbf{v}^i(t, u) \mathbf{v}^j(t, \tilde{u}) \nabla_1 K^{ij}(\mathbf{x}(t, u), \mathbf{x}(t, \tilde{u})) d\tilde{u}. \end{cases} \quad (66)$$

If K_V is furthermore invariant by rotation and translation, quotienting out these operations results in additional conditions on $\boldsymbol{\alpha}$. Invariance by translation requires

$$\int_0^{2\pi} \boldsymbol{\alpha}(u) \mathbf{v}(u) du = 0,$$

and the constraint associated to rotations is

$$\int_0^{2\pi} \boldsymbol{\alpha}(u) (\mathbf{v}(u) \mathbf{x}(u)^T - \mathbf{x}(u) \mathbf{v}(u)^T) du = 0.$$

Extension to More General Shape Spaces

The construction based on the Riemannian submersion from groups of diffeomorphisms can be reproduced in a large variety of contexts, essentially for any class of objects that can be deformed by diffeomorphisms. This can be applied to provide metrics on space of surfaces and spaces of images, of vector fields, of measures, etc.

Let us consider, for example, the case of images that we will take as differentiable functions $I : \mathbb{R}^d \rightarrow \mathbb{R}$. Define the left action of a diffeomorphism φ on an image I to be

$$\varphi \cdot I = I \circ \varphi^{-1}.$$

From this, one sees that the infinitesimal action of a vector field V on I is

$$\mathbf{v} \cdot I = -\mathbf{v}^T \nabla I.$$

(This is why we assumed that the images are differentiable. For non-differentiable images, $\mathbf{v} \cdot I$ is not a function, but a distribution, with, if ρ is a smooth function,

$$(\mathbf{v} \cdot I | \rho) = \int_{\mathbb{R}^d} I \nabla \cdot (\rho \mathbf{v}) dx,$$

where $\nabla \cdot$ is the divergence operator. The reader is referred to [75, 76] for the analysis of the inexact matching approach in the more general case of images with bounded variations.)

Fix a reference image I_0 and consider the space

$$M = \{\varphi \cdot I_0, \varphi \in G\},$$

the surjection being as usual $\pi(\varphi) = \varphi \cdot I_0$. Consider covectors on M that are associated to measures, namely,

$$(\rho | \xi) = \int_{\mathbb{R}^d} \xi(x) d\rho(x),$$

where ξ is a real-valued function (which represents a tangent vector to M). The differential of $\pi(\varphi) = I_0 \circ \varphi^{-1}$ is (letting $\psi = \varphi^{-1}$)

$$D\pi(\varphi)v = -(\nabla I_0 \circ \varphi^{-1}) D(\varphi^{-1})v \circ \varphi^{-1} = -\nabla I^T v \circ \varphi^{-1}$$

with $I = \varphi \cdot I_0$, so that the horizontal covector at $\varphi \in G$ associated to a measure ρ is $p = D\pi(\varphi)^* \rho$ defined by

$$(p | v) = - \int_{\mathbb{R}^d} v(\varphi^{-1}(x))^T \nabla I(x) d\rho(x),$$

where $I = \varphi \cdot I_0$. Starting from a Hamiltonian associated to a right-invariant metric on G yields the reduced Hamiltonian

$$\begin{aligned} H_M(I, \rho) &= \frac{1}{2} \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} \nabla I(x)^T K_\varphi(\varphi^{-1}(x), \varphi^{-1}(y)) \nabla I(y) d\rho(y) d\rho(x) \\ &= \frac{1}{2} \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} \nabla I(x)^T K_V(x, y) \nabla I(y) d\rho(y) d\rho(x) \end{aligned}$$

with $K_\varphi(x, y) = K_V(\varphi(x), \varphi(y))$. The associated Hamiltonian equations are

$$\begin{cases} \partial_t I(x) = \int_{\mathbb{R}^d} \nabla I(x)^T K_V(x, y) \nabla I(y) d\rho(y) dy \\ \partial_t \alpha = \nabla \cdot (\alpha K_V(\nabla I \rho)) \end{cases}$$

A limitation in the image case is that two given images are very rarely connected by diffeomorphisms, so that working with images that are deformations of a reference image is a strong restriction. This issue can be addressed by extending the projection to a larger set than the sole group of diffeomorphisms. One can use a simple construction for this: call M the space of *all* smooth images (instead of just an orbit, as it was defined before), and still let G denote a group of smooth diffeomorphisms. Consider the surjection $\pi : G \times M \rightarrow M$ defined by

$$\pi(\varphi, I) = \varphi \cdot I.$$

(This is obviously a surjection since $I = \pi(\text{id}_{\mathbb{R}^d}, I)$.)

Letting $J = I \circ \varphi^{-1}$, one has

$$D\pi(\varphi, I)(v, \xi) = -\nabla J^T v \circ \varphi^{-1} + \xi \circ \varphi^{-1},$$

so that the horizontal covector at (φ, I) associated to a measure ρ on M is $\bar{p} = D\pi(\varphi, I)^*\rho$ such that

$$(p| (v, \xi)) = \int_{\mathbb{R}^d} (-\nabla J^T v \circ \varphi^{-1} + \xi \circ \varphi^{-1}) d\rho$$

with $J = I \circ \varphi^{-1}$. Thinking of a covector $\bar{p} \in T_{(\varphi, I)}(G \times M)^*$ as a pair (p, η) with $p \in T_\varphi G^*$ and $\eta \in T_I M^*$, one can identify $(p, \eta) = D\pi(\varphi, I)^*\rho$ as

$$(p| v) = - \int_{\mathbb{R}^d} \nabla J^T v \circ \varphi^{-1} d\rho \text{ and } (\eta| \xi) = \int_{\mathbb{R}^d} \xi \circ \varphi^{-1} d\rho.$$

If $d\rho = \rho dx$ is absolutely continuous with respect to Lebesgue's measure, the second term gives $\eta = \rho \circ \varphi \det D\varphi dx$.

If one starts with a Hamiltonian on $G \times M$ for which

$$H((\varphi, I), (p, \eta dx)) = \frac{1}{2}(p| K_\varphi p) + \frac{\lambda}{2} \int_{\mathbb{R}^d} \eta(x)^2 (\det D\varphi(x))^{-1} dx$$

with K_φ as above, the resulting reduced Hamiltonian on M is

$$\begin{aligned} H_M(J, \rho dx) &= \frac{1}{2} \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} \rho(x) \nabla J(x)^T K_V(x, y) \nabla J(y) \rho(y) dx dy \\ &\quad + \frac{\lambda}{2} \int_{\mathbb{R}^d} \rho(x)^2 dx. \end{aligned}$$

The corresponding evolution equations then are

$$\begin{cases} \partial_t J = \nabla J^T K_V(\rho \nabla J) + \lambda \rho \\ \partial_t \rho = \nabla \cdot (\rho K_V(\rho \nabla J)). \end{cases}$$

This is a particular instance of the theory of metamorphosis applied to images (the interested reader can refer to [35, 71] for further developments).

Applications to Statistics on Shape Spaces

An important situation in which the previously discussed concepts are relevant is for the analysis of shape samples, that is, families $\mathbf{x}_1, \dots, \mathbf{x}_n$, in which each \mathbf{x}_j is a shape, possibly represented as a collection of landmarks or a plane curve (or another representation, like surfaces, images, etc.), and interpreted as a point in a manifold M . A simple and commonly used approach to analyze such samples is to "normalize" them using the exponential or momentum representation relative to a fixed template $\bar{\mathbf{x}}$. Each shape \mathbf{x}_k is then transformed into a tangent or cotangent vector, say $\xi_k \in T_{\bar{\mathbf{x}}}M$ so that $\mathbf{x}_k = \exp_{\bar{\mathbf{x}}}(\xi_k)$.

The problem is then reduced to the well-explored context of data analysis in a linear space, and how it is analyzed afterward depends on the specific problem at hand and is out of the scope of the present discussion. An important thing that one should remember is that this reduction can be accompanied with significant metric distortion, related to curvature as described in section “Metric Distortion and Curvature” (in spaces with positive curvature, the representation may even fail to be one to one). The approach has however proved to be a powerful analysis tool in several applications [20, 42], including the analysis of medical data [74].

This distortion being larger when the distances between the represented shapes and the template are large, it is natural to select the template in a way that minimizes these distances, the most widespread approach being to define it as a Karcher (or geometric) mean, that is, as a minimizer of

$$U(\mathbf{x}) = \sum_{k=1}^n d_M(\mathbf{x}, \mathbf{x}_k)^2. \quad (67)$$

This well-posedness of this definition is also related to the curvature. The function U is convex and the minimum is unique if M has negative curvature [39]. Negative curvature is unfortunately difficult to obtain in shape spaces because the reduction process always increases the sectional curvature [59] (notice however that the representation in [63] has negative curvature, but it seems to be the only such example). The sectional curvature on the landmark manifold, as shown in [53], can be both positive and negative. As proved in [39], a sufficient condition ensuring the convexity of U (67) is that the diameter of the sample set (the largest geodesic distance between two of the points) is smaller than $\pi / (2\sqrt{s_{\max}})$, where s_{\max} is a positive upper bound of the sectional curvature (U is always convex with negative curvature). Interestingly, in that case, the optimality condition of the Karcher mean is that it constitutes a sample average in the exponential representation, that is, $\mathbf{x}_k = \exp_{\bar{\mathbf{x}}}(\xi_k)$ with $\sum_{k=1}^n \xi_k = 0$. This leads to an algorithm for the computation of the mean, which can be proved to converge under similar curvature conditions [46, 47]: start with an initial guess for $\bar{\mathbf{x}}$ and compute the exponential representation ξ_k over the sample set. Compute $\bar{\xi} = \sum_{k=1}^n \xi_k / n$, replace $\bar{\mathbf{x}}$ by $\exp_{\bar{\mathbf{x}}}(-\bar{\xi})$, and iterate until stabilization. A variation of this algorithm has been proposed in [21]. One can also mention the interesting algorithm proposed in [13] in which kernel regression is generalized to shape manifolds.

4 Numerical Methods and Case Examples

The most important numerical method on the previously discussed shape spaces is related to the computation of geodesics (i.e., solving the geodesic equation) and, most importantly in practice, to the computation of the representation in the exponential chart or of the momentum representation.

This section will focus on the latter problem (which anyway includes the first one as a subproblem) that will first be addressed in the simpler case of the landmark manifold.

To compute exponential coordinates around some object \mathbf{x}_0 , one needs to solve, for some target object \mathbf{y} , the equation

$$\exp_{\mathbf{x}_0}(\xi) = \mathbf{y} \quad (68)$$

or, if the momentum representation is more convenient,

$$\exp_{\mathbf{x}_0}^b(\alpha) = \mathbf{y}. \quad (69)$$

Since these representations are defined by nonlinear evolution equations, this is a highly nonlinear problem, in which the function to be inverted cannot be written in closed form. Also, in the case of curves, the problem is infinite dimensional and must therefore be properly discretized. Another non-negligible issue is that, even if the equation has a solution (which is often the case in the discussed framework), this solution is not necessarily unique unless \mathbf{y} is close enough to \mathbf{x}_0 . For this reason, it may be impossible to represent a generic shape dataset using only one of these charts, but this may be achievable for a more focused one (like shapes of fish, or leaves, of fixed anatomical organs).

There are mainly two options to address the computation. The first one is to directly solve the equation (using zero-finding methods, like Newton's algorithm). The second one is to return to the definition of geodesics as curves with minimal energy and to solve the variational problem of finding minimal energy paths between \mathbf{x}_0 and \mathbf{y} .

Landmark Matching via Shooting

Let us start with the first approach. Recall that given some differentiable function $F : \mathbb{R}^n \rightarrow \mathbb{R}^n$, Newton's method to solve the equation $F(z) = 0$ iterates (starting with a good guess of the solution, z_0)

$$z_{k+1} = z_k - DF(z_k)^{-1} F(z_k).$$

This scheme can be directly applied to the solution of (69) in the landmark case, with $F(\alpha_0) = \exp_{\mathbf{x}_0}^b(\alpha_0) - \mathbf{y}$, since it is finite dimensional; one needs this to compute the differential of the momentum representation, which is only described in (6) via the solution of a differential equation. As a result, the differential of F , which is also the differential of $\exp_{\mathbf{x}_0}^b$, must also be computed by solving a differential equation. Noting that (6) takes the form

$$\begin{cases} \partial_t \mathbf{x} = Q(\mathbf{x}, \boldsymbol{\alpha}) \\ \partial_t \boldsymbol{\alpha} = R(\mathbf{x}, \boldsymbol{\alpha}, \boldsymbol{\alpha}) \end{cases} \quad (70)$$

with Q linear and R quadratic in $\boldsymbol{\alpha}$, and that $\mathbf{x}(t) = \exp_{\mathbf{x}_0}^b(t\boldsymbol{\alpha}_0)$, we have denoting

$$J(t) = D\exp_{\mathbf{x}_0}^b(t\boldsymbol{\alpha}_0) \quad (71)$$

$$\begin{cases} \partial_t J\boldsymbol{\beta} = \partial_1 Q(\mathbf{x}, \boldsymbol{\alpha}) J\boldsymbol{\beta} + Q(\mathbf{x}, H\boldsymbol{\beta}) \\ \partial_t H\boldsymbol{\beta} = \partial_1 R(\mathbf{x}, \boldsymbol{\alpha}, \boldsymbol{\alpha}) J\boldsymbol{\beta} + 2R(\mathbf{x}, \boldsymbol{\alpha}, H\boldsymbol{\beta}) \end{cases} \quad (72)$$

in which H is an auxiliary operator that represents the variation in $\boldsymbol{\alpha}$ (and ∂_1 is the differential with respect to the first variable). Solving (70) and (72) up to time $t = 1$ provides $\mathbf{x}(1)$ and $J(1)$, and the Newton step is given by

$$\boldsymbol{\alpha}_0^{k+1} = \boldsymbol{\alpha}_0^k - J(1)^{-1}(\mathbf{x}(1) - \mathbf{y}).$$

Making explicit the expressions of $\partial_1 Q$ and $\partial_1 R$ is not difficult, but rather lengthy, and these expressions will not be provided here (the interested reader can refer to [1] for more details). An important limitation for the feasibility of this kind of approach is the cost involved in the computation of the full matrix $J(t)$. With N landmarks in d dimensions, the size of \mathbf{x} and $\boldsymbol{\alpha}$ is $n = Nd$ and the size of J is n^2 . The computation of the right-hand side of (72) requires an order of n^3 operations if one takes advantages of the special structure of the operator $Q(\mathbf{x}, \cdot)$ (it would be n^4 otherwise). Even with this reduction, a computation cost which is cubic in the number of landmarks rapidly becomes unfeasible, and it is difficult to run this algorithm with, say, more than a few hundred landmarks. On the other hand, convergence (when it happens) can require a very small number of steps.

Another limitation of Newton's method is the fact that it is not guaranteed to converge, unless the starting point ($\boldsymbol{\alpha}_0^0$ with our notation) is close enough to the solution, in a way which is generally impossible to quantify a priori. For this reason, the method is often usefully complemented (and possibly replaced if the number of landmarks is too large) by simple gradient descent in which the minimized function is

$$F(\boldsymbol{\alpha}_0) = (\exp_{\mathbf{x}_0}^b(\boldsymbol{\alpha}_0) - \mathbf{y})^T (\exp_{\mathbf{x}_0}^b(\boldsymbol{\alpha}_0) - \mathbf{y}).$$

The first variation of F is, with the previous notation,

$$\partial_\varepsilon F(\boldsymbol{\alpha}_0 + \varepsilon\boldsymbol{\beta})|_{[\varepsilon=0]} = 2 (\exp_{\mathbf{x}_0}^b(\boldsymbol{\alpha}_0) - \mathbf{y})^T J(1)\boldsymbol{\beta}.$$

It is natural to define gradients relative to the Riemannian metric at \mathbf{x}_0 , as defined in Eq. (4). When working with momenta as done here, the gradient should be identified using

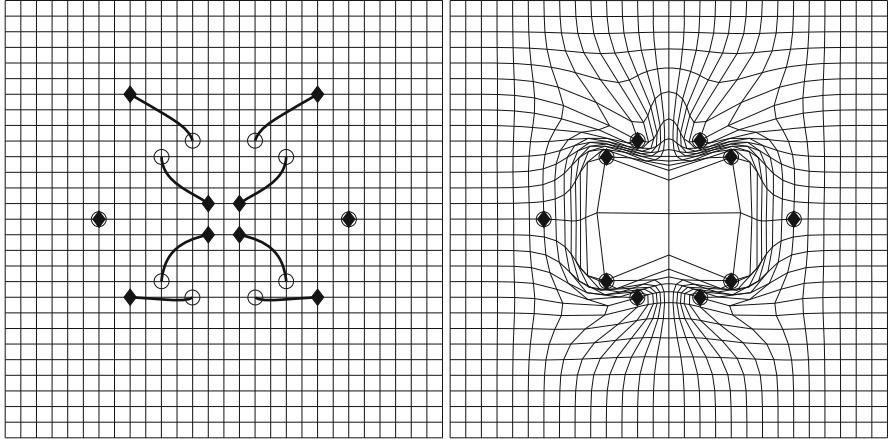

Fig. 5 Example of geodesics between two landmark configurations: *left*, trajectories (diamonds move onto circles), and *right*, resulting diffeomorphism

$$\boldsymbol{\beta}^T S_V(\mathbf{x}_0) \nabla F(\boldsymbol{\alpha}_0) = 2 (\exp_{\mathbf{x}_0}^b(\boldsymbol{\alpha}_0) - \mathbf{y})^T J(1) \boldsymbol{\beta}$$

yielding

$$\nabla F(\boldsymbol{\alpha}_0) = 2 S_V(\mathbf{x}_0)^{-1} (J(1)^T (\exp_{\mathbf{x}_0}^b(\boldsymbol{\alpha}_0) - \mathbf{y})). \quad (73)$$

The computation, for a given vector \mathbf{z} , of $J(t)^T \mathbf{z}$ can be done by solving backward in time the system

$$\begin{cases} \partial_t \boldsymbol{\xi} = -(\partial_1 Q(\mathbf{x}, \boldsymbol{\alpha}))^T \boldsymbol{\xi} - (\partial_1 R(\mathbf{x}, \boldsymbol{\alpha}, \boldsymbol{\alpha}))^T \mathbf{a} \\ \partial_t \mathbf{a} = -Q(\mathbf{x})^T \boldsymbol{\xi} - 2R(\mathbf{x}, \boldsymbol{\alpha})^T \mathbf{a} \end{cases} \quad (74)$$

initialized with $(\boldsymbol{\xi}(1), \mathbf{a}(1)) = (\mathbf{z}, 0)$, with the notation $Q(\mathbf{x})\boldsymbol{\beta} = Q(\mathbf{x}, \boldsymbol{\beta})$ and $R(\mathbf{x}, \boldsymbol{\alpha})\boldsymbol{\beta} = R(\mathbf{x}, \boldsymbol{\alpha}, \boldsymbol{\beta})$. One then has $J(1)^T \mathbf{z} = \mathbf{a}(0)$. The proof of this statement derives from elementary computations on linear dynamical systems.

This implies that the term $J(1)^T (\exp_{\mathbf{x}_0}^b(\boldsymbol{\alpha}_0) - \mathbf{y})$ can be computed by solving an ODE which has the same dimension as the geodesic Eq. (70). Notice, however, that (74) requires using the solution of (70) with a backward time evolution (from $t = 1$ to $t = 0$). This implies that the solution of (70) must be first computed and stored with a fine enough time discretization to allow for an accurate solution of (74). This may cause memory issues for high-dimensional models. An example of trajectories and deformations estimated using this algorithm is provided in Fig. 5.

The above discussion only addressed the computation of geodesics in landmark shape space without quotienting out rotations and translations. Recall that this operation, when done starting from a metric for which the projection on the quotient space is a Riemannian submersion, only requires to constrain the momentum

representation with a finite number of linear relations. The associated reduction in the number of degrees of freedom is balanced by the reduced requirement of connecting the reference shape to some element of the orbit of the target under the quotiented out group action, instead of the target itself. More explicitly, the equations that need to be solved to compute the momentum representation of \mathbf{y} relative to \mathbf{x}_0 are

$$\begin{cases} \exp_{\mathbf{x}_0}^{\mathbf{b}}(\boldsymbol{\alpha}_0) - g \cdot \mathbf{y} = 0 \\ \sum_{k=1}^N \alpha_{0,k} = 0 \\ \sum_{k=1}^N (\alpha_{0,k} \mathbf{x}_{0,k}^T - \mathbf{x}_{0,k} \boldsymbol{\alpha}_{0,k}^T) = 0, \end{cases} \quad (75)$$

where $g \in SE(\mathbb{R}^d)$. A transformation g in this space is represented by a rotation part, R , and a translation part, b , and classically parameterized in the form

$$\begin{pmatrix} R & b \\ 0 \dots 0 & 1 \end{pmatrix} = \exp \begin{pmatrix} A & \omega \\ 0 \dots 0 & 0 \end{pmatrix}$$

with A skew symmetric and $\omega \in \mathbb{R}^d$. System (75) therefore has $Nd + d(d+1)/2$ equations and variables and can be solved as above using Newton iterations when feasible or gradient descent. Since the exponential is the solution of a differential equation ($\partial_t \exp(tU) = U \exp(tU)$), optimization in A and ω above can be treated exactly like the optimization in $\boldsymbol{\alpha}_0$. Another option is to directly use the formula

$$\partial_\varepsilon \exp(U + \varepsilon h)|_{\varepsilon=0} = \int_0^1 \exp(tU) h \exp(-tU) dt.$$

Landmark Matching via Path Optimization

The other option, in order to compute the momentum representation, is to solve the shortest path problem between \mathbf{x}_0 and \mathbf{y} , that is, to minimize

$$E(\mathbf{x}(\cdot)) = \int_0^1 \|\dot{\mathbf{x}}_t\|_{\mathbf{x}(t)}^2 dt,$$

with the constraints $\mathbf{x}(0) = \mathbf{x}_0$ and $\mathbf{x}(1) = \mathbf{y}$, using gradient descent on the space of all trajectories $t \mapsto \mathbf{x}(t)$. Letting $P(\mathbf{x}, \boldsymbol{\xi}) = \|\boldsymbol{\xi}\|_{\mathbf{x}}^2$, one has

$$\partial_\varepsilon E(\mathbf{x}(\cdot) + \varepsilon \boldsymbol{\xi}(\cdot))|_{\varepsilon=0} = \int_0^1 \left(2 \langle \dot{\mathbf{x}}_t, \dot{\boldsymbol{\xi}}_t \rangle_{\mathbf{x}(t)} + \partial_1 P(\mathbf{x}, \dot{\mathbf{x}}_t)^T \boldsymbol{\xi} \right) dt.$$

Using gradient descent requires selecting an appropriate metric on the space of all time-dependent objects, and interesting developments arise when selecting a metric for which the constraints are continuous functionals [26, 37]. Consider, as an example, the inner product

$$\langle \xi(\cdot), \eta(\cdot) \rangle = \int_0^1 \dot{\xi}_t^T \dot{\eta}_t dt$$

that we restrict to the space of time-dependent ξ and η that vanish at $t = 0$ and $t = 1$. One can check that, defining

$$\begin{aligned} \eta_x(t) &= \int_0^t S_V(\mathbf{x}(u)) \dot{\mathbf{x}}_t(u) du - \int_0^t \int_0^u \partial_1 \mathbf{P}(\mathbf{x}(\tilde{u}), \dot{\mathbf{x}}_t(\tilde{u})) d\tilde{u} du \\ &\quad + (1+t) \int_0^t \partial_1 \mathbf{P}(\mathbf{x}(u), \dot{\mathbf{x}}_t(u)) du, \end{aligned}$$

one has

$$\partial_\varepsilon E(\mathbf{x}(\cdot) + \varepsilon \xi(\cdot))|_{\varepsilon=0} = \langle \xi, \nabla E(\mathbf{x}) \rangle$$

with

$$\nabla E(\mathbf{x})(t) = \eta_x(t) - t \eta_x(1).$$

One can therefore use gradient descent to minimize the geodesic energy, in the form

$$\mathbf{x}^{(n+1)}(t) = \mathbf{x}^{(n)}(t) - \varepsilon (\eta_{x^{(n)}}(t) - t \eta_{x^{(n)}}(1)).$$

Computing Geodesics Between Curves

We now discuss whether, and how, the previous methods extend to the computation of minimizing geodesics in Riemannian spaces of curves. We start with the metric associated with the projection from 2D diffeomorphisms, since it belongs to the same family as the one discussed with landmarks. In fact, there is a simple way to discretize a curve matching problem so that it boils down to a landmark matching problem. Assume that a reference curve \mathbf{x}_0 and a target curve \mathbf{y} are given but that they are only observable in discrete versions, as sequences of points $\mathbf{x}_0^{\text{disc}} = (x_{0,1}, \dots, x_{0,N})$ and $\mathbf{y}^{\text{disc}} = (y_1, \dots, y_N)$. Then, as we have remarked, Eq. (25) when restricted to discrete momenta of the form

$$\mu = \sum_{k=1}^N a_k \otimes \delta_{x_k},$$

boils down to Eq. (6), and one can now solve the problem of finding a solution of this equation that transports $x_{0,k}$ to y_k exactly as in the previous sections.

Unfortunately, such an approach has little practical use, given that it is very unlikely that two discrete curves are observed such that the points that constitute them are exactly homologous. This means that one should not require a given $x_{0,k}$ to transform exactly into y_k , but maybe to another y_l or in between two of them. Most of the time, anyway, the curves are given with different numbers of points.

This issue is obviously the discrete form of the parameterization invariance that has been discussed in section “Spaces of Plane Curves.” We know that the horizontality condition for parameterization invariance induces the constraint that a_k is perpendicular to the reference curve. In this context, the problem in the continuum is formulated as: given \mathbf{x}_0 and \mathbf{y} , find an initial momentum μ_0 which is horizontal at \mathbf{x}_0 and such that the solution of (25) transforms the curve \mathbf{x}_0 into a deformed curve $\varphi(1, \mathbf{x}_0)$ which coincides with \mathbf{y} up to a change of parameterization.

A change of parameter being a diffeomorphism of S^1 , it can be generated with an equation like (25). Roughly speaking, this change of parameter can be generated by momenta that are scalar functions on the unit circle. Horizontal geodesics in spaces of curves (still roughly speaking) are generated by momenta that are normal to the reference curve, which can also be represented as scalar functions on the unit disc. So, one needs to find two scalar functions (one for the reparameterization and one for the deformation) that bring the reference curve \mathbf{x}_0 to the target \mathbf{y} ; the target being also characterized by two scalar functions (its coordinates), one sees that the dimensions match and that an approach based on zero finding is possible, at least in principle (there has been no attempt so far in the literature to solve the curve comparison problem in this way). The problem needs to be properly discretized, using, for example, the same number of points to represent \mathbf{x}_0 , \mathbf{y} , the reparameterization momentum, and the deformation momentum.

One can also use a variational approach in the initial momentum, using an objective function like

$$E(\mathbf{a}_0) = d(\exp_{\mathbf{x}_0}^b(\mathbf{a}_0), \mathbf{y})^2 \quad (76)$$

where d is a reparameterization-invariant distance, like the ones in Eqs. (46) and (47), which are, since they derive from Hilbert norms, well amenable to variational computations. The initial momentum a_0 can be discretized as

$$\mathbf{a}_0 = \sum_{k=1}^N a_{0,k} \otimes \delta_{u_k},$$

where u_1, \dots, u_N is a discretization of the unit disc, which, as already noticed, lead to geodesic equations identical to the ones considered with landmarks in (6), the initial “landmark positions” being $x_{0,k} = \mathbf{x}_0(u_k)$. This implies that the variational methods discussed in section “Landmark Matching via Shooting” directly apply, simply changing the objective function.

In fact, the same point of view can also be used with other metrics on curves, with the correct version of the exponential chart or of the momentum representation (whichever is more convenient). Notice that enforcing the fact that the initial momentum is horizontal for reparameterization is optional for these methods, as long as the objective function (the distance d) is parameterization invariant. Disregarding discretization issues, the optimal solution will always be horizontal, so one does not need to make an exact count of the minimal number of degrees of freedom, as was required by zero-finding methods. In practice, the computational efficiency resulting from the reduction of the number of variables can be counterbalanced by the additional flexibility in moving in the space of solutions which is offered by over-parameterized formulations, the choice between the two options being problem dependent.

Finally, notice that path-minimizing methods are also available for curve matching (an approach similar to the one discussed for landmarks in the previous section has been proposed in [37]).

Inexact Matching and Optimal Control Formulation

Inexact Matching

In many cases, requiring an exact representation of the target \mathbf{y} in the exponential chart is not needed and even undesirable. In most instances, indeed, there is an inherent inaccuracy in the way objects are acquired. Landmarks, whether manually or automatically selected, are rarely well defined, and the process can lead to significant variability. The same holds for curves, or surfaces, which are generally extracted using segmentation algorithms, sometimes applied to noisy data, with results that cannot be assumed to be perfect.

Formulations in which geodesics are only required to provide a good approximation of the target then make sense and have a large range of applications. They are akin to the variational methods that were discussed for exact representation, in that they minimize an appropriate distance between the end point of a geodesic and the target, but they also include a penalty term on the length or the energy of the geodesic. In other terms, instead of minimizing $d(\exp_{\mathbf{x}_0}^b(\mathbf{a}_0), \mathbf{y})^2$ like in (76), for example, one would minimize

$$E(\mathbf{a}_0) = d(\exp_{\mathbf{x}_0}^b(\mathbf{a}_0), \mathbf{y})^2 + \sigma^2 \|\mathbf{a}_0\|_{\mathbf{x}_0}^2$$

(in the momentum representation, the norm is for the dual metric in the cotangent space at \mathbf{x}_0). If it is more convenient to use an exponential chart instead of the momentum representation, just minimize, over all tangent vectors ξ_0 at \mathbf{x}_0 ,

$$E(\xi_0) = d(\exp_{\mathbf{x}_0}(\xi_0), \mathbf{y})^2 + \sigma^2 \|\xi_0\|_{\mathbf{x}_0}^2$$

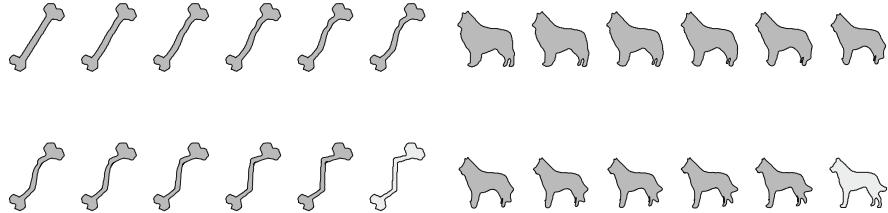

Fig. 6 Two results of inexact matching with the vector-measure distance between curves as error term. The lower right curve (*light gray*) is the target. The first 11 curves provide the geodesic evolution

Since this formulation only adds the term $2\sigma^2 \mathbf{a}_0$ (or $2\sigma^2 \xi_0$) to the gradient of the objective function that was used for exact representation (i.e., with $\sigma^2 = 0$), the methods that were described in the previous paragraphs can be adapted with minor changes and yield, for example, results like those provided in Fig. 6. Interestingly, in this context, additional methods, deriving from optimal control theory, become available too.

Optimal Control Formulation

Let us first return to the general principles discussed in section “General Principles” and consider an optimal control problem with an additional end-point cost E :

$$\text{minimize} \int_0^1 L(q, u) dt + E(q(1)) \text{ subject to } \dot{q} = f(q, u) \text{ and } q(0) \text{ fixed.}$$

Notice that here $q(1)$ is free, but this situation is handled quite similarly to the one with fixed $q(1)$. Introduce

$$\begin{aligned} J_E(q, p, u) &= J_0(q, p, u) + E(q(1)) \\ &= \int_0^1 (L(q, u) + (p | \dot{q}_t - f(q, u))) dt + E(q(1)). \end{aligned}$$

The only change in the analysis arises when working out the variation in q which now gives the extra end-point condition

$$p(1) + DE(q(1)) = 0, \quad (77)$$

which come in addition to the previously obtained (13).

The conservation of the momentum map can be extended to this case when a group G acts on Q and the Hamiltonian H is G -invariant. If, in addition, E is also G -invariant, one deduces from $E(qg) = E(q)$ for all g the fact that $(DE(q)|\xi g) = 0$ for all $\xi \in \mathfrak{G}$ which is exactly $\mathbf{m}(q, DE(q)) = 0$ where the momentum map \mathbf{m} is

defined in (16). Therefore, (77) implies that $\mathfrak{m}(q(1), p(1)) = 0$, which, combined with the conservation of momentum, implies that

$$\mathfrak{m}(q(t), p(t)) = 0.$$

for any $t \in [0, 1]$. Thus, the momentum map is not only invariant but vanishes along solutions of the optimal control problem. In the context of the reduction discussed in section ‘‘Reduction: Transitive Group Action,’’ this says that the momentum associated to a solution is horizontal.

Gradient w.r.t. the Control

One can compute the variations with respect to u of

$$C \doteq \int_0^1 L(q, u) dt + E(q(1))$$

subject to the constraint $\dot{q} = f(q, u)$ and $q(0)$ fixed.

Taking the variation with respect to this constraint yields

$$\partial_t \delta q = \partial_q f \delta q + \partial_u f \delta u.$$

Introduce the semigroup $P_{s,t}$ solution of $\partial_t P_{s,t} = \partial_q f P_{s,t}$ with $P_{s,s} = \text{id}$, so that

$$\delta q_t = \int_0^t P_{s,t}(\partial_u f)_s \delta u_s ds.$$

One can write

$$\begin{aligned} \delta C &= \int_0^1 \left(\left((\partial_q L)_t | \int_0^t P_{s,t}(\partial_u f)_s \delta u_s ds \right) + (\partial_u L | \delta u(t)) \right) dt \\ &\quad + \left(D E(q(1)) | \int_0^1 P_{s,1}(\partial_u f)_s \delta u_s ds \right). \end{aligned}$$

Interverting integrals in s and t yields

$$\delta C = \int_0^1 (\partial_u L - (\partial_u f)_s^* p(s) | \delta u(s)) ds = \int_0^1 (-\partial_u H | \delta u(s)) ds \quad (78)$$

with

$$p(s) \doteq - \left(\int_s^1 P_{s,t}^* (\partial_q L)_t dt + P_{s,1}^* D E(q(1)) \right)$$

which is characterized by $p(1) + DE(q(1)) = 0$ and $\partial_t p = \partial_q L - \partial_q f^* p = -\partial_q H(q, p, u)$. The last two conditions are precisely $\delta J_E / \delta q = 0$ for

$$J_E = \int_0^1 ((p|\dot{q}) - H(q, p, u)) dt + E(q(1))$$

as above. Since $\dot{q}_t = f(q, u)$ is $\delta J_E / \delta p = 0$, one gets from (78) that $\delta C / \delta u = \delta J_E / \delta u$ for $\delta J_E / \delta p = \delta J_E / \delta q = 0$.

Application to the Landmark Case

In the landmark case $u = \alpha$, $q = \mathbf{x}$, $L(\mathbf{x}, \alpha) = \alpha^T S_V(\mathbf{x})\alpha / 2$, and $\dot{\mathbf{x}} = f(\mathbf{x}, \alpha) = S_V(\mathbf{x})\alpha$, so that $\partial_u H(\mathbf{x}, p, \alpha) = S_V(\mathbf{x})(p - \alpha)$ and

$$\delta C = \int_0^1 \langle \alpha - p, \delta \alpha(s) \rangle_{\mathbf{x}} ds$$

The gradient of C is therefore particularly simple to compute if one chooses along the path the natural metric given on the α 's by the matrix $S_V(\mathbf{x})$ (cf. section “A Riemannian Manifold of Deformable Landmarks”). This gives the updating rule (see [22]): $\alpha^{n+1} = \alpha^n - \Delta t(\alpha - p^n)$, $\dot{q}_t^{n+1} = f(q^{n+1}, \alpha^{n+1})$, where p^n is computed by the backward integration of the ode $\dot{p}_t^n = -\partial_q H(q^n, p^n, \alpha^n)$ with end-point condition $p^n(1) + E(q^n(1)) = 0$.

5 Conclusion

Even if it would be impossible to provide a comprehensive description of every method that has been devised in this domain, this chapter provides an introduction to many of the mathematical constructions of spaces of shapes. The combined description of the Riemannian and of the Hamiltonian point of views, which are complementary, should help the reader to a more thorough understanding of the range of available methods, whether they were described in this chapter or elsewhere in the literature. The described numerical methods are basic components that can also be found in most of the contributions that were not directly addressed here.

Mathematical shape analysis remains a domain of intensive research, with open problems arising both for fundamental aspects (e.g., with building spaces of three-dimensional shapes) and for numerical issues and their connections with applications. It is however likely that the concepts introduced here will remain relevant and serve as foundations for future work.

Abstract

The concept of a shape space is linked both to concepts from geometry and from physics. On one hand, a path-based viscous flow approach leads to Riemannian distances between shapes, where shapes are boundaries of objects that mainly behave like fluids. On the other hand, a state-based elasticity approach induces a (by construction) non-Riemannian dissimilarity measure between shapes, which is given by the stored elastic energy of deformations matching the corresponding objects. The two approaches are both based on variational principles. They are analyzed with regard to different applications, and a detailed comparison is given.

1 Introduction

The analysis of shapes as elements in a frequently infinite-dimensional space of shapes has attracted increasing attention over the last decade. There are pioneering contributions in the theoretical foundation of shape space as a Riemannian manifold as well as path-breaking applications to quantitative shape comparison, shape recognition, and shape statistics. The aim of this chapter is to adopt a primarily physical perspective on the space of shapes and to relate this to the prevailing geometric perspective. Indeed, we here consider shapes given as boundary contours of volumetric objects, which consist either of a viscous fluid or an elastic solid.

In the first case, shapes are transformed into each other via viscous transport of fluid material, and the flow naturally generates a connecting *path* in the space of shapes. The viscous dissipation rate – the rate at which energy is converted into heat due to friction – can be defined as a metric on an associated Riemannian manifold. Hence, via the computation of the shortest transport paths, one defines a distance measure between shapes.

In the second case, shapes are transformed via elastic deformations, where the associated elastic energy only depends on the final *state* of the deformation and not on the path along which the deformation is generated. The minimal elastic energy required to deform an object into another one can be considered as a dissimilarity measure between the corresponding shapes.

In what follows, we discuss and extensively compare the *path*-based and the *state*-based approach. As applications of the elastic shape model, we consider shape averages and a principal component analysis of shapes. The viscous flow model is used to exemplarily cluster 2D and 3D shapes and to construct a flow-type nonlinear interpolation scheme. Furthermore, we show how to approximate the viscous, path-based approach with a time-discrete sequence of state-based variational problems.

2 Background

The structure of shape spaces and statistical analyses of shapes have been examined in various settings, and applications range from the computation of priors for segmentation [16, 17, 43] and shape classification [25, 44, 48, 50] to the construction of standardized anatomical atlases [14, 37, 66]. Among all existing approaches, a number of different concepts of a shape are employed, including landmark vectors [16, 39], planar curves [41, 52, 84], surfaces in \mathbb{R}^3 [24, 25, 40], boundary contours of objects [31, 44, 67], multiphase objects [83], as well as the morphologies of images [22].

The analysis of a shape space is typically based on a notion of a distance or dissimilarity measure $d(\cdot, \cdot)$ between shapes [10, 31, 50, 51, 54, 67], whose definition frequently takes a variational form. This distance can be used to define an average [26, 67] or a median [4, 28] \mathcal{S} of given shapes $\mathcal{S}_1, \dots, \mathcal{S}_n$ according to $\mathcal{S} = \operatorname{argmin}_{\tilde{\mathcal{S}}} \sum_{i=1}^n d(\tilde{\mathcal{S}}, \mathcal{S}_i)^p$ for $p = 1$ and $p = 2$, respectively (cf.

section ‘‘Elastic Shape Averaging’’). Likewise, shape variations can be obtained by a principal component analysis (PCA, cf. section ‘‘Elasticity-Based PCA’’) or a more general covariance analysis in a way which is consistent with the dissimilarity measure between shapes [11, 16, 26, 68]. From the conceptional point of view, one can distinguish two types of these dissimilarities or distance measures which may be characterized as rather state based or path based, respectively. While the first approach is independent of the notion of paths of shapes, the latter distance definition requires the computation of an optimal, connecting path in shape space. In some cases, both concepts coincide: The Euclidean distance between two points, e.g., can equivalently be interpreted in a state-based manner as the norm of the difference vector or as the length of the shortest connecting path (we shall provide a physical interpretation for each case in section ‘‘Recalling the Finite-Dimensional Case’’).

The notion of a shape space was already introduced by Kendall in 1984 [39], who considers shapes as k -tuples of points in \mathbb{R}^d , endowed with the quotient metric of \mathbb{R}^{kd} with respect to similarity transforms. Often, however, a shape space is just modeled as a linear vector space which is not invariant with respect to shift or rotation a priori. In the simplest case, such a shape space is made up of vectors of landmark positions, and distances between shapes can be evaluated in a state-based manner as the Euclidean norm of their difference. Chen and Parent [12] investigated averages of 2D contours already in 1989. Cootes et al. perform a PCA on training shapes with consistently placed landmarks to obtain priors for edge-based image segmentation [16]. Hafner et al. use a PCA of position vectors covering the proximal tibia to reconstruct the tibia surface just from six dominant modes [35]. Perperidis et al. automatically assign consistent landmarks to training shapes by a nonrigid registration as a preprocessing step for a PCA of the cardiac anatomy [63]. Söhn et al. compute dominant eigenmodes of landmark displacement on human organs, also using registration for preprocessing [73].

As an infinite-dimensional vector space, the Lebesgue-space L^2 has served as shape space, where again shape alignment is a necessary preprocessing step. Leventon et al. identify shapes with their signed distance functions and impose the Hilbert space structure of L^2 on them to compute an average and dominant modes of variation [43]. Tsai et al. apply the same technique to 3D prostate images [79]. Dambreville et al. also compute shape priors, but using characteristic instead of signed distance functions [19].

A more sophisticated state-based shape space is obtained by considering shapes as subsets of an ambient space with a metric $d(\cdot, \cdot)$ and endowing them with the Hausdorff distance

$$d_H(\mathcal{S}_1, \mathcal{S}_2) = \max\{\sup_{x \in \mathcal{S}_1} \inf_{y \in \mathcal{S}_2} d(x, y), \sup_{y \in \mathcal{S}_2} \inf_{x \in \mathcal{S}_1} d(x, y)\}$$

between any two shapes $\mathcal{S}_1, \mathcal{S}_2$. Charpiat et al. employ smooth approximations of the Hausdorff distance based on a comparison of the signed distance functions of shapes [10]. For a given set of shapes, the gradient of the shape distance functional at the average shape is regarded as shape variation of the average and used to

analyze its dominant modes of variation [11]. Frame indifference is mimicked by an inner product that weights rotations, shifts, scalings, and the orthogonal complement to these transformations differently. Charpiat et al. also consider gradient flow morphing from one shape onto another one which can be regarded as a means to obtain meaningful paths even in shape spaces with state-based distance measures.

An isometrically invariant distance measure between shapes (or more general metric spaces) that is also not based on connecting paths is provided by the Gromov–Hausdorff distance, which can be defined variationally as

$$d_{\text{GH}}(\mathcal{S}_1, \mathcal{S}_2) = \frac{1}{2} \inf_{\substack{\phi: \mathcal{S}_1 \rightarrow \mathcal{S}_2 \\ \psi: \mathcal{S}_2 \rightarrow \mathcal{S}_1}} \sup_{\substack{y_i = \phi(x_i) \\ \psi(y_i) = x_i}} |d_{\mathcal{S}_1}(x_1, x_2) - d_{\mathcal{S}_2}(y_1, y_2)|,$$

where $d_{\mathcal{S}_i}(\cdot, \cdot)$ is a distance measure between points in \mathcal{S}_i . The Gromov–Hausdorff distance represents a global, supremum-type measure of the lack of isometry between two shapes. Memoli and Sapiro use this distance for clustering shapes described by point clouds, and they discuss efficient numerical algorithms to compute Gromov–Hausdorff distances based on a robust notion of intrinsic distances $d_S(\cdot, \cdot)$ on the shapes [50]. Bronstein et al. incorporate the Gromov–Hausdorff distance concept in various classification and modeling approaches in geometry processing [6]. Memoli investigates the relation between the Gromov–Hausdorff distance and the Hausdorff distance under the action of Euclidean isometries as well as L^p -type variants of the Gromov–Hausdorff distance [49].

In [46], Manay et al. define shape distances via integral invariants of shapes and demonstrate the robustness of this approach with respect to noise.

Another distance or dissimilarity measure which also measures the lack of isometry between shapes can be obtained by interpreting shapes as boundaries of physical objects and measuring the (possibly nonlinear) deformation energy of an elastic matching deformation ϕ between two objects [36, 67]. Since, by the axiom of elasticity, this energy solely depends on the original and the final configuration of the deformed object but not on the deformation path, the elastic dissimilarity measure can clearly be classified as state based (as will be detailed in section “State-Based, Path-Independent Elastic Setup”). This physical approach comes along with a natural linearization of shapes via boundary stresses to perform a covariance analysis [68] and will be presented in section “Elasticity-Based Shape Space.” Pennec et al. define a nonlinear elastic energy as the integral over the ambient space of an energy density that depends on the logarithm of the Cauchy–Green strain tensor $\mathcal{D}\phi^T \mathcal{D}\phi$ [61, 62], which induces a symmetric state-based distance.

Typical path-based shape spaces have the structure of a Riemannian manifold. Here, the strength of a shape variation is measured by a Riemannian metric, and the square root of the Riemannian metric evaluated on the temporal shape variation is integrated along a path of shapes to yield the path length. The length of the shortest path between two shapes represents their geodesic distance $d(\cdot, \cdot)$. Averages are obtained via the Fréchet mean [30], which was further analyzed by Karcher [38].

There is also a natural linear representation of shapes in the tangent space at the Fréchet mean via the logarithmic map, which enables a PCA.

A Riemannian shape space which might still be regarded as rather static than path oriented is given by the space of polygonal medial axis representations, where each shape is described by a polygonal lattice and spheres around each vertex [87]: Here, the Lie group structure of the medial representation space can be exploited to approximate the Fréchet mean as exponential map of the average of the logarithmic maps of the input. Fletcher et al. perform a PCA on these log-maps to obtain the dominant geometric variations of kidney shapes [26] and brain ventricles [27]. Fuchs and Scherzer use the PCA on log-maps to obtain the covariance of medial representations, and they use a covariance-based Mahalanobis distance to impose a new metric on the shape manifold. This metric is employed to obtain priors for edge-based image segmentation [32, 33].

Kilian et al. compute and extrapolate geodesics between triangulated surfaces of fixed mesh topology, using isometry invariant Riemannian metrics that measure the local distortion of the grid [40]. Eckstein et al. employ different metrics in combination with a smooth approximation to the Hausdorff distance to perform gradient flows for shape matching [24]. Liu et al. use a discrete exterior calculus approach on simplicial complexes to compute geodesics and geodesic distances in the space of triangulated shapes, in particular taking care of higher genus surfaces [45].

An infinite-dimensional Riemannian shape space has been developed for planar curves. Klassen et al. propose to use as a Riemannian metric the L^2 -metric on variations of the direction or curvature functions of arc length-parameterized curves. They implement a shooting method to find geodesics [41], while Schmidt and Cremers present an alternative variational approach [70]. Srivastava et al. assign different weights to the L^2 -metric on stretching and on bending variations and obtain an elastic model of curves [75]. Michor and Mumford examine Riemannian metrics on the manifold of smooth regular curves [51]. They show the standard L^2 -metric in tangent space, leading to arbitrarily short geodesics and hence employ a curvature-weighted L^2 -metric instead. Yezzi and Mennucci resolved the problem taking into account the conformal factor in the metric [84]. Sundaramoorthi et al. use Sobolev metrics in the tangent space of planar curves to perform gradient flows for image segmentation via active contours [76]. Michor et al. discuss a specific metric on planar curves, for which geodesics can be described explicitly [52]. In particular, they demonstrate that the sectional curvature on the underlying shape space is bounded from below by zero, which points out a close relation to conjugate points in shape space and thus to only locally the shortest geodesics. Finally, Younes considers a left-invariant Riemannian distance between planar curves by identifying shapes with elements of a Lie group acting on one reference shape [85].

When warping objects bounded by shapes in \mathbb{R}^d , a shape tube in \mathbb{R}^{d+1} is formed. Delfour and Zolésio [20] rigorously develop the notion of a Courant metric in this context. A further generalization to classes of non-smooth shapes and the derivation of the Euler–Lagrange equations for a geodesic in terms of a shortest shape tube is investigated by Zolésio in [88].

Dupuis et al. [23] and Miller et al. [53, 54] define the distance between shapes based on a flow formulation in the embedding space. They exploit the fact that in case of sufficient Sobolev regularity for the motion field v on the whole surrounding domain Ω , the induced flow consists of a family of diffeomorphisms. This regularity is ensured by a functional $\int_0^1 \int_{\Omega} Lv \cdot v \, dx \, dt$, where L is a higher-order elliptic operator [76, 85]. Geometrically, $\int_{\Omega} Lv \cdot v \, dx$ is the underlying Riemannian metric, and we will discuss related, path-based concepts in section “Path-Based, Viscous Riemannian Setup.” Under sufficient smoothness assumptions, Beg et al. derive the Euler–Lagrange equations for the diffeomorphic flow field [3]. To compute geodesics between hypersurfaces in the flow of diffeomorphism framework, a penalty functional measures the distance between the transported initial shape and the given end shape. Vaillant and Glaunès [80] identify hypersurfaces with naturally associated two forms and used the Hilbert space structures on the space of these forms to define a mismatch functional. The case of planar curves is investigated under the same perspective by Glaunès et al. in [34]. To enable the statistical analysis of shape structures, parallel transport along geodesics is proposed by Younes et al. [86] as the suitable tool to transfer structural information from subject-dependent shape representations to a single-template shape.

In most applications, shapes represent boundary contours of physical objects. Fletcher and Whitaker adopt this viewpoint to develop a model for geodesics in shape space which avoids overfolding [29]. Fuchs et al. [31] propose a Riemannian metric on a space of shape contours, motivated by linearized elasticity. This metric can be interpreted as the rate of physical dissipation during the deformation of a viscous liquid object [82, 83] and will be elaborated in section “Viscous Fluid-Based Shape Space.”

Finally, a shape space is sometimes understood as a manifold, learned from training shapes, and embedded in a higher-dimensional (often linear) space. Many related approaches are based on kernel density estimation in feature space. Here, the manifold is described by a probability distribution in the embedding space, which is computed by mapping points of the embedding space into a higher-dimensional feature space and assuming a Gaussian distribution there. In general, points in feature space have no exact preimage in shape space, so that approximate preimages have to be obtained via a variational formulation [64]. Cremers et al. use this technique to obtain 2D silhouettes of 3D objects as priors for image segmentation [17]. Rathi et al. provide a comparison between kernel PCA, local linear embedding (LLE), and kernel LLE (kernel PCA only on the nearest neighbors) [65]. Thorstensen et al. approximate the shape manifold using weighted Karcher means of the nearest neighbor shapes obtained by diffusion maps [77].

3 Mathematical Modeling and Analysis

Recalling the Finite-Dimensional Case

At first, let us investigate distances and their relation to concepts from physics in the simple case of Euclidian space. In Euclidean space, the shortest paths are

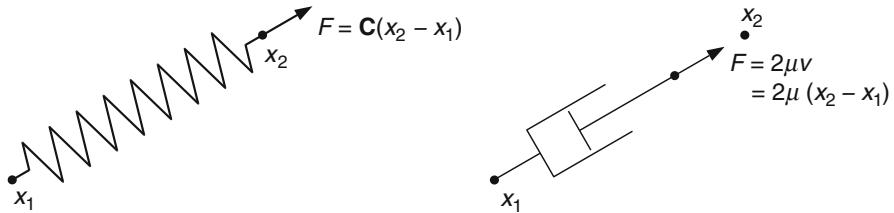

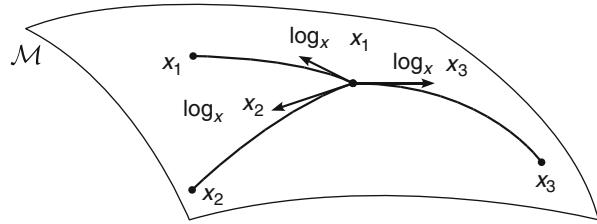

Fig. 1 The force F of an elastic spring between x_1 and x_2 is proportional to $(x_2 - x_1)$, as well as the force F of a dashpot which is extended from x_1 to x_2 within time 1 at constant velocity v . The spring energy reads $\mathcal{W} = \int F dx = \frac{1}{2}\mathbf{C} \|x_2 - x_1\|_2^2$ and the dashpot dissipation $\mathbf{Diss} = \int F \cdot v dt = 2\mu \|x_2 - x_1\|_2^2$

straight lines, and they are unique, so that the distance computation involves only the states of the two end points: The geodesic distance between any two points $x_1, x_2 \in \mathbb{R}^d$ is given by the norm of the difference, $\|x_2 - x_1\|_2$, which implies the equivalence of the state-based and the path-based perspective. A corresponding physical view might be the following. Considering that – by Hooke's law – the stored elastic energy of an elastic spring extended from x_1 to x_2 is given by $\mathcal{W} = \frac{1}{2}\mathbf{C} \|x_2 - x_1\|_2^2$ for the spring constant \mathbf{C} , the distance can be interpreted in a state-based manner as the square root of the elastic spring energy (Fig. 1). Likewise, from a path-based point of view, the minimum dissipated energy of a dashpot which is extended from x_1 to x_2 at constant speed within the fixed time interval $[0, 1]$ reads $\mathbf{Diss} = \int_0^1 2\mu \|v\|_2^2 dt = 2\mu \|x_2 - x_1\|_2^2$, where 2μ is the dashpot parameter and the velocity is given by $v = x_2 - x_1$. Using this physical interpretation, we can express, for instance, the arithmetic mean $x = \frac{1}{n} \sum_{i=1}^n x_i = \operatorname{argmin}_{\tilde{x}} \sum_{i=1}^n \|x_i - \tilde{x}\|_2^2$ of a given set of points $x_1, \dots, x_n \in \mathbb{R}^d$ either as the minimizer of the total elastic deformation energy in a system, where the average x is connected to each x_i by elastic springs or as the minimizer of the total viscous dissipation when extending dashpots from x_i to x .

Before we investigate the same concepts on more general Riemannian manifolds, let us briefly recall some basic notation. A Riemannian manifold is a set \mathcal{M} that is locally diffeomorphic to Euclidean space. Given a smooth path $x(t) \in \mathcal{M}$, $t \in [0, 1]$, we can define its derivative $\dot{x}(t)$ at time t as a tangent vector to \mathcal{M} at $x(t)$. The vector space of all such tangent vectors makes up the tangent space $T_{x(t)}\mathcal{M}$, and it is equipped with the metric $g_{x(t)}(\cdot, \cdot)$ as the inner product. The length of a path $x(t) \in \mathcal{M}$, $t \in [0, 1]$, is defined as $\int_0^1 \sqrt{g_{x(t)}(\dot{x}(t), \dot{x}(t))} dt$, and locally the shortest paths are denoted geodesics. They can be shown to minimize $\int_0^1 g_{x(t)}(\dot{x}(t), \dot{x}(t)) dt$ [21, Lemma 2.3]. Let us emphasize that a general geodesic is only locally the shortest curve. In particular, there might be multiple geodesics of different lengths connecting the same end points. The geodesic distance between two points is the length of the shortest connecting path. Finally, for a given $x \in \mathcal{M}$, there is a bijection $\exp_x : T_x\mathcal{M} \rightarrow \mathcal{M}$ of a neighborhood of $0 \in T_x\mathcal{M}$ into a neighborhood of $x \in \mathcal{M}$ that assigns to each tangent vector $v \in T_x\mathcal{M}$ the end point

Fig. 2 The logarithmic map assigns each point x_i on the manifold \mathcal{M} a vector in the tangent space $T_x \mathcal{M}$, which may be seen as a linear representative

of the geodesic emanating from x with initial velocity v and running over the time interval $[0, 1]$ [42, Theorem 1.6.12] or [74, Chap. 9, Theorem 14].

We can now define the (possibly nonunique, cf. Sect. 5) mean x of a number of n points $x_1, \dots, x_n \in \mathcal{M}$ in analogy to the Euclidian case as $x = \operatorname{argmin}_{\tilde{x}} \sum_{i=1}^n d(x_i, \tilde{x})^2$, where $d(\cdot, \cdot)$ is the Riemannian distance on \mathcal{M} . This average is uniquely defined as long as the geodesics involved in the distance computation are unique, and it has been investigated in differential geometry by Karcher [38]. Furthermore, on a Riemannian manifold \mathcal{M} , the inverse exponential map $\log_x = \exp_x^{-1}$ provides a method to obtain representatives $\log_x(x_i) \in T_x \mathcal{M}$ of given input points $x_i \in \mathcal{M}$ in the (linear) vector space $T_x \mathcal{M}$ (Fig. 2). On these, we can perform a PCA, which is by definition a linear statistical tool.

In a Riemannian space \mathcal{M} , the path-based approach can immediately be applied by exploiting the Riemannian structure, and $\int_0^1 g_{x(t)}(\dot{x}(t), \dot{x}(t)) dt$ can be considered as the energy dissipation spent to move a point from $x(0)$ to $x(1)$ along a geodesic. The logarithms $\log_x(x_i)$ in this model correspond to the initial velocities of the transport process leading from x to x_i . When applying the state-based elastic model in \mathcal{M} , however, there is no mechanically motivated notion of paths and thus also no logarithmic map. Only if we suppose that the Riemannian structure of the space \mathcal{M} is not induced by changes in the inner structure of our objects, the physical model based on elastic springs still coincides with the viscous model: We consider elastic springs stretched on the surface \mathcal{M} and connecting the points x and x_i with a stored energy $\frac{1}{2}C d(x, x_i)^2$. Then, as before in the Euclidian case, a state-based average x of input points x_1, \dots, x_n can be defined. Furthermore, interpreting spring forces acting on x and pointing toward x_i as linear representatives of the input points x_i , one can run a PCA on these forces as well. However, for any reasonable (even finite-dimensional) model of shape space, objects are not rigid, and the inner relation between points as subunits (such as the vertex points of polygonal shapes) essentially defines the Riemannian (and thus the path-based) structure of the space \mathcal{M} : The rate of dissipation along a path in shape space depends on the interaction of object points. Physically, the corresponding point interaction energy is converted into thermal energy via friction. This dissipation depends significantly on the path in shape space traversed from one shape to the other. In contrast, when applying the state-based approach to the same shape space, we directly compare the inner relations between the subunits, i.e., we have no history of these relations. This comparison can be quantified based on a stored (elastic) interaction energy which is

then a quantitative measure of the dissimilarity of the two objects but in general no metric distance.

Path-Based Viscous Dissipation Versus State-Based Elastic Deformation for Nonrigid Objects

In the following, we will especially consider two different physically motivated perspectives on a shape space of nonrigid volumetric objects in more detail. In the first case, we will adopt a path-based view, motivated by the theory of viscous fluids, while the second, state-based approach will be motivated by elasticity.

We will regard shapes \mathcal{S} as boundaries $\mathcal{S} = \partial\mathcal{O}$ of domains $\mathcal{O} \subset \mathbb{R}^d$ which will be interpreted as physical objects. The resulting shape space structure depends on the particular type of physical objects \mathcal{O} : An interpretation of \mathcal{O} as a blob of a viscous fluid will yield an actually Riemannian, path-based shape space, while the interpretation as an elastic solid results in a state-based perspective, which will turn out to be non-Riemannian by construction.

Path-Based, Viscous Riemannian Setup

Shapes will be modeled as the boundary contour of a physical object that is made of a viscous fluid. The object might be surrounded by a different fluid (e.g., with much lower viscosity and compression modulus), nevertheless, without any restriction we will assume void outside the object in the derivation of our model. Here, *viscosity* describes the internal resistance in a fluid and is a macroscopic measure of the friction between fluid particles, e.g., the viscosity of honey is significantly larger than that of water. The friction is described in terms of the stress tensor $\sigma = (\sigma_{ij})_{ij=1,\dots,d}$, whose entries describe a force per area element. By definition, σ_{ij} is the force component along the i th coordinate direction acting on the area element with a normal pointing in the j th coordinate direction. Hence, the diagonal entries of the stress tensor σ refer to normal stresses, e.g., due to compression, and the off-diagonal entries represent tangential (shear) stresses. The Cauchy stress law states that due to the preservation of angular momentum, the stress tensor σ is symmetric [13].

In a *Newtonian fluid*, the stress tensor is assumed to depend linearly on the gradient $\mathcal{D}v := \left(\frac{\partial v_i}{\partial x_j}\right)_{ij=1,\dots,d}$ of the velocity v . In case of a rigid body motion, the stress vanishes. A rotational component of the local motion is generated by the antisymmetric part $\frac{1}{2}(\mathcal{D}v - (\mathcal{D}v)^T)$ of the velocity gradient, and it has the local rotation axis $\nabla \times v$ and local angular velocity $|\nabla \times v|$ [78]. Thus, as rotations are rigid body motions, the stress only depends on the symmetric part $\epsilon[v] := \frac{1}{2}(\mathcal{D}v + (\mathcal{D}v)^T)$ of the velocity gradient. For an isotropic Newtonian fluid, we get $\sigma_{ij} = \lambda \delta_{ij} \sum_k (\epsilon[v])_{kk} + 2\mu (\epsilon[v])_{ij}$, or in matrix notation $\sigma = \lambda \text{tr}(\epsilon[v]) \mathbb{1} + 2\mu \epsilon[v]$, where $\mathbb{1}$ is the identity matrix. The parameter λ is denoted Lamé's first coefficient. The local rate of viscous dissipation – the rate at which mechanical energy is locally converted into heat due to friction – can now be computed as

$$\mathbf{diss}[v] = \frac{\lambda}{2} (\text{tr}\epsilon[v])^2 + \mu \text{tr}(\epsilon[v]^2) . \quad (1)$$

This is in direct correspondence to the mechanical definition of the stress tensor σ as the first variation of the local dissipation rate with respect to the velocity gradient, i.e., $\sigma = \delta_{Dv} \mathbf{diss}$. Indeed, by a straightforward computation, we obtain $\delta_{(Dv)ij} \mathbf{diss} = \lambda \text{tr}\epsilon[v] \delta_{ij} + 2\mu (\epsilon[v])_{ij} = \sigma_{ij}$. Here, $\text{tr}(\epsilon[v]^2)$ measures the averaged local change of length and $(\text{tr}\epsilon[v])^2$ the local change of volume induced by the transport. Obviously, $\text{div}v = \text{tr}(\epsilon[v]) = 0$ characterizes an incompressible fluid.

Now, let us consider a path $(\mathcal{O}(t))_{t \in [0,1]}$ of objects connecting $\mathcal{O}(0)$ with $\mathcal{O}(1)$ and generated by a time-continuous deformation. If each point $x \in \mathcal{O}(t)$ of the object $\mathcal{O}(t)$ at time $t \in [0, 1]$ moves in an Eulerian framework at the velocity $v(t, x)$ ($\dot{x} = v(t, x)$), so that the total deformation of $\mathcal{O}(0)$ into $\mathcal{O}(t)$ can be obtained by integrating the velocity field v in time, then the accumulated global dissipation of the motion field v in the time interval $[0, 1]$ takes the form

$$\mathbf{Diss}[(v(t), \mathcal{O}(t))_{t \in [0,1]}] = \int_0^1 \int_{\mathcal{O}(t)} \mathbf{diss}[v] dx dt . \quad (2)$$

This is the same concept as employed by Dupuis et al. [23] and Miller et al. [53] in their pioneering diffeomorphism approach. They minimize a dissipation functional under the simplifying assumption that the material behaves equally viscous inside and outside the object. Also, $\mathbf{diss}[v] = \frac{\lambda}{2} (\text{tr}\epsilon[v])^2 + \mu \text{tr}(\epsilon[v]^2)$ is replaced by a higher-order quadratic form $Lv \cdot v$ which plays the role of the local rate of dissipation in a multipolar fluid model [57]. Multipolar fluids are characterized by the fact that the stresses depend on higher spatial derivatives of the velocity. If the quadratic form associated with L acts only on $\epsilon[v]$ and is symmetric, then rigid body motion invariance is incorporated in the multipolar fluid model (cf. section “Viscous Fluid-Based Shape Space”). In contrast to this approach, we here measure the rate of dissipation differently inside and outside the object and rely on classical (monopolar) material laws from fluid mechanics.

On this physical background, we will now derive a Riemannian structure on the space of shapes \mathcal{S} in an admissible class of shapes \mathbf{S} . The associated metric $\mathcal{G}_{\mathcal{S}}$ on the (infinite-dimensional) manifold \mathbf{S} is in abstract terms a bilinear mapping that assigns each element $\mathcal{S} \in \mathbf{S}$ an inner product on variations $\delta\mathcal{S}$ of \mathcal{S} (cf. section “Recalling the Finite-Dimensional Case” above). The associated length of a tangent vector $\delta\mathcal{S}$ is given by $\|\delta\mathcal{S}\| = \sqrt{\mathcal{G}_{\mathcal{S}}(\delta\mathcal{S}, \delta\mathcal{S})}$. Furthermore, as we have already seen above, the length of a differentiable curve $\mathcal{S} : [0, 1] \rightarrow \mathbf{S}$ is then defined by $\mathbf{L}[\mathcal{S}] = \int_0^1 \|\dot{\mathcal{S}}(t)\| dt = \int_0^1 \sqrt{\mathcal{G}_{\mathcal{S}(t)}(\dot{\mathcal{S}}(t), \dot{\mathcal{S}}(t))} dt$, where $\dot{\mathcal{S}}(t)$ is the temporal variation of \mathcal{S} at time t . The Riemannian distance between two shapes \mathcal{S}_A and \mathcal{S}_B on \mathbf{S} is given as the minimal length taken over all curves with $\mathcal{S}(0) = \mathcal{S}_A$ and $\mathcal{S}(1) = \mathcal{S}_B$ or equivalently (cf. section “Recalling the Finite-Dimensional Case” above) as the length of a minimizer of the functional $\int_0^1 \mathcal{G}_{\mathcal{S}(t)}(\dot{\mathcal{S}}(t), \dot{\mathcal{S}}(t)) dt$. For shapes $\mathcal{S} \in \mathbf{S}$, an infinitesimal variation $\delta\mathcal{S}$ of a shape $\mathcal{S} = \partial\mathcal{O}$ is associated with

a transport field $v : \overline{\mathcal{O}} \rightarrow \mathbb{R}^d$. This transport field is obviously not unique. Indeed, given any vector field w on $\overline{\mathcal{O}}$ with $w(x) \in T_x\mathcal{S}$ for all $x \in \mathcal{S} = \partial\mathcal{O}$ (where $T_x\mathcal{S}$ denotes the $(d - 1)$ -dimensional tangent space to \mathcal{S} at x), the transport field $v + w$ is another possible representation of the shape variation $\delta\mathcal{S}$. Let us denote by $\mathcal{V}(\delta\mathcal{S})$ the affine space of all these representations. As a geometric condition for $v \in \mathcal{V}(\delta\mathcal{S})$, we obtain $v(x) \cdot n[\mathcal{S}](x) = \delta\mathcal{S}(x) \cdot n[\mathcal{S}](x)$ for all $x \in \mathcal{S}$, where $n[\mathcal{S}](x) \in \mathbb{R}^d$ denotes the outer normal to $\mathcal{S} \subset \mathbb{R}^d$ in $x \in \mathcal{S}$. Given all possible representations, we are interested in the optimal transport, i.e., the transport leading to the least dissipation. Thus, using definition (1) of the local dissipation rate, we finally define the metric $\mathcal{G}_{\mathcal{S}}(\delta\mathcal{S}, \delta\mathcal{S})$ as the minimal dissipation rate on motion fields v which are consistent with the variation of the shape $\delta\mathcal{S}$,

$$\mathcal{G}_{\mathcal{S}}(\delta\mathcal{S}, \delta\mathcal{S}) := \min_{v \in \mathcal{V}(\delta\mathcal{S})} \int_{\mathcal{O}} \mathbf{diss}[v] \, dx = \min_{v \in \mathcal{V}(\delta\mathcal{S})} \int_{\mathcal{O}} \frac{\lambda}{2} (\text{tr}\epsilon[v])^2 + \mu \text{tr}(\epsilon[v]^2) \, dx. \quad (3)$$

Let us remark that we distinguish explicitly between the metric $\mathbf{g}(v, v) := \int_{\mathcal{O}} \mathbf{diss}[v] \, dx$ on motion fields and the metric $\mathcal{G}_{\mathcal{S}}(\delta\mathcal{S}, \delta\mathcal{S})$ on shape variations. Finally, integration in time leads to the total dissipation (2) to be invested in the transport along a path $(\mathcal{S}(t))_{t \in [0,1]}$ in the shape space \mathbf{S} . This implies the following definition of a time-continuous geodesic path in shape:

Definition 1 (Geodesic path). Given two shapes \mathcal{S}_A and \mathcal{S}_B in a shape space \mathbf{S} , a geodesic path between \mathcal{S}_A and \mathcal{S}_B is a curve $(\mathcal{S}(t))_{t \in [0,1]} \subset \mathbf{S}$ with $\mathcal{S}(0) = \mathcal{S}_A$ and $\mathcal{S}(1) = \mathcal{S}_B$ which is a local solution of

$$\min_{v(t) \in \mathcal{V}(\dot{\mathcal{S}}(t))} \mathbf{Diss}[(v(t), \mathcal{O}(t))_{t \in [0,1]}]$$

among all differentiable paths in \mathbf{S} .

The Riemannian distance between two shapes \mathcal{S}_A and \mathcal{S}_B induced by this definition is given by the length of the shortest (geodesic) path $\mathcal{S}(t)$ between the two shapes, i.e.,

$$d_{\text{viscous}}(\mathcal{S}_A, \mathcal{S}_B) = \mathbf{L}[(\mathcal{S}(t))_{t \in [0,1]}].$$

Figure 3 shows two different paths between the same pair of shapes, one of them being a (numerically approximated) geodesic. Note that the chosen dissipation model combines the control of infinitesimal length changes via $\text{tr}(\epsilon[v]^2)$, and the control of compression via $\text{tr}(\epsilon[v])^2$. Figure 4 evaluates the impact of these two terms on the shapes along a geodesic path.

State-Based, Path-Independent Elastic Setup

Now, objects bounded by a shape contour \mathcal{S} are no longer composed of a viscous fluid but are considered to be elastic solids. To describe object deformations, we

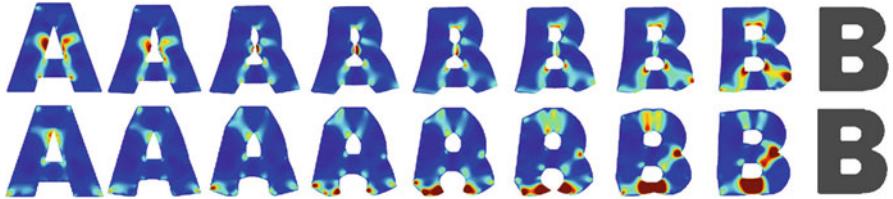

Fig. 3 A geodesic (*top*, path length $\mathbf{L} = 0.2225$ and total dissipation $\mathbf{Diss} = 0.0497$) and a non-geodesic path (*bottom*, $\mathbf{L} = 0.2886$, $\mathbf{Diss} = 0.0880$) between an A and a B. The intermediate shapes of the *bottom row* are obtained via linear interpolation between the signed distance functions of the end shapes. The local dissipation rate is color coded as

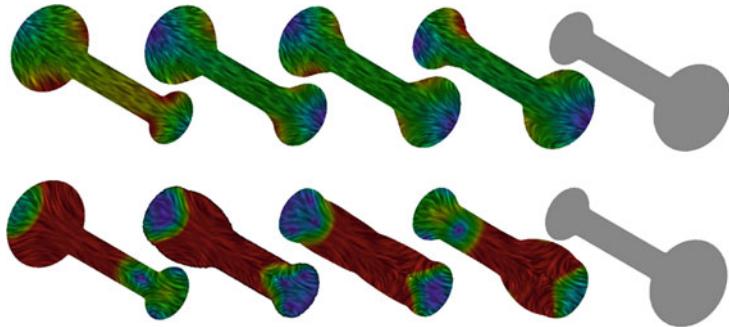

Fig. 4 Two geodesic paths between dumbbell shapes varying in the size of the ends. In the *top* example, the ratio λ/μ between the dissipation parameters is 0.01 (leading to rather independent compression and expansion of the ends since the associated change of volume implies relatively low dissipation), and 100 in the *bottom* row (now mass is actually transported from one end to the other). The underlying texture on the objects is aligned to the transport direction, and the absolute value of the velocity v is color coded as

aim for an elastic energy which is not restricted to small displacements and which is consistent with the first principles. Alongside the shape space modeling, we will recall some background from elasticity. For details, we refer to the comprehensive introductions in the books by Ciarlet [15] and Marsden and Hughes [47].

For two objects \mathcal{O}_A and \mathcal{O}_B with shapes $\mathcal{S}_A = \partial\mathcal{O}_A$ and $\mathcal{S}_B = \partial\mathcal{O}_B$, we assume a deformation ϕ to be defined on $\overline{\mathcal{O}}_A$ and constrained by the assumption $\phi(\mathcal{S}_A) = \mathcal{S}_B$. For practical reasons, one might consider \mathcal{O}_A to be embedded in a very soft elastic material occupying $\Omega \setminus \mathcal{O}_A$ for some computational domain Ω . There is an elastic energy $\mathcal{W}_{\text{deform}}[\phi, \mathcal{O}_A]$ associated with the deformation $\phi : \Omega \rightarrow \mathbb{R}^d$. By definition, elastic means that this energy solely depends on the state and not on the path along which the deformation proceeds in time. More precisely, for so-called hyper-elastic materials, $\mathcal{W}_{\text{deform}}[\phi, \mathcal{O}_A]$ is the integral of an energy density W depending solely on the Jacobian $\mathcal{D}\phi$ of the deformation ϕ , i.e.,

$$\mathcal{W}_{\text{deform}}[\phi, \mathcal{O}_A] = \int_{\mathcal{O}_A} W(\mathcal{D}\phi) \, dx. \quad (4)$$

This elastic energy is considered as a dissimilarity measure between the shapes \mathcal{S}_A and \mathcal{S}_B . As a fundamental requirement, one postulates the invariance of the deformation energy with respect to rigid body motions, $\mathcal{W}_{\text{deform}}[Q \circ \phi + b, \mathcal{S}_A] = \mathcal{W}_{\text{deform}}[\phi, \mathcal{S}_A]$ for any orthogonal matrix $Q \in SO(d)$ and translation vector $b \in \mathbb{R}^d$ (the axiom of frame indifference in continuum mechanics). From this, one deduces that the energy density only depends on the right Cauchy–Green deformation tensor $\mathcal{D}\phi^T \mathcal{D}\phi$. Hence, there is a function $\tilde{W} : \mathbb{R}^{d,d} \rightarrow \mathbb{R}$ such that the energy density W satisfies $W(F) = \tilde{W}(F^T F)$ for all $F \in \mathbb{R}^{d,d}$. The Cauchy–Green deformation tensor geometrically represents the metric measuring the deformed length in the undeformed reference configuration. For an isotropic material and for $d = 3$, the energy density W can be further rewritten as a function $\hat{W}(I_1, I_2, I_3)$ solely depending on the principal invariants of the Cauchy–Green tensor, namely, $I_1 = \text{tr}(\mathcal{D}\phi^T \mathcal{D}\phi)$, controlling the local average change of length; $I_2 = \text{tr}(\text{cof}(\mathcal{D}\phi^T \mathcal{D}\phi))$ ($\text{cof}F := \det F F^{-T}$), reflecting the local average change of area; and $I_3 = \det(\mathcal{D}\phi^T \mathcal{D}\phi)$, which controls the local change of volume. For a detailed discussion, we refer to [15, 78]. We shall furthermore assume that the energy density is polyconvex [18], i.e., a convex function of $\mathcal{D}\phi$, $\text{cof}\mathcal{D}\phi$, and $\det \mathcal{D}\phi$, and that isometries, i.e., deformations with $\mathcal{D}\phi^T(x)\mathcal{D}\phi(x) = \mathbb{1}$, are local minimizers with $W(\mathcal{D}\phi) = \tilde{W}(\mathbb{1}) = 0$ [15]. Typical energy densities in this class are of the form

$$\hat{W}(I_1, I_2, I_3) = a_1 I_1^{\frac{p}{2}} + a_2 I_2^{\frac{q}{2}} + \Gamma(I_3) \quad (5)$$

for $a_1, a_2 > 0$ and a convex function $\Gamma : [0, \infty) \rightarrow \mathbb{R}$ with $\Gamma(I_3) \rightarrow \infty$ for $I_3 \rightarrow 0$ and $I_3 \rightarrow \infty$. In nonlinear elasticity, such material laws have been proposed by Ogden [58], and for $p = q = 2$ (the case considered in our computations), we obtain the Mooney–Rivlin model [15]. The built-in penalization of volume shrinkage, i.e., $\hat{W}(I_1, I_2, I_3) \xrightarrow{I_3 \rightarrow 0} \infty$, enables us to control local injectivity (cf. [2]).

Incorporation of such a nonlinear elastic energy allows to describe large deformations with strong material and geometric nonlinearities, which cannot be treated by a linear elastic approach (cf. Hong et al. [36]). Furthermore, it balances in an intrinsic way expansion and collapse of the elastic objects and hence frees us from imposing artificial boundary conditions or constraints.

As in the previous section, the local force per area, induced by the deformation, is described at a point $\phi(x) \in \phi(\mathcal{O})$ by the Cauchy stress tensor σ . It is related to the first Piola–Kirchhoff stress tensor $\sigma^{\text{ref}} = W_F(\mathcal{D}\phi) := \frac{\partial W(F)}{\partial F}|_{F=\mathcal{D}\phi}$, which measures the force density in the undeformed reference configuration, by $\sigma^{\text{ref}} = \sigma \circ \phi \, \text{cof} \mathcal{D}\phi$.

Based on these concepts from nonlinear elasticity, we can now define a dissimilarity measure on shapes

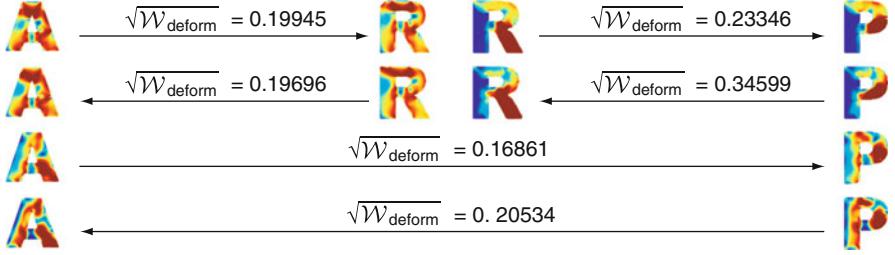

Fig. 5 Example of elastic dissimilarities between different shapes. The arrows indicate the direction of the deformation, the color coding represents the local deformation energy density (in the reference as well as the deformed state)

$$d_{\text{elast}}(\mathcal{S}_A, \mathcal{S}_B) := \min_{\phi, \phi(\mathcal{S}_A) = \mathcal{S}_B} \sqrt{\mathcal{W}_{\text{deform}}[\phi, \mathcal{O}_A]}. \quad (6)$$

Figure 5 shows some applications of this measure. Obviously, the elastic energy is in general not symmetric so that $d_{\text{elast}}(\mathcal{S}_A, \mathcal{S}_B) \neq d_{\text{elast}}(\mathcal{S}_B, \mathcal{S}_A)$. Indeed, by construction, $d_{\text{elast}}(\cdot, \cdot)$ does not impose a metric structure on the space of shapes (we refer to section “Conceptual Differences Between the Path- and State-Based Dissimilarity Measures” for a detailed discussion). Nevertheless, it can be applied to develop physically sound statistical tools for shapes such as shape averaging and a PCA on shapes, as outlined below in section “Elasticity-Based Shape Space.”

Let us make a brief remark on the mathematical relation between the two different concepts of elasticity and viscous fluids. If we assume the Hessian of the energy density W at the identity to be given by $W_{,FF}(1)(G, G) = \lambda(\text{tr}G)^2 + \frac{\mu}{2}\text{tr}((G + G^T)^2)$ (which can be realized in (5) for a particular choice of a_1, a_2 , and Γ , depending on the exponents p and q), then by the ansatz $\phi(x) = x + \tau v(x)$ and a second-order Taylor expansion, we obtain

$$\begin{aligned} W(\mathcal{D}\phi) &= W(1) + \tau W_{,F}(1)(\mathcal{D}v) + \frac{\tau^2}{2} W_{,FF}(1)(\mathcal{D}v, \mathcal{D}v) + O(\tau^3) \\ &= 0 + 0 + \tau^2 \left(\frac{\lambda}{2} (\text{tr} \mathcal{D}v)^2 + \frac{\mu}{4} \text{tr}((\mathcal{D}v + (\mathcal{D}v)^T)^2) \right) + O(\tau^3). \end{aligned} \quad (7)$$

In effect, the Hessian of the nonlinear elastic energy leads to the energy density in linearized, isotropic elasticity

$$W^{\text{lin}}(\mathcal{D}u) = \frac{\lambda}{2} (\text{tr} \epsilon[u])^2 + \mu \text{tr}(\epsilon[u]^2) \quad (8)$$

for displacements u with $\phi(x) = x + u(x)$. This energy density, acting on displacements u , formally coincides with the local dissipation rate $\text{diss}[v]$, acting on velocity fields v , in the viscous flow approach.

Finally, let us deal with the hard constraint $\phi(\mathcal{S}_A) = \mathcal{S}_B$, which is often inadequate in applications. Due to local shape fluctuations or noise in the shape acquisition, the shape \mathcal{S}_A frequently contains details that are not present in \mathcal{S}_B and vice versa. These defects would imply high energies in a strict 1–1 matching approach. Hence, we have to relax the constraint and introduce some penalty functional. Here, we either measure the symmetric difference of the input shapes \mathcal{S}_A and the pullback $\phi^{-1}(\mathcal{S}_B)$ of the shape \mathcal{S}_B given by

$$\mathcal{F}[\mathcal{S}_A, \phi, \mathcal{S}_B] = \mathcal{H}^{d-1} (\mathcal{S}_A \Delta \phi^{-1}(\mathcal{S}_B)) , \quad (9)$$

where $A \Delta B = A \setminus B \cup B \setminus A$, or alternatively the volume mismatch

$$\mathcal{F}[\mathcal{S}_A, \phi, \mathcal{S}_B] = \text{vol} (\mathcal{O}_A \Delta \phi^{-1}(\mathcal{O}_B)) . \quad (10)$$

Conceptual Differences Between the Path- and State-Based Dissimilarity Measures

The concept of the state-based, elastic approach to dissimilarity measurement between shapes differs significantly from the path-based viscous flow approach. In the elastic setup, the axiom of elasticity implies that the energy at the deformed configuration $\mathcal{S}_B = \phi(\mathcal{S}_A)$ is independent of the path from shape \mathcal{S}_A to shape \mathcal{S}_B along which the deformation is generated in time. Hence, there is no notion of the shortest paths if we consider a purely elastic shape model, and different from a path-based approach, there might not even exist an intermediate shape \mathcal{S}_C with $d_{\text{elast}}(\mathcal{S}_A, \mathcal{S}_B) = d_{\text{elast}}(\mathcal{S}_A, \mathcal{S}_C) + d_{\text{elast}}(\mathcal{S}_C, \mathcal{S}_B)$.

Unlike in the elasticity model, in the Newtonian model of viscous fluids, the rate of dissipation and the induced stresses solely depend on the gradient of the motion field v . Even though the dissipation functional (2) looks like the deformation energy from linearized elasticity as outlined above, the underlying physics is only related in the sense that an infinitesimal displacement in the fluid leads to stresses caused by viscous friction, and these stresses are immediately absorbed via dissipation.

Surely, every (path-based) Riemannian space is metrizable (and in that sense state-based), and for many sufficiently regular (state-based) metric spaces, we can devise a corresponding (path-based) Riemannian metric. However, from our mechanical perspective, the conceptual difference between the path-based, viscous and the state-based elastic approach is striking. In the *path-based* approach, the structure of the space is too complicated for a closed formula of the geodesic distance, so that the actual computation of a path is required. In the *state-based* approach, there is either no underlying path (i.e., no $\mathcal{S}(t)_{t \in [0,1]}$ such that for any $0 \leq t_1 \leq t_2 \leq t_3 \leq 1$, we have $d(\mathcal{S}(t_1), \mathcal{S}(t_3)) = d(\mathcal{S}(t_1), \mathcal{S}(t_2)) + d(\mathcal{S}(t_2), \mathcal{S}(t_3))$), or the shape space structure is simple enough to allow for a closed formula of the geodesic distance as in Euclidean space.

Mathematically, the path-based nature of the viscous flow approach and the fact that an inversion of the motion field $v \rightarrow -v$ leads to a path from shape \mathcal{S}_B to \mathcal{S}_A in shape space with the same dissipation and length, i.e.,

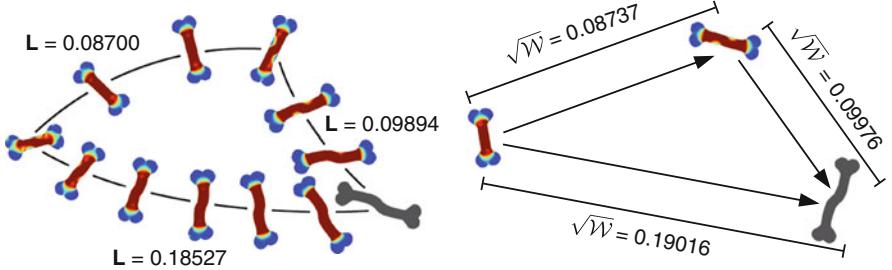

Fig. 6 *Left:* viscosity-based (time-discrete) geodesics between the shapes at the corners (the shapes are taken from [31]). The triangle inequality holds. *Right:* elastic dissimilarities $d_{\text{elast}}(\cdot, \cdot) = \sqrt{W} \equiv \sqrt{W}_{\text{deform}}$ between the same shapes, where the arrows point from the reference to the deformed configuration. The triangle inequality does not hold

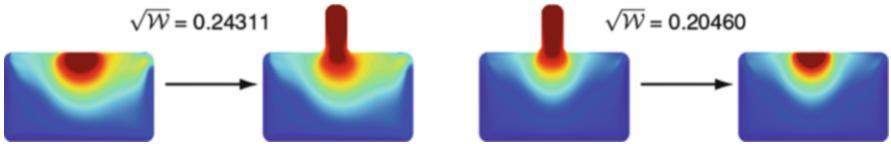

Fig. 7 The state-based elastic dissimilarity measure d_{elast} is not symmetric (as opposed to the path-based, viscous distance d_{viscous}): In this example, it costs much more energy to drag out the protrusion than to push it in. The color coding represents the local deformation energy density in the reference and the deformed configuration

$$\mathbf{Diss}[(v(t), \mathcal{O}(t))_{t \in [0,1]}] = \mathbf{Diss}[(-v(1-t), \mathcal{O}(1-t))_{t \in [0,1]}]$$

ensure that the associated distance d_{viscous} is actually a metric. In particular, the symmetry condition $d_{\text{viscous}}(\mathcal{S}_A, \mathcal{S}_B) = d_{\text{viscous}}(\mathcal{S}_B, \mathcal{S}_A)$ and the triangle inequality $d_{\text{viscous}}(\mathcal{S}_A, \mathcal{S}_C) \leq d_{\text{viscous}}(\mathcal{S}_A, \mathcal{S}_B) + d_{\text{viscous}}(\mathcal{S}_B, \mathcal{S}_C)$ hold. As we have already seen, the symmetry condition does not hold for the elastic dissimilarity measure. Also, the triangle inequality cannot be expected to hold. Indeed, if a deformation $\phi_{A,B}$ maps \mathcal{O}_A onto \mathcal{O}_B and a deformation $\phi_{B,C}$ maps \mathcal{O}_B onto \mathcal{O}_C , then $\phi_{A,C} := \phi_{B,C} \circ \phi_{A,B}$ deforms \mathcal{O}_A onto \mathcal{O}_C . However, based on our elastic model, \mathcal{O}_B is considered to be stress free when applying the deformation $\phi_{B,C}$ (although it is actually obtained as the image of object \mathcal{O}_A under the deformation $\phi_{A,B}$). Hence, the ‘‘history’’ of the deformation $\phi_{A,B}$ is lost when measuring the energy of $\phi_{B,C}$. In addition, the energy density is highly nonlinear. As a consequence, in general, we cannot expect $d_{\text{elast}}(\mathcal{S}_A, \mathcal{S}_C) \leq d_{\text{elast}}(\mathcal{S}_A, \mathcal{S}_B) + d_{\text{elast}}(\mathcal{S}_B, \mathcal{S}_C)$. Indeed, Fig. 6 gives an example where the triangle inequality holds in the viscous, path-based and fails in the elastic, state-based approach. Furthermore, Fig. 7 depicts another example for the lack of symmetry already apparent in Fig. 5 with a particularly pronounced mechanical difference of the two dissimilarity measures.

4 Numerical Methods and Case Examples

Elasticity-Based Shape Space

In this section, we will perform a statistical analysis on shapes up to the second moment, i.e., we will consider shape averaging and a principal component analysis on shapes as two exemplary applications of the state-based elastic shape space.

Elastic Shape Averaging

As usual, we consider objects \mathcal{O} as open sets in \mathbb{R}^d with the object shape given as $\mathcal{S} := \partial\mathcal{O}$. Given n sufficiently regular shapes $\mathcal{S}_i = \partial\mathcal{O}_i$, $i = 1, \dots, n$, we are interested in an average shape which reflects the geometric characteristics of the input shapes in a physically intuitive manner. Suppose $\mathcal{S} = \partial\mathcal{O} \subset \mathbb{R}^d$ denotes a candidate for this unknown shape. As it is characteristic for the elastic approach, the similarity of the input shapes \mathcal{S}_i to \mathcal{S} is measured by taking into account optimal elastic deformations $\phi_i : \overline{\mathcal{O}}_i \rightarrow \mathbb{R}^d$ with $\phi_i(\mathcal{S}_i) = \mathcal{S}$. The elastic energy $\mathcal{W}_{\text{deform}}[\phi_i, \mathcal{O}_i]$ of these deformations has the interpretation of a dissimilarity measure (cf. section “State-Based, Path-Independent Elastic Setup”), so that we obtain a natural definition of an average shape as the minimizer of the sum of these terms (cf. Sect. 2).

Definition 2 (Elastic shape average). Given shapes $\mathcal{S}_1, \dots, \mathcal{S}_n$ in some shape space \mathbf{S} , the elastic shape average \mathcal{S} is the minimizer of

$$\sum_{i=1}^n d_{\text{elast}}(\mathcal{S}_i, \mathcal{S})^2 = \sum_{i=1}^n \inf_{\phi_i : \overline{\mathcal{O}}_i \rightarrow \mathbb{R}^d, \phi_i(\mathcal{S}_i) = \mathcal{S}} \mathcal{W}_{\text{deform}}[\phi_i, \mathcal{O}_i].$$

If the input objects \mathcal{O}_i have Lipschitz boundary and the integrand of the deformation energy $\mathcal{W}_{\text{deform}}[\phi_i, \mathcal{O}_i] = \int_{\mathcal{O}_i} W(\mathcal{D}\phi_i) dx$ is polyconvex and bounded below by $C_1 \|\mathcal{D}\phi_i\|^p - C_2$ for $p > d$, $C_1, C_2 > 0$, the existence of a Hölder-continuous elastic shape average and deformations $\phi_i \in W^{1,p}(\mathcal{O}_i)$ which realize the above infimum is guaranteed [81].

An example of a shape average is provided in Fig. 8. Obviously, the process of shape averaging is a constrained variational problem in which we simultaneously have to minimize over n deformations ϕ_i and the unknown shape \mathcal{S} under the n constraints $\phi_i(\mathcal{S}_i) = \mathcal{S}$.

The necessary conditions for a set of minimizing deformations are the corresponding Euler–Lagrange equations. As usual, inner variations of one of the deformations lead to the classical system of PDEs $\text{div } W_F(\mathcal{D}\phi_i) = 0$ for every deformation ϕ_i on $\mathcal{O}_i \setminus \mathcal{S}_i$, meaning a divergence-free, equilibrated stress field (cf. section “State-Based, Path-Independent Elastic Setup”). Furthermore, the coupling between the deformations via the constraints $(\phi_i(\mathcal{S}_i) = \mathcal{S})_{i=1, \dots, n}$ allows to derive a stress balance relation on \mathcal{S} : Consistent variation of all deformations ϕ_i and the average \mathcal{S} by some displacement $u : \overline{\mathcal{O}} \rightarrow \mathbb{R}^d$ via $(\mathbb{1} + \delta u) \circ \phi_i$ and $(\mathbb{1} + \delta u)(\mathcal{S})$

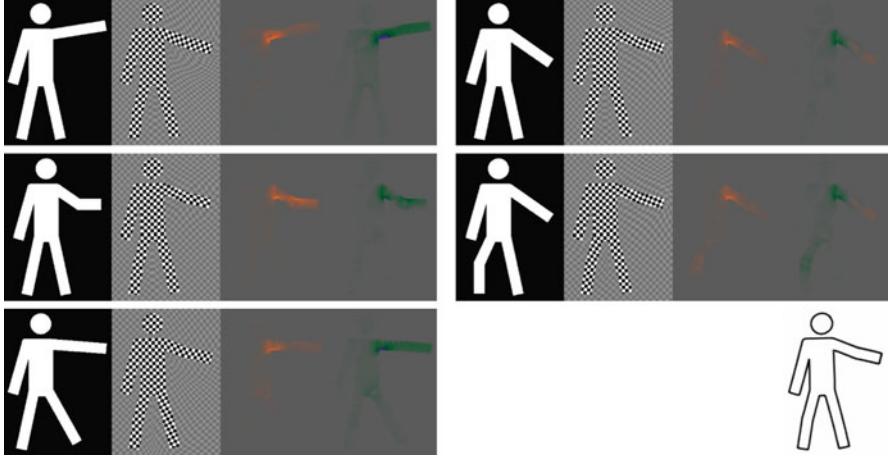

Fig. 8 Elastic shape average (*bottom right*) of five human silhouettes. For the computation, all shapes have actually been described as phase fields, and the elastic deformations are extended outside the input objects \mathcal{O}_i (cf. section “Shapes Described via Phase Fields”). The objects \mathcal{O}_i are depicted along with their deformations ϕ_i (acting on a checkerboard) and the distribution of local length change $\frac{1}{\sqrt{2}} \|\mathcal{D}\phi_i\|$ and volume change $\det(\mathcal{D}\phi_i)$ (range $[0.97, 1.03]$) color coded as (color bar).

results in the optimality condition $\frac{d}{d\delta} \sum_{i=1}^n \mathcal{W}_{\text{deform}} [(\mathbb{1} + \delta u) \circ \phi_i, \mathcal{O}_i] \Big|_{\delta=0} = 0$, which after integration by parts leads to $\sum_{i=1}^n \int_{\mathcal{S}_i} W_{,F}(\mathcal{D}\phi_i)(u \circ \phi_i) \cdot v[\mathcal{S}_i] da[\mathcal{S}_i] = 0$ for the outer normal $v[\mathcal{S}_i]$ to \mathcal{S}_i . We have here exploited $\text{div}W_{,F}(\mathcal{D}\phi_i) = 0$ on $\mathcal{O}_i \setminus \mathcal{S}_i$. Now, we consider displacements u with local support and let this support collapse at some point x on \mathcal{S} . This yields the pointwise condition

$$0 = \sum_{i=1}^n (\sigma_i^{\text{ref}} v[\mathcal{S}_i] da[\mathcal{S}_i]) (\phi_i^{-1}(x)) \quad \text{and thus} \quad 0 = \sum_{i=1}^n (\sigma_i v[\mathcal{S}]) (x) \quad (11)$$

for $x \in \mathcal{S}$, where we have used the relation

$$(\sigma_i^{\text{ref}} v[\mathcal{S}_i] da[\mathcal{S}_i]) (\phi_i^{-1}(x)) = (\sigma_i v[\mathcal{S}] da[\mathcal{S}]) (x)$$

between the first Piola–Kirchhoff stress $\sigma_i^{\text{ref}} = W_{,F}(\mathcal{D}\phi_i)$ and Cauchy stress $\sigma_i = (\sigma_i^{\text{ref}} (\text{cof} \mathcal{D}\phi_i)^{-1}) \circ \phi_i^{-1}$. Hence, the shape average can be interpreted as that stable shape at which the boundary stresses of all deformed input shapes balance each other (Fig. 9). Obviously, there is a straightforward generalization involving jumps of normal stresses on interior interfaces in case of multicomponent objects.

In order to ensure a certain regularity of the average shape \mathcal{S} , in addition to the sum of deformation energies in Definition 2, one can consider a further energy contribution which acts as a prior on \mathcal{S} in the variational approach. In the exemplary

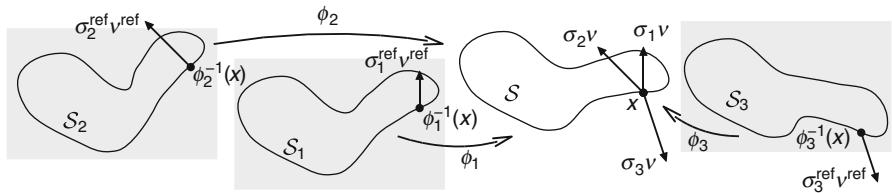

Fig. 9 Sketch of the pointwise stress balance relation on the averaged shape

Fig. 10 Average of 18 hand silhouettes (Taken from [16])

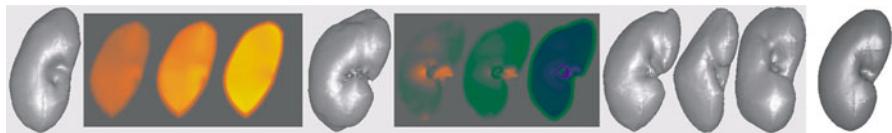

Fig. 11 Five segmented kidneys and their average (*right*). For the first two input kidneys, the distribution of $\frac{1}{\sqrt{3}}\|\mathcal{D}\phi_i\|$, $\frac{1}{\sqrt{3}}\|\text{cof}(\mathcal{D}\phi_i)\|$, and $\det(\mathcal{D}\phi_i)$ is shown on sagittal cross sections (the range $[0.85, 1.15]$ is color coded as). While the first kidney is dilated toward the average, the second is compressed

computations shown (Figs. 10–12), the $(d - 1)$ -dimensional Hausdorff measure $\mathcal{L}[\mathcal{S}] = \mathcal{H}^{d-1}(\mathcal{S})$ has been employed as regularization.

Elasticity-Based PCA

As already explained in section “Recalling the Finite-Dimensional Case,” a principal component analysis (PCA) is a linear statistical tool which decomposes a vector space into the direct sum of orthogonal subspaces. These subspaces are ordered according to the strength of variation which occurs along each subspace within a random set of sample vectors. We would like to interpret a given set of input shapes $\mathcal{S}_1, \dots, \mathcal{S}_n$ as such a random sample and perform a corresponding PCA; however,

due to the linearity of a PCA, we first have to identify linear representatives for each shape on which a PCA can then be performed. For a Riemannian shape space, we have outlined in section ‘‘Recalling the Finite-Dimensional Case’’ that such linear representatives are given by the logarithmic map of the input shapes, but we have also learned in section ‘‘Conceptual Differences Between the Path- and State-Based Dissimilarity Measures’’ that a state-based elastic shape space is incompatible with a Riemannian structure.

To prepare the definition of appropriate linear representatives of shapes in an elastic shape space, let us briefly review the physical concept of boundary stresses. By the Cauchy stress principle, each deformation $\phi_k : \mathcal{O}_k \rightarrow \mathcal{O}$ is characterized by pointwise boundary stresses on $\mathcal{S} = \partial\mathcal{O}$ in the deformed configuration. The stress at some point x on \mathcal{S} is given by the application of the Cauchy stress tensor σ_k to the outer normal v on \mathcal{S} . The resulting stress $\sigma_k v$ is a force density acting on a local surface element of \mathcal{S} . The shape \mathcal{S} is in an equilibrium configuration if the opposite force is applied as an external surface load (cf. Fig. 9). Otherwise, by the axiom of elasticity, releasing the object \mathcal{O} , the elastic body will snap back to the original reference configuration \mathcal{O}_k . Let us assume the relation between the energetically favorable deformation and its induced stresses to be one to one, so that the average shape \mathcal{S} can be described in terms of the input shape \mathcal{S}_k and the boundary stress $\sigma_k v$, and we write $\mathcal{S} = \mathcal{S}_k[\sigma_k v]$. Upon scaling the stress with a weight $t \in [0, 1]$, we obtain a one-parameter family of shapes $\mathcal{S}(t) = \mathcal{S}_k[t\sigma_k v]$, connecting $\mathcal{S}_k = \mathcal{S}(0)$ with $\mathcal{S} = \mathcal{S}(1)$. Thus, we can regard $\sigma_k v$ as a representative of shape \mathcal{S}_k in the linear space of vector fields on \mathcal{S} .

Physically, it is more intuitive to identify a displacement u_k instead of the normal stress $\sigma_k v$ as the representative of an input shape \mathcal{S}_k . Hence, let us study how the average shape \mathcal{S} varies if we increase the impact of a particular input shape \mathcal{S}_k for some $k \in \{1, \dots, n\}$. For this purpose, we apply the Cauchy stress $\sigma_k v$ to the average shape \mathcal{S} , scaled with a small constant δ . This additional boundary stress $\delta\sigma_k v$ may be seen as a first Piola–Kirchhoff stress acting on the (reference) configuration \mathcal{S} . The elastic response is given by a correspondingly scaled displacement $u_k : \mathcal{O} \rightarrow \mathbb{R}^d$. Here, to properly incorporate the nonlinear nature of the second moment analysis, \mathcal{O} should be interpreted as the compound object which is composed of all deformed and thus prestressed input objects $\phi_i(\mathcal{O}_i)$. This interpretation is reflected by the elastic material law employed to compute the displacements u_k . In detail, u_k is obtained as the minimizer of the free mechanical energy

$$\mathcal{E}_k[\delta, u] = \frac{1}{n} \sum_{i=1}^n \mathcal{W}_{\text{deform}}[(1 + \delta u) \circ \phi_i, \mathcal{O}_i] - \delta^2 \int_{\mathcal{S}} \sigma_k v \cdot u \, da \quad (12)$$

under the constraints $\int_{\mathcal{O}} u_k \, dx = 0$ and $\int_{\mathcal{O}} x \times u_k \, dx = 0$ of zero average translation and rotation. These displacements u_k are considered as representatives of the variation of the average shape \mathcal{S} with respect to the input shape \mathcal{S}_k , on which a PCA will be performed.

As long as $F \mapsto W(F)$ is not quadratic in F , u_k still solves a nonlinear elastic problem. The advantage of this nonlinear variational formulation is that it is of the same type as the one for shape averaging, and it encodes in a natural way the compound elasticity configuration of the averaged shape domain \mathcal{O} . However, for the linearization of shape variations, we are actually only interested in the displacements δu_k for small δ . Therefore, we consider the limit of the Euler–Lagrange equations for $\delta \rightarrow 0$ and, after a little algebra, obtain u_k as the solution of the linearized elasticity problem

$$\operatorname{div}(\mathbf{C}\epsilon[u]) = 0 \text{ in } \mathcal{O}, \quad \mathbf{C}\epsilon[u]v = \sigma_k v \text{ on } \mathcal{S} \quad (13)$$

for the symmetrized displacement gradient $\epsilon[u] = \frac{1}{2}(\mathcal{D}u + \mathcal{D}u^T)$ under the constraints $\int_{\mathcal{O}} u \, dx = 0$ and $\int_{\mathcal{O}} x \times u \, dx = 0$, where the in general inhomogeneous and anisotropic elasticity tensor \mathbf{C} reads

$$\mathbf{C} = \frac{1}{n} \sum_{i=1}^n \left(\frac{1}{\det \mathcal{D}\phi_i} \mathcal{D}\phi_i W_{FF}(\mathcal{D}\phi_i) \mathcal{D}\phi_i^T \right) \circ \phi_i^{-1}.$$

Next, for a PCA on the linearized shape variations u_k , we select a suitable inner product (metric) $g(u, \tilde{u})$ on displacements $u, \tilde{u} : \mathcal{O} \rightarrow \mathbb{R}^d$. Note that g induces a metric $\tilde{g}(\sigma v, \tilde{\sigma} v) := g(u, \tilde{u})$ on the associated boundary stresses so that instead of analyzing the u_k , the covariance analysis can equivalently be performed directly on the boundary stresses $\sigma_1 v, \dots, \sigma_n v$, which we originally derived as linear shape representatives. Indeed, the solvability condition $\int_{\mathcal{O}} \operatorname{div}(\mathbf{C}\nabla u) \, dx = \int_{\mathcal{S}} \mathbf{C}\nabla u v \, da[\mathcal{S}]$ is fulfilled, and thus the solution u_k for given boundary stress $\sigma_k v = \mathbf{C}\nabla u v$ is uniquely determined up to a linearized rigid body motion (i.e., an affine displacement with skew-symmetric matrix representation), which is fixed by the conditions of zero mean displacement and angular momentum for u . Then, due to the linearity of the operator $\sigma v \mapsto u$, the metric \tilde{g} is bilinear and symmetric as well, and its positive definiteness follows from the positive definiteness of g and the injectivity of the map $\sigma v \mapsto u$.

We consider two different inner products on displacements $u : \mathcal{O} \rightarrow \mathbb{R}^d$:

- *The L^2 -product.* Given two square integrable displacements u, \tilde{u} , we define

$$g(u, \tilde{u}) := \int_{\mathcal{O}} u \cdot \tilde{u} \, dx.$$

This product weights local displacements equally on the whole object \mathcal{O} .

- *The Hessian of the energy as inner product.* Different from the L^2 -metric, we now measure displacement gradients in a nonhomogeneous way. We define

$$g(u, \tilde{u}) := \int_{\mathcal{O}} \mathbf{C}\epsilon[u] : \epsilon[\tilde{u}] \, dx$$

for displacements u, \tilde{u} with square integrable gradients. Hence, the contribution to the inner product is larger in areas of the compound object which are in a significantly stressed configuration.

Given an inner product, we can define the covariance operator **Cov** by

$$\mathbf{Cov} u := \frac{1}{n} \sum_{k=1}^n g(u, u_k) u_k$$

(note that the stresses $\sigma_k v$ and thus also the displacements u_k have zero mean due to (11)). Obviously, **Cov** is symmetric positive definite on $\text{span}(u_1, \dots, u_n)$. Hence, we can diagonalize **Cov** on this finite-dimensional space and obtain a set of g -orthonormal eigenfunctions $w_k : \mathcal{O} \rightarrow \mathbb{R}^d$ and eigenvalues $\lambda_k > 0$ with $\mathbf{Cov} w_k = \lambda_k w_k$. These eigenfunctions can be considered as the principal modes of variation of the average object \mathcal{O} and hence of the average shape \mathcal{S} , given the n sample shapes $\mathcal{S}_1, \dots, \mathcal{S}_n$. Their eigenvalues encode the variation strength. The diagonalization of **Cov** can be performed by diagonalizing the symmetric matrix $\frac{1}{n} (g(u_i, u_j))_{ij} = O \Lambda O^T$, where $\Lambda = \text{diag}(\lambda_1, \lambda_2, \dots)$ and O is orthogonal. The eigenfunctions are then obtained as $w_k = \frac{1}{\sqrt{\lambda_k}} \sum_{j=1}^n O_{jk} u_j$.

Being displacements on \mathcal{O} , the modes of variation w_k can easily be visualized via a scalar modulation δw_k for varying δ (cf. the visualization in Figs. 16–18 or the red lines in Figs. 13 and 15). If an amplified visualization of the modes is required, it is preferable to depict displacements w_δ^k which are defined as minimizers of the nonlinear variational energy $\frac{1}{n} \sum_{i=1}^n \mathcal{W}_{\text{deform}}[(\mathbb{1} + w) \circ \phi_i, \mathcal{O}_i] - \delta^2 \int_S \mathbf{C} \nabla w_k v \cdot w \, da$ (cf. (12)).

Let us underline that this covariance analysis properly takes into account the usually strong geometric nonlinearity in shape analysis via the transfer of geometric shape variation to elastic stresses on the average shape, based on paradigms from nonlinear elasticity. Displacements or stresses are interpreted as the proper linearization of shapes. In abstract terms, either the space of displacements or stresses can be considered as the tangent space of shape space at the average shape, where the identification of displacements and stresses via (13) provides a suitable physical interpretation of stresses as shape variations.

The impact of the chosen metric. Naturally, the modes of variation depend on the chosen inner product. We have already mentioned that in order to be physically meaningful, the inner product should act on displacements u_k of the compound object (which is composed of all deformed input shapes). If instead the u_k were obtained by applying the boundary stresses $\sigma_k v$ to an object which just looks like the average shape but does not contain the information how strongly the input shapes had to be deformed to arrive at the average, we obtain a different result (Fig. 13, left): If the prestressed state of some object regions is neglected, it becomes easier to deform them which causes the prediction of stronger variations. Figure 13 also hints at the differences between the employed metrics: The L^2 -metric pronounces

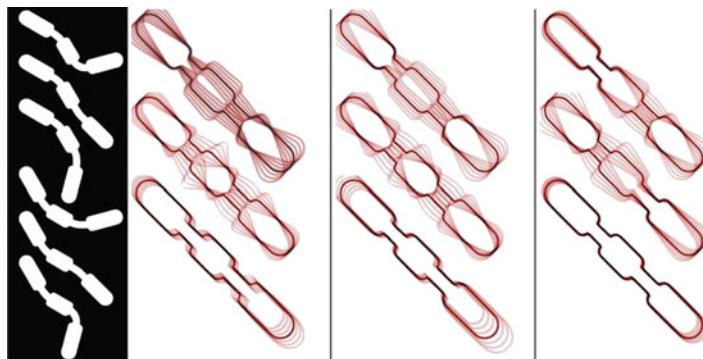

Fig. 13 First three dominant modes of variation for six input shapes (*left*), based on different metrics. *Left*: L^2 -metric on displacements of a non-prestressed object (modes w_k with ratios $\frac{\lambda_k}{\lambda_1}$ of 1, 0.23, 0.07). *Middle*: L^2 -metric on displacements of the compound object ($\frac{\lambda_k}{\lambda_1} = 1, 0.28, 0.03$). *Right*: energy Hessian-based metric on displacements of the compound object ($\frac{\lambda_k}{\lambda_1} = 1, 0.61, 0.24$)

shape variations with large displacements even though they are energetically cheap (e.g., a rotation of some structure around a joint), while the Hessian of the elastic energy measures distances between displacements solely based on the associated change of elastic energy. Thus, displacements are weighted strongly in regions and directions which are significantly loaded.

The impact of the nonlinear elasticity model. Likewise, the particular choice of the nonlinear elastic energy density has a considerable effect on the average shape and its modes of variation. Figure 14 has been obtained using $W(\mathcal{D}\phi) = \frac{\mu}{2} \|\mathcal{D}\phi\|^2 + \frac{\lambda}{4} \det \mathcal{D}\phi^2 - (\mu + \frac{\lambda}{2}) \log \det \mathcal{D}\phi - \mu - \frac{\lambda}{4}$, where μ and λ are the coefficients of length and volume change penalization, respectively. A low penalization of volume changes apparently leads to independent compression and inflation at the dumbbell ends (left), while for deformations with a strong volume change penalization (right), material is squeezed from one end to the other. Here, the underlying metric is the based on the Hessian of the energy.

Figures 15–17 show the dominant modes of variation for the examples from the previous section. A statistical analysis of the hand shapes in Fig. 15 has also been performed in [16] and [28], where the shapes are represented as vectors of landmark positions. The average and the modes of variation are quite similar, representing different kinds of spreading the fingers. The dominant modes of variation for a set of 48 three-dimensional kidney shapes is depicted in Fig. 16, where for all modes w_k , we show the average (middle) and its variation according to δw_k for varying δ . Local structures seem to be quite well represented and preserved during the averaging process and the subsequent covariance analysis compared to, e.g., the PCA on kidney shapes in [26] where a medial representation is used.

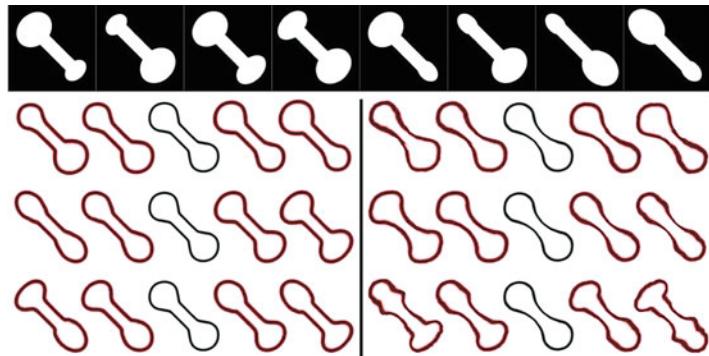

Fig. 14 First three modes of variation for eight dumbbell shapes, *left* for a 100 times stronger penalization of length than of volume changes (with ratios $\frac{\lambda_i}{\lambda_1}$ of 1, 0.22, 0.05), *right* for the reverse ($\frac{\lambda_i}{\lambda_1} = 1, 0.41, 0.07$). Each row represents the variation of the average (*middle shape*) by δw_k for the mode w_k and varying δ

Fig. 15 First four modes of variation with ratios $\frac{\lambda_i}{\lambda_1}$ of 1, 0.88, 0.42, and 0.25 for the 18 hand silhouettes from Fig. 10

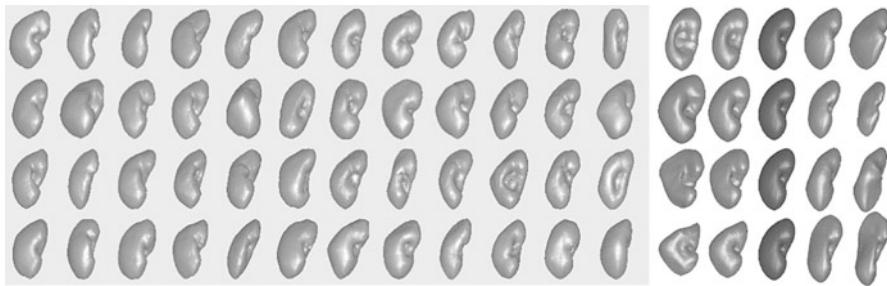

Fig. 16 Forty-eight input kidneys (Courtesy of Werner Bautz, radiology department at the University Hospital Erlangen, Germany) and their first four modes of variation with ratios $\frac{\lambda_i}{\lambda_1}$ of 1, 0.72, 0.37, and 0.31

The PCA of the 24 ft shapes from Fig. 12 is shown in Fig. 17 and is much more intuitive than the color coding in Fig. 12. The first mode apparently represents changing foot lengths, the second and third mode belong to different variants of combined width and length variation, and the fourth to sixth mode correspond to variations in relative heel position, ankle thickness, and instep height. Finally, Fig. 18 shows that the approach also works for image morphologies instead of

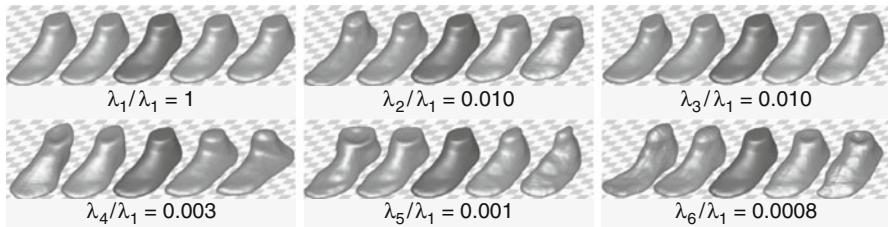

Fig. 17 The first six dominant modes of variation for the feet from Fig. 12

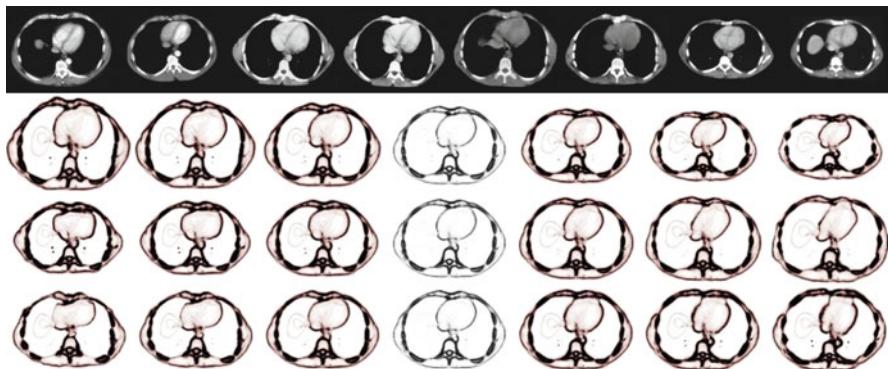

Fig. 18 Eight thorax CT scans from different patients (Courtesy of Bruno Wirth, urology department at the Hospital zum hl. Geist, Kempen, Germany) and their first three modes of variation with ratios $\frac{\lambda_i}{\lambda_1}$ of 1, 0.12, and 0.07. Note that the thin lines which can be seen left of the heart correspond to contours of the liver, which are only visible in the first and last input image

shapes, using thorax CT scans as input. Here, the image edge set is considered as the corresponding shape, which is typically quite complex and characterized by nested contours. The first mode of variation represents a variation in chest size, the next mode corresponds to a change of heart and scapula shape, while the third mode mostly concerns the rib position.

Viscous Fluid-Based Shape Space

As explained in section “Path-Based, Viscous Riemannian Setup,” the viscous fluid shape space is by construction a (infinite-dimensional) Riemannian manifold and as such is based on the computation of shape paths as opposed to state-based approaches like the elastic shape space from the previous section. In the elastic, state-based approach, we have to find for each pair of shapes $S_A = \partial\mathcal{O}_A$ and $S_B = \partial\mathcal{O}_B$ one single optimal matching deformation $\phi : \mathcal{O}_A \rightarrow \mathbb{R}^d$ via which the similarity between S_A and S_B is determined. In contrast, here we require more information to measure the distance between the two shapes, namely, an optimal

velocity field $v(t) : \mathcal{O}(t) \rightarrow \mathbb{R}^d$ at each time t within the given time interval $[0, 1]$. In effect, this implies an increase of the dimension of the variational problem by the time component.

The two qualitatively different types of coordinates, the space coordinates (that span the space in which the shapes lie) and the time coordinate, are intuitively treated in different ways. One possibility is to regard the variational problem of computing a geodesic as a classical elliptic boundary value problem in time, in which each shape on a path seeks to be in equilibrium with its local neighborhood on the path. The equilibrizing force can be interpreted as an acceleration acting on the velocity field v . In this setting, it seems most natural to discretize first the time variable and approximate geodesics in shape space as discrete sequences $\mathcal{S}_0, \dots, \mathcal{S}_K$ of shapes, where each shape is connected to and equilibrates with its neighbors and the path length along the discrete path $\mathcal{S}_0, \dots, \mathcal{S}_K$ is approximated as a sum $\sum_{k=1}^K \tilde{d}(\mathcal{S}_{k-1}, \mathcal{S}_k)$ of approximations $\tilde{d}(\mathcal{S}_{k-1}, \mathcal{S}_k)$ of the geodesic distance between neighboring shapes. The distance \tilde{d} can be based on a matching deformation energy which will be elaborated on further down.

An alternative view starts from the underlying velocity field which generates the geodesic. Dupuis et al. [23] and Beg et al. [3] consider shapes (or rather images) embedded in a domain $\Omega \subset \mathbb{R}^d$. These shapes deform according to smooth, compactly supported velocity fields $v \in L^2([0, 1]; W_0^{n,2}(\Omega; \mathbb{R}^d))$ with $n > 2 + \frac{2}{d}$. The regularity of the velocity fields is ensured by defining the path dissipation as $\int_0^1 \int_{\Omega} Lv \cdot v \, dx \, dt$ and the path length as $\int_0^1 \sqrt{\int_{\Omega} Lv \cdot v \, dx} \, dt$ for a differential operator L of sufficiently high order (cf. section ‘Path-Based, Viscous Riemannian Setup’). The corresponding shape deformation ϕ which is induced by the velocity field is obtained as the solution $\phi = \phi_1$ of the pointwise, Lagrangian ordinary differential equation $\frac{d}{dt} \phi_t(x) = v(\phi_t(x), t)$.

In the first approach, the computation of a geodesic was seen as the concatenation of a number of local subproblems, each of which represents the approximation of a geodesic segment between two intermediate shapes and each of which thus inherits the constraint that one shape is transferred exactly into the other. In contrast, in the second approach, we have one single constraint, acting at the end of the geodesic and expressing that the accumulated flow ϕ deforms the starting shape \mathcal{S}_A into the final shape \mathcal{S}_B , $\phi(\mathcal{S}_A) = \mathcal{S}_B$.

Let us now focus on the first approach in which a geodesic path will be approximated via a finite sequence of shapes $\mathcal{S}_0, \dots, \mathcal{S}_K$, connected by deformations $\phi_k : \mathcal{O}_{k-1} \rightarrow \mathbb{R}^d$ which are optimal in a variational sense and fulfil the constraint $\phi_k(\mathcal{S}_{k-1}) = \mathcal{S}_k$.

Given two shapes $\mathcal{S}_A, \mathcal{S}_B$ in some given space of shapes \mathbf{S} , we define a discrete path of shapes as a sequence of shapes $\mathcal{S}_0, \dots, \mathcal{S}_K \in \mathbf{S}$ with $\mathcal{S}_0 = \mathcal{S}_A$ and $\mathcal{S}_K = \mathcal{S}_B$. For the time step $\tau = \frac{1}{K}$, the shape \mathcal{S}_k is supposed to be an approximation of $\mathcal{S}(t_k)$ with $t_k = k\tau$, where $(\mathcal{S}(t))_{t \in [0,1]}$ is a continuous path connecting $\mathcal{S}_A = \mathcal{S}(0)$ and $\mathcal{S}_B = \mathcal{S}(1)$. For each pair of consecutive shapes \mathcal{S}_{k-1} and \mathcal{S}_k , we now consider a matching deformation $\phi_k : \mathcal{O}_{k-1} \rightarrow \mathbb{R}^d$ which

satisfies $\phi_k(\mathcal{S}_{k-1}) = \mathcal{S}_k$. With each deformation ϕ_k , we associate a deformation energy $\mathcal{W}_{\text{deform}}[\phi_k, \mathcal{O}_{k-1}] = \int_{\mathcal{O}_{k-1}} W(\mathcal{D}\phi_k) dx$ of the same type as described in section ‘‘State-Based, Path-Independent Elastic Setup.’’ If appropriately chosen, this energy will ensure sufficient regularity and a 1–1 matching property for deformations ϕ_k with finite energy. As in elasticity, the energy is assumed to depend only on the local deformation, reflected by the Jacobian $\mathcal{D}\phi$. Yet, different from elasticity, we suppose the material to relax instantaneously so that object \mathcal{O}_k is again in a stress-free configuration when applying ϕ_{k+1} at the next time step. Let us also emphasize that the stored energy does not depend on the deformation history as in most plasticity models in engineering. This energy is now employed to define time-discrete counterparts to the dissipation and length of continuous paths from section ‘‘Path-Based, Viscous Riemannian Setup.’’

Definition 3 (Discrete dissipation and discrete path length). Given a discrete path $\mathcal{S}_0, \dots, \mathcal{S}_K \in \mathbf{S}$, its dissipation is defined as

$$\mathbf{Diss}_\tau(\mathcal{S}_0, \dots, \mathcal{S}_K) := \sum_{k=1}^K \frac{1}{\tau} \mathcal{W}_{\text{deform}}[\phi_k, \mathcal{O}_{k-1}],$$

where $\phi_k : \overline{\mathcal{O}}_{k-1} \rightarrow \mathbb{R}^d$ is a minimizer of the deformation energy $\mathcal{W}_{\text{deform}}[\phi_k, \cdot]$ under the constraint $\phi_k(\mathcal{S}_{k-1}) = \mathcal{S}_k$. Furthermore, the discrete path length is defined as

$$\mathbf{L}_\tau(\mathcal{S}_0, \dots, \mathcal{S}_K) := \sum_{k=1}^K \sqrt{\mathcal{W}_{\text{deform}}[\phi_k, \mathcal{O}_{k-1}]}.$$

Let us make a brief remark on the proper scaling factors. The deformation energy $\mathcal{W}_{\text{deform}}[\phi_k, \mathcal{O}_{k-1}]$ is expected to scale like τ^2 (cf. (7)). Hence, the factor $\frac{1}{\tau}$ ensures the discrete dissipation measure to be conceptually independent of the time step size. The same holds for the discrete length measure $\mathbf{L}_\tau(\mathcal{S}_0, \dots, \mathcal{S}_K)$.

To ensure that the above-defined dissipation and length of discrete paths in shape space are well defined, a minimizing deformation ϕ_k of the elastic energy $\mathcal{W}_{\text{deform}}[\cdot, \mathcal{O}_{k-1}]$ with $\phi_k(\mathcal{S}_{k-1}) = \mathcal{S}_k$ has to exist. In fact, this holds for objects \mathcal{O}_{k-1} and \mathcal{O}_k with Lipschitz boundaries \mathcal{S}_{k-1} and \mathcal{S}_k for which there exists at least one bi-Lipschitz deformation $\hat{\phi}_k$ of \mathcal{O}_{k-1} into \mathcal{O}_k for $k = 1, \dots, K$ [83].

With the notion of dissipation at hand, we can define a discrete geodesic path following the standard paradigms in differential geometry.

Definition 4 (Discrete geodesic path). A discrete path $\mathcal{S}_0, \mathcal{S}_1, \dots, \mathcal{S}_K$ in a set of admissible shapes \mathbf{S} connecting two shapes $\mathcal{S}_A = \mathcal{S}_0$ and $\mathcal{S}_B = \mathcal{S}_K$ is a discrete geodesic if there exists an associated family of deformations $(\phi_k)_{k=1, \dots, K}$ such

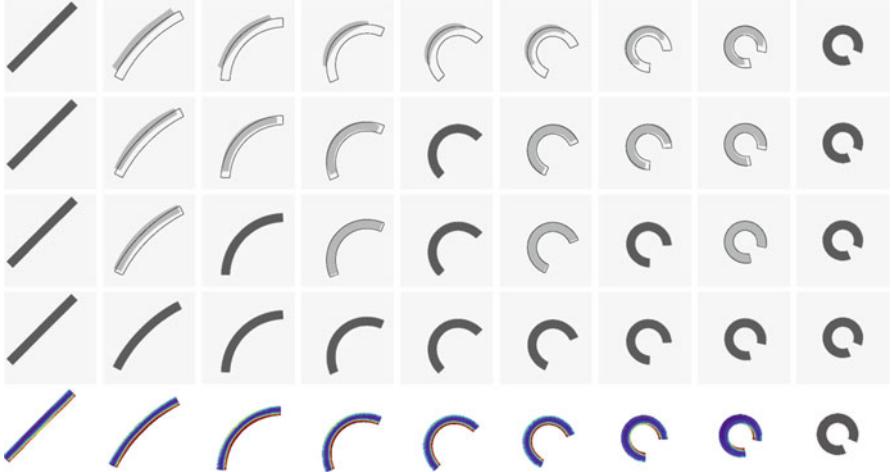

Fig. 19 Discrete geodesics between a straight and a rolled up bar, from first row to fourth row based on one, two, four, and eight time steps. The light gray shapes in the first, second, and third row show a linear interpolation of the deformations connecting the dark gray shapes. The shapes from the finest time discretization are overlayed over the others as thin black lines. In the last row, the rate of viscous dissipation is rendered on the shape domains $\mathcal{O}_1, \dots, \mathcal{O}_7$ from the previous row, color coded as

that $(\phi_k, \mathcal{S}_k)_{k=1, \dots, K}$ minimize the total energy $\sum_{k=1}^K \frac{1}{\tau} \mathcal{W}_{\text{deform}}[\tilde{\phi}_k, \tilde{\mathcal{O}}_{k-1}]$ over all intermediate shapes $\tilde{\mathcal{S}}_1 = \partial \tilde{\mathcal{O}}_1, \dots, \tilde{\mathcal{S}}_{K-1} = \partial \tilde{\mathcal{O}}_{K-1} \in \mathbf{S}$ and all possible matching deformations $\tilde{\phi}_1, \dots, \tilde{\phi}_K$ with $\tilde{\phi}_k(\tilde{\mathcal{S}}_{k-1}) = \tilde{\mathcal{S}}_k$ for $k = 1, \dots, K$.

Examples of discrete geodesics are provided in Figs. 19 and 20. Apparently, the frame indifference and the (local) injectivity property of the matching deformations, which are ensured by the nonlinear deformation energy $\mathcal{W}_{\text{deform}}$, allow the computation of reasonable discrete geodesics with only few intermediate shapes. Under sufficient growth conditions on the integrand of the deformation energy $\mathcal{W}_{\text{deform}}$, the existence of discrete geodesics is guaranteed at least for certain compact sets \mathbf{S} of admissible shapes, e.g., shapes \mathcal{S} which can be described by spline curves with a finite set of control points from some compact domain and which satisfy a uniform cone condition in the sense that each $x \in \mathcal{S}$ is the tip of two cones with fixed height and opening angle which lie completely on either side of \mathcal{S} [83]. Such requirements on \mathbf{S} are necessary since the known regularity theory for deformation energies of the employed type does not allow to prove Lipschitz regularity of optimal deformations so that the intermediate shapes might degenerate.

The discrete dissipation as the sum of matching deformation energies indeed represents an approximation to the time-continuous dissipation of a velocity field from section ‘‘Path-Based, Viscous Riemannian Setup.’’ If a smooth path in shape space is considered which is interpolated at discrete times $t_k = k\tau$, $k = 0, \dots, K$

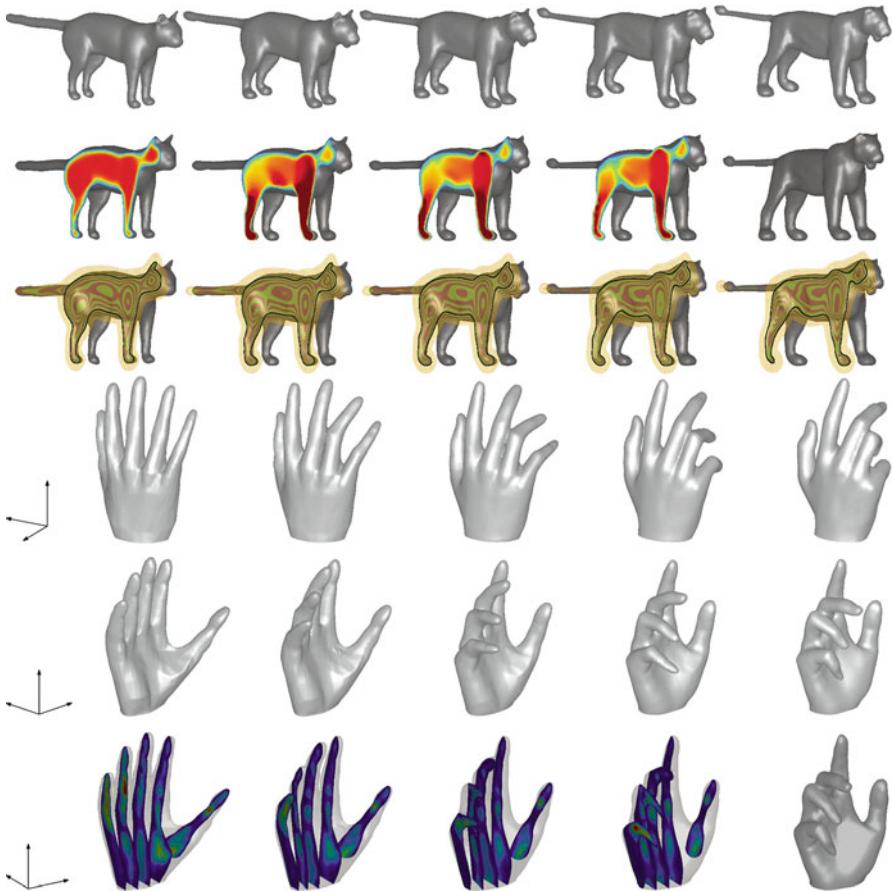

Fig. 20 Discrete geodesic between a cat and a lion and between the hand shapes m336 and m324 from the Princeton Shape Benchmark [72]. For both examples, the local dissipation is color coded on slices through the shapes as

and if for $t \in [t_{k-1}, t_k]$, $v_\tau(t) = \frac{(\phi_k - 1)}{\tau} \circ \left(\frac{t_k - t}{\tau} \mathbb{1} + \frac{t - t_{k-1}}{\tau} \phi_k \right)^{-1}$ denotes the velocity field which generates the associated matching deformations ϕ_k , then as the time step size $\tau = \frac{1}{K}$ decreases and v_τ converges against a smooth velocity field v , the discrete dissipation converges against the time-continuous dissipation (2) induced by v (cf. [83] for details).

Within this framework of geodesics in shape space, the strict constraints that one shape is deformed exactly into another one are often inadequate in applications as has already been discussed in section “State-Based, Path-Independent Elastic Setup” for the state-based, elastic setup. For the computation of an elastic dissimilarity measure, the single matching constraint could be relaxed as a mismatch penalty. In the Riemannian, viscous setting, we pursue the same concept; however, the particular

Fig. 21 Discrete geodesic between the straight and the folded bar from Fig. 19, where the *black region* of the initial shape is constrained to be matched to the *black region* of the final shape. The *bottom row* shows a color coding of the corresponding viscous dissipation. Due to the strong change in relative position of the *black region*, the intermediate shapes exhibit a strong asymmetry and high dissipation near the bar ends

form of the employed constraints depends on the chosen view on shape geodesics. In the framework of geodesics as paths of diffeomorphisms, which we introduced at the beginning of this section, there is the single constraint $\phi(\mathcal{S}_A) = \mathcal{S}_B$, meaning that the induced diffeomorphism ϕ maps the initial shape \mathcal{S}_A onto the final shape \mathcal{S}_B . This constraint can be relaxed in the same manner as in section ‘‘State-Based, Path-Independent Elastic Setup’’ via a penalty measuring the mismatch of the shapes or of the corresponding objects. For the time-discrete geodesic setting, we have a sequence of matching constraints $\phi_k(\mathcal{S}_{k-1}) = \mathcal{S}_k$, $k = 1, \dots, K$, each of which can again be relaxed by the same means. In fact, we add to the discrete dissipation of a set $(\phi_k)_{k=1, \dots, K}$ of deformations a sum of mismatch penalties $\sum_{k=1}^K \text{vol}(\mathcal{O}_{k-1} \Delta \phi_k^{-1}(\mathcal{O}_k))$. In the limit for vanishing time step size $\tau = \frac{1}{K}$ and under the same conditions as above, this sum can be shown to converge against the optical flow-type functional $\int_{\mathcal{T}} |(1, v(t)) \cdot n[t, \mathcal{S}(t)]| da$ for the unit outward normal $n[t, \mathcal{S}(t)]$ to the space time shape tube $\mathcal{T} = \bigcup_{t \in [0, 1]} \{t\} \times \mathcal{S}(t)$. Furthermore, $\sum_{k=1}^K \tau \mathcal{L}[\mathcal{S}_k]$ with $\mathcal{L}[\mathcal{S}_k] = \mathcal{H}^{d-1}(\mathcal{S}_k)$ has been employed as regularization, which in the limit for $\tau \rightarrow 0$ converges against the integral $\int_0^1 \mathcal{H}^{d-1}(\mathcal{S}(t)) dt$.

Real-world objects are most often not only characterized by their outer contour but also contain internal structures that have to be matched properly when computing the similarity between two objects. As an example, consider the straight and the folded rod in Fig. 21. The rods consist of three distinct components, which imposes a constraint on reasonable connecting paths: Each component is to be mapped onto its correct counterpart. A shortest path under this constraint obviously differs significantly from the geodesic which just matches the outer contours (cf. Fig. 19).

This observation calls for a generalization of shapes, an example of which we have already seen in the context of an elastic shape space in Fig. 18, where the edge set of an image was considered as a shape. Here, let us adopt a slightly different approach and regard shapes as being composed of a number of subcomponents. In detail, instead of a geodesic between just two shapes $\mathcal{S}_A = \partial \mathcal{O}_A$ and $\mathcal{S}_B = \partial \mathcal{O}_B$, we now seek a geodesic path $(\mathcal{S}^i(t))_{i=1, \dots, m}$ with $\mathcal{S}^i(t) = \partial \mathcal{O}^i(t)$ for $t \in [0, 1]$, between two collections of m separate shapes, $(\mathcal{S}_A^i)_{i=1, \dots, m}$ with $\mathcal{S}_A^i(t) = \partial \mathcal{O}_A^i(t)$ and $(\mathcal{S}_B^i)_{i=1, \dots, m}$ with $\mathcal{S}_B^i(t) = \partial \mathcal{O}_B^i(t)$. The geodesic path is supposed to

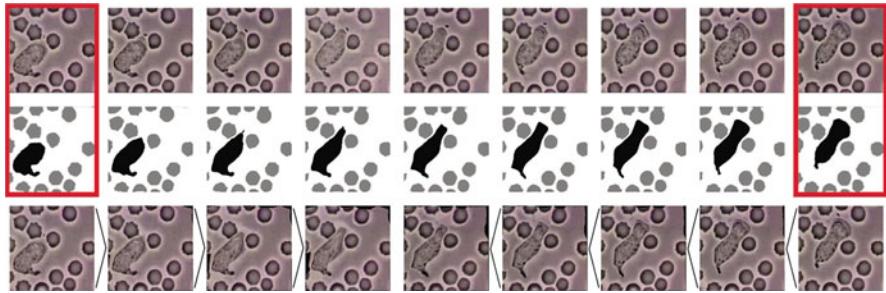

Fig. 22 *Top:* frames from a real video sequence of a white blood cell among a number of red ones (Courtesy of Robert A. Freitas, Institute for Molecular Manufacturing, California, USA). *Middle:* computed discrete geodesic between the segmented shapes in the first and the last frame. *Bottom:* pushforward of the initial (first four shapes) and pullback of the final frame (last five shapes) according to the geodesic flow

be generated by a joint motion field $v(t) : \bigcup_{i=1}^m \mathcal{O}^i(t) \rightarrow \mathbb{R}^d$. The single objects $\mathcal{O}^i(t)$ can then be regarded as the subcomponents of an overall object $\bigcup_{i=1}^m \mathcal{O}^i(t)$. The total dissipation along the path is measured exactly as before by

$$\mathbf{Diss} \left[(v(t), (\mathcal{O}^i(t))_{i=1, \dots, m})_{t \in [0, 1]} \right] = \int_0^1 \int_{\bigcup_{i=1}^m \mathcal{O}^i(t)} \frac{\lambda}{2} (\text{tr}\epsilon[v])^2 + \mu \text{tr}(\epsilon[v]^2) \, dx \, dt.$$

This naturally translates to the discrete dissipation of a path with $K+1$ intermediate shape collections $(\mathcal{S}_k^i)_{i=1, \dots, m}$, $k = 0, \dots, K$,

$$\sum_{k=1}^K \mathcal{W}_{\text{deform}} \left[\phi_k, (\mathcal{O}_{k-1}^i)_{i=1, \dots, m} \right] := \sum_{k=1}^K \int_{\bigcup_{i=1}^m \mathcal{O}_{k-1}^i} W(\mathcal{D}\phi_k) \, dx,$$

where the deformations ϕ_k satisfy the constraints $\phi_k(\mathcal{S}_{k-1}^i) = \mathcal{S}_k^i$ for $k = 1, \dots, K$, $i = 1, \dots, m$, and $\mathcal{S}_0^i = \mathcal{S}_A^i$, $\mathcal{S}_K^i = \mathcal{S}_B^i$, $i = 1, \dots, m$.

The different object components can of course be assigned different material properties. Figure 22 shows frames from a real video sequence of moving white and red blood cells (top) as well as a discrete geodesic between the first and last frame (middle) for which the material parameters of the white blood cell were chosen twenty times weaker than for the red blood cells. The result is a nonlinear interpolation between distant frames which is in good agreement with the actually observed motion. Once geodesic distances between shapes are defined, one can statistically analyze ensembles of shapes and cluster them in groups based on the geodesic distance as a reliable measure for the similarity of shapes. Two exemplary examples are provided by the evaluation of geodesic distances between different 2D letters (Fig. 23, left) and between six different 3D foot shapes (Fig. 23, right). In the 2D example, we clearly identify three distinct clusters (*Bs*, *Xs*, and *M*).

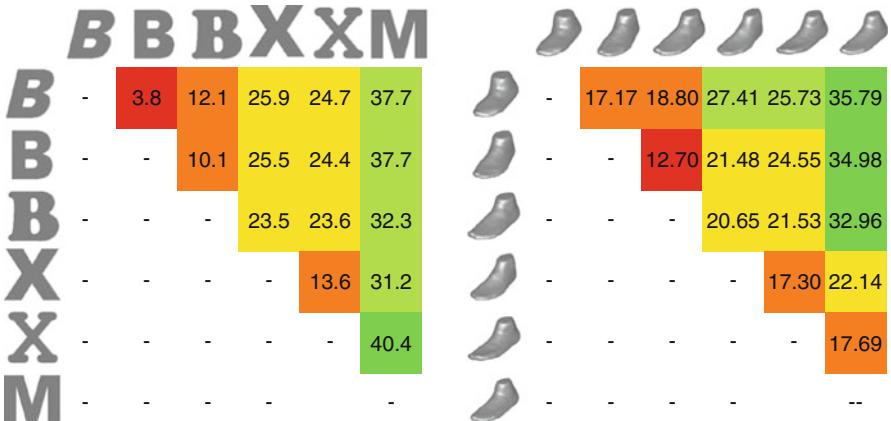

Fig. 23 Left: pairwise geodesic distances between (also topologically) different letter shapes. Right: pairwise geodesic distances between different scanned 3D feet. The feet have volumes 499.5, 500.6, 497.6, 434.7, 432, and 381 cm³, respectively

A Collection of Computational Tools

So far, we have investigated some of the many aspects on mathematical models in shape space without any discussion of the corresponding computational tools and numerical algorithms. Hence, let us at least briefly mention some fundamental computational aspects to effectively deal with general classes of shapes as boundary contours of volumetric objects.

At first, we replace the strict separation between material inside the object and void outside by substituting the void with a material which is several orders of magnitude softer than inside the object. This relaxation is important with respect to the existence analysis and the stabilization of the computational method. In fact, we replace the deformation energy $\mathcal{W}_{\text{deform}}[\phi, \mathcal{O}] = \int_{\mathcal{O}} W(\mathcal{D}\phi) dx$ by the energy $\mathcal{W}_{\text{deform}}^{\eta}[\phi, \mathcal{O}] = \int_{\mathcal{O}} ((1 - \eta)\chi_{\mathcal{O}} + \eta) W(\mathcal{D}\phi) dx$ for a small constant η . In the implementation which underlies the above applications, for $\eta = 10^{-4}$ one observes no significant qualitative impact of this regularization on the solution. Furthermore, as mentioned above, to ensure regularity of the shape contour \mathcal{S} , we take into account the area functional $\mathcal{L}[\mathcal{S}] = \int_{\mathcal{S}} da$ as a prior, weighted with a small factor.

Compared to a parametric description of shapes, e.g., as a polygonal line or a triangulated surface, an implicit description has several advantages. In particular, it does not require a remeshing even in case of large deformations, it allows for topological transitions without any extra handling of the associated singularities, and it can be combined with multi-scale relaxation schemes for an efficient minimization of the involved functionals.

In what follows, we consider a level set and a phase field description of shapes and outline the general framework of a multi-scale method based on finite element calculus. In fact, the phase field model has been used in the examples for the

elastic shape averaging and the PCA, whereas the level set method has served as a numerical building block for the computation of time-discrete shape geodesics.

Shapes Described by Level Set Functions

The level set method first presented by Osher and Sethian [60] has been used for a wide range of applications [59, 71]. Burger and Osher gave an overview in the context of shape optimization [7]. To numerically solve variational problems in shape space, we assume a shape \mathcal{S} to be represented by the zero level set $\{x \in \Omega : u(x) = 0\}$ of a scalar function $u : \Omega \rightarrow \mathbb{R}$ on a computational domain $\Omega \subset \mathbb{R}^d$. Furthermore, the zero super level set $\{x \in \Omega : u(x) > 0\}$ defines the corresponding object domain \mathcal{O} . This shape description can be incorporated in a variational approach following the approximation proposed by Chan and Vese [9]. In fact, the partition of the domain Ω into object and background is encoded via a regularized Heaviside function $H_\varepsilon \circ u$. As in [9], we consider the function $H_\varepsilon(x) := \frac{1}{2} + \frac{1}{\pi} \arctan\left(\frac{x}{\varepsilon}\right)$, where ε is a scale parameter representing the width of the smeared-out shape contour. Then, a deformation energy $\mathcal{W}_{\text{deform}}^\eta[\phi, \mathcal{O}] = \int_{\Omega} ((1 - \eta)\chi_{\mathcal{O}} + \eta) W(D\phi) dx$ is approximated by

$$\mathcal{W}_{\text{deform}}^{\varepsilon, \eta}[\phi, u] = \int_{\Omega} ((1 - \eta)H_\varepsilon(u) + \eta) W(D\phi) dx.$$

Furthermore, the energy $\mathcal{F}[\mathcal{S}_A, \phi, \mathcal{S}_B] = \text{vol}(\mathcal{O}_A \Delta \phi^{-1}(\mathcal{O}_B))$ measuring the volumetric mismatch between an object \mathcal{O}_A and the pullback of an object \mathcal{O}_B under a deformation ϕ can be approximated by

$$\mathcal{F}^\varepsilon[u_A, \phi, u_B] = \int_{\Omega} (H_\varepsilon(u_B \circ \phi) - H_\varepsilon(u_A))^2 dx,$$

where u_A, u_B are level set representations of the shapes \mathcal{S}_A and \mathcal{S}_B , respectively. Finally, the surface area of a shape \mathcal{S} , which appears as a prior, is replaced by the total variation of $H_\varepsilon \circ u$, and we obtain

$$\mathcal{L}^\varepsilon[u] = \int_{\Omega} |\nabla H_\varepsilon(u)| dx.$$

Let us emphasize that in the actual energy minimization algorithm, the guidance of an initial zero level set toward the final shape relies on the nonlocal support of the derivative of the regularized Heaviside function (cf. [8]).

Shapes Described via Phase Fields

An alternative to a level set description of shapes is a phase field representation. Physically, the phase field approach is inspired by the observation that interfaces are usually not sharp but characterized by a diffusive transition. Mathematically, there are two basic types of such phase field representations, a single phase approach as the one presented by Ambrosio and Tortorelli [1] for the approximation of the

Mumford–Shah model [56] and the double phase approach by Modica and Mortola [55] used to approximate surface integrals. In the shape context studied here, let us focus on the single phase model. Thus, a shape \mathcal{S} is encoded by a continuous, piecewise smooth phase field function $u : \Omega \rightarrow \mathbb{R}$ which is zero on \mathcal{S} , but close to one everywhere else. The specific profile of the phase field function u for a shape \mathcal{S} is determined via the phase field approximation

$$\mathcal{L}^\varepsilon[u] = \frac{1}{2} \int_{\Omega} \varepsilon |\nabla u|^2 + \frac{1}{\varepsilon} (u - 1)^2 \, dx$$

of the involved surface area $\int_{\mathcal{S}} da$. As in the above level set model, the phase field parameter ε determines the width of the diffusive interface. Different from the level set model by Chan and Vese, the interface profile is not explicitly prescribed but implicitly encoded in the variational approach as the profile attained by minimizers of the functional. Based on this phase field model the penalty functional $\mathcal{F}[\mathcal{S}_A, \phi, \mathcal{S}_B] = \mathcal{H}^{d-1}(\mathcal{S}_A \Delta \phi^{-1}(\mathcal{S}_B))$ measuring the area mismatch between a shape \mathcal{S}_A and the pullback of a shape \mathcal{S}_B under a deformation ϕ can be approximated by

$$\mathcal{F}^\varepsilon[u_A, \phi, u_B] = \frac{1}{\varepsilon} \int_{\Omega} (u_B \circ \phi)^2 (1 - u_A)^2 + u_A^2 (1 - u_B \circ \phi)^2 \, dx,$$

where u_A, u_B are phase fields representing the shapes \mathcal{S}_A and \mathcal{S}_B , respectively. In this type of models, the deformation energy $\mathcal{W}_{\text{deform}}^\eta[\phi, \mathcal{O}]$ cannot be realized based on a phase field function u due to the fact that a single phase model allows to identify the shape itself but does not distinguish its inside and outside. Therefore, in the presented applications of elastic shape averaging and the elastic PCA, the input objects and thus their characteristic functions $\chi_{\mathcal{O}}$ were given a priori.

Multi-scale Finite Element Approximation

For the spatial discretization of the functionals in the above variational approaches, the finite element method can be applied. Hence, the level set function or the phase field u , representing a (unknown) shape \mathcal{S} , and the different components of the deformations ϕ are represented by continuous, piecewise multilinear (trilinear in 3D and bilinear in 2D) finite element functions U and Φ on a regular grid superimposed on the domain $\Omega = [0, 1]^d$. For the ease of implementation, a dyadic grid resolution with $2^L + 1$ vertices in each direction and a grid size $h = 2^{-L}$ is chosen.

Descent algorithm. The functionals depend nonlinearly both on the discrete deformations Φ (due to the concatenation $U \circ \Phi$ and the nonlinear integrand $W(\cdot)$ of the deformation energy) as well as on the discrete level set or phase field functions U (e.g., due to the concatenation of the level set function with the regularized Heaviside function $H_\varepsilon(\cdot)$). In our energy relaxation algorithm for fixed grid size, we employ a gradient descent approach. We constantly alternate between performing a

single gradient descent step for all deformations and the level set or phase field functions.

Numerical quadrature. Integral evaluations in the descent algorithm are performed by Gaussian quadrature of third order on each grid cell. For various terms, we have to evaluate pullbacks $U \circ \Phi$ of a discretized level set function U or a test function under a discretized deformation Φ . Let us emphasize that quadrature based on nodal interpolation of $U \circ \Phi$ would lead to artificial displacements near the shape edges accompanied by strong artificial tension. Hence, in our algorithm, if $\Phi(x)$ lies inside Ω for a quadrature point x , then the pullback is evaluated exactly at x . Otherwise, we project $\Phi(x)$ back onto the boundary of Ω and evaluate U at that projection point.

Cascadic multi-scale algorithm. The variational problem considered here is highly nonlinear, and for fixed time step size, the proposed scheme is expected to have very slow convergence; also it might end up in some nearby local minimum. Here, a multilevel approach (initial optimization on a coarse scale and successive refinement) turns out to be indispensable in order to accelerate convergence and not to be trapped in undesirable local minima. Due to our assumption of a dyadic resolution $2^L + 1$ in each grid direction, we are able to build a hierarchy of grids with $2^l + 1$ nodes in each direction for $l = L, \dots, 0$. Via a simple restriction operation, we project every finite element function to any of these coarse grid spaces. Starting the optimization on a coarse grid, the results from coarse scales are successively prolonged onto the next grid level for a refinement of the solution [5]. Hence, the construction of a grid hierarchy allows to solve coarse scale problems in our multi-scale approach on coarse grids. Since the width ε of the diffusive shape representation should naturally scale with the grid width h , we choose $\varepsilon = h$.

5 Conclusion

Let us close with a comparison of path- and state-based shape space. Already in section “Conceptual Differences Between the Path- and State-Based Dissimilarity Measures,” we have studied the difference between the state-based dissimilarity measure d_{elast} and the path-based distance d_{viscous} . Based on the applications considered in the previous sections, let us compare the underlying concepts now more on a conceptual level of the geometry of shape space:

- *Non-uniqueness of shape averages.* Due to the nonlinearity of the elastic variational problem, local minimizers of the elastic energy might be nonunique. There might even exist different minimizing deformations with the same elastic energy. Mechanically, this nonuniqueness is frequently associated with different buckling modes, which occur in case of large, geometrically nonlinear deformations. Hence, the shape average need not be uniquely defined, except in the small displacement case, where a linear elastic model (8) applies. In case of the path-

based approach, geodesics (shortest) do not have to be unique either. Indeed, a geodesic is the unique shortest path only until the first conjugate point. Hence, the shape average is in a strict sense not well defined if the distances are sufficiently large.

- *Different physical interpretation of the PCA.* In the Riemannian setup with the metric being the rate of viscous dissipation, the $\log_{\mathcal{S}} \mathcal{S}_k$ corresponds to the initial velocity $v_k : \mathcal{S} \rightarrow \mathbb{R}^d$ in the (optimal transport) flow of \mathcal{O} associated with shape \mathcal{S} into \mathcal{O}_k associated with the k th input shape \mathcal{S}_k . In the elastic model, the boundary stress $\sigma_k v : \partial\mathcal{O} \rightarrow \mathbb{R}^d$ results from the deformation ϕ_k of \mathcal{O}_k onto the average object \mathcal{O} and effectively is the restoring force acting on the average shape \mathcal{S} . Via the linearized elasticity problem in the prestressed compound configuration of the average object \mathcal{O} , these restoring forces are identified with displacements u_k . Depending on the model, either the flow velocities v_k or the linear elastic displacements u_k form the basis of a covariance analysis in the linear vector space of mappings $\overline{\mathcal{O}} \rightarrow \mathbb{R}^d$. The outcome are principal shape variations of the average shape, either generated by motion fields or displacements, respectively.
- *Quantitative shape analysis.* The Riemannian metric given by the rate of viscous dissipation in the path-based viscous fluid approach allows direct comparison of multiple ensembles of shapes via pairwise distance computations. Due to the lack of a triangle inequality, this is possible only in a restricted sense in the state-based elastic approach, where dissimilarity measures for one fixed shape and a set of varying shapes can be computed.
- The method of choice depends on the *specific application*. If shapes are considered as boundaries of objects with a viscous fluid inside, then the path-based approach would be more appropriate. The state-based elastic approach is favorable for objects which behave more like deformable solids.

Acknowledgments The model proposed in section “Viscous Fluid-Based Shape Space” has been developed in cooperation with Leah Bar and Guillermo Sapiro from the University of Minnesota. Benedikt Wirth has been funded by the Bonn International Graduate School in Mathematics. Furthermore, the work was supported by the Deutsche Forschungsgemeinschaft, SPP 1253 “Optimization with Partial Differential Equations.” Part of Figs. 3–4 and 19–23 have been taken from [83], the results from Figs. 6, 8, and 10–18 stem from [67, 69].

Abstract

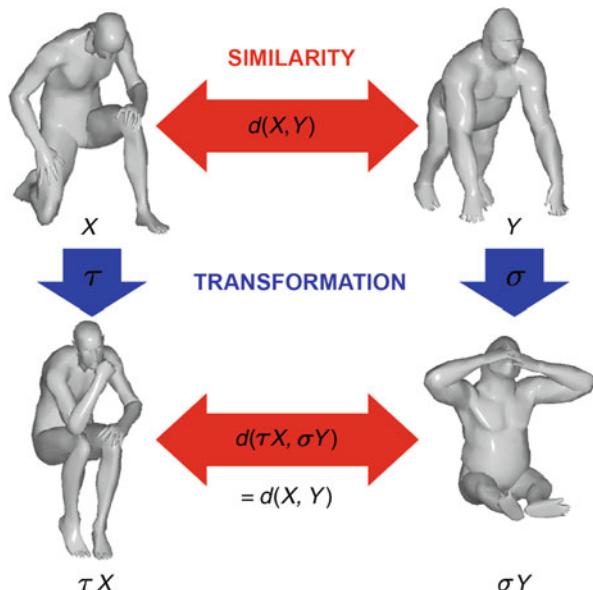

Nonrigid shapes are ubiquitous in nature and are encountered at all levels of life, from macro to nano. The need to model such shapes and understand their behavior arises in many applications in imaging sciences, pattern recognition, computer vision, and computer graphics. Of particular importance is understanding which properties of the shape are attributed to deformations and which are invariant, i.e., remain unchanged. This chapter presents an approach to nonrigid shapes from the point of view of metric geometry. Modeling shapes as metric spaces, one can pose the problem of shape similarity as the similarity of metric spaces and harness tools from theoretical metric geometry for the computation of such a similarity.

1 Introduction

Those who played the game Rock, Paper, and Scissors in their childhood certainly remember the three gestures used in the game: Rock, represented by a clenched fist; Paper, represented by an open hand; and Scissors, represented by the extended index and middle fingers. These gestures are a toy example of the *nonrigid shape similarity* problem, which is the central topic of this chapter. No matter how one bends the fingers, he will immediately recognize the underlying object: the human hand.

More generally, the problem of determining the similarity of shapes undergoing certain class of transformations is termed *invariant shape similarity*. A similarity criterion is said to be invariant if it is not influenced by the transformation (Fig. 1). Different classes of transformations prescribe different similarity criteria based on geometric shape properties that are invariant under such transformations. The wider is the class, the less properties are preserved, and as a thumb rule, the more difficult is the problem. Specifically, in this chapter, we will consider rigid, inelastic, topology-changing, and scaling transformations. In many cases, such transformations are a good approximation of real transformations that natural objects may undergo.

Fig. 1 Invariant shape similarity

Problems

Since nonrigid shapes are ubiquitous in the world and are encountered at all scales from macro to nano, nonrigid shape similarity plays a key role in many applications in imaging sciences, pattern recognition, computer vision, and computer graphics. Two archetype problems in shape analysis considered in this chapter are *invariant similarity* and *correspondence*. As will be discussed in the following, these two problems are interrelated: finding the best correspondence between two shapes also allows quantifying their similarity.

A good example of shape similarity is the problem of face recognition [19,21,24]. As the crudest approximation, one can think of faces as rigid surfaces and compare them using similarity criteria invariant under rigid transformations. However, such an approach does not account for surface deformations due to facial expressions, which can be approximated by inelastic deformations. Accounting for such deformations requires different similarity criteria. Yet, even elastic deformations are not enough to model the behavior of human faces: many facial expressions involve elastic deformations that change the facial shape topology (think of open and closed mouth). This extension of the model will require revisiting the similarity criterion once again.

The problem of correspondence is often encountered in shape synthesis applications such as morphing. In order to morph one shape into the other, one needs to know which point on the first shape will be transformed into a point on the second shape, in other words, establishing a correspondence between the shapes.

Methods

Many different approaches to shape similarity and correspondence can be considered as instances of the *minimum-distortion correspondence problem*, in which two shapes are endowed with certain structure, and one attempts to find the best (least distorting) matching between these structures. Such structures can be *local* (e.g., multiscale heat kernel signatures [106], local photometric properties [107, 119], or conformal factor [12]) or *global* (e.g., geodesic [24, 47, 78], diffusion [28], and commute time [31]) distances. The distortion of the best possible correspondence can be used as a criterion of shape similarity. By defining a structure invariant under certain class of transformations, it is possible to obtain invariant correspondence or similarity.

Local structures can be regarded as feature descriptors. As a model for global structures, metric spaces are used.

Chapter Outline

This chapter tries to present a unifying view on the archetypical problems in shape analysis. The first part presents a metric view on the problem of nonrigid shape similarity and correspondence, a common denominator allowing to deal with different types of invariance. According to this model, shapes are represented as metric spaces. The mathematical foundations of this model are provided in Sect. 2. Sections 3 and 4 deal with discrete representation of shapes, which is of essence in practical numerical computations. Section 5 provides a rigorous formulation of the invariant shape similarity problem and reviews different algorithms for its computation. Section 6 deals with an extension of invariant similarity to shapes which are partially similar, and Sect. 7 deals with a particular case of self-similarity and symmetry. Local feature-based methods and their use to create global shape descriptors are presented in Sect. 8. Finally, concluding remarks in Sect. 9 end the chapter. This chapter is based in part on the book [26], to which the reader is referred for further discussion and details.

2 Shapes as Metric Spaces

Elad and Kimmel [47, 48], Mémoli and Sapiro [78], and Bronstein et al. [23, 24] suggested to model shapes as metric spaces. The key idea of this model is that it allows to compare shapes as metric spaces. Since the model allows arbitrariness in the definition of the metric, desired invariance considerations guide the choice of the metric.

This section introduces the mathematical formalism and notation of this model and shows the construction of three different types of metric geometries: Euclidean, Riemannian, and diffusion.

Basic Notions

Topological Spaces

Given a set X , a *topology* T on X is a collection of subsets of X satisfying (Ti) $X, \emptyset \in T$; (Tii) $\bigcup_{\alpha} U_{\alpha} \in T$ for $U_{\alpha} \in T$; and (Tiii) $\bigcap_{i=1}^N U_i \in T$ for $U_i \in T$. X together with T is called a *topological space*. By convention, sets in T are referred to as *open sets* and their complements as *closed sets*.

A *neighborhood* $N(x)$ of x is a set containing an open set $U \in T$ such that $x \in U$. Points with neighborhood are called *interior*.

A topological space is called *Hausdorff* if distinct points in it have disjoint neighborhoods.

Two topological spaces X and Y are *homeomorphic* if there exists bijection $\alpha : X \rightarrow Y$ which is continuous and has continuous inverse α^{-1} . Since homeomorphisms copy topologies, homeomorphic spaces are topologically equivalent [1].

Metric Spaces

A function $d : X \times X \rightarrow \mathbb{R}$ which is (Mi) *positive-definite* ($d(x, y) > 0$ for all $x \neq y$ and $d(x, y) = 0$ for $x = y$) and (Mii) *subadditive* ($d(x, z) \leq d(x, y) + d(y, z)$ for all x, y, z) is called a *metric* on X . The metric is an abstraction of the notion of distance between pairs of points on X . Property (Mii) is called *triangle inequality* and generalizes the known fact: the sum of the lengths of two edges of a triangle is greater or equal to the length of the third edge. The pair (X, d) is called a *metric space*.

A metric induces topology through the definition of *open metric ball* $B_r(x) = \{x' \in X : d(x, x') < r\}$. A neighborhood of x in a metric space is a set containing a metric ball $B_r(x)$ [34].

Isometries

Given two metric spaces (X, d) and (Y, δ) , the set $C \subset X \times Y$ of pairs such that for every $x \in X$ there exists at least one $y \in Y$ such that $(x, y) \in C$, and similarly, for every $y \in Y$, there exists an $x \in X$ such that $(x, y) \in C$ is called a *correspondence* between X and Y . Note that a correspondence C is not necessarily a function. The correspondence is called *bijection* if every point in X has a unique corresponding point in Y and vice versa.

The discrepancy of the metrics d and δ between the corresponding points is called the *distortion* of the correspondence,

$$\text{dis}(C) = \sup_{(x,y),(x',y') \in C} |d(x, x') - \delta(y, y')|.$$

Metric spaces (X, d) and (Y, δ) are said to be ϵ -*isometric* if there exists a correspondence C with $\text{dis}(C) \leq \epsilon$. Such a C is called an ϵ -*isometry*.

A particular case of a 0-isometry is called an *isometry*. In this case, the correspondence is a bijection and X and Y are called *isometric*.

Euclidean Geometry

Euclidean space \mathbb{R}^m (hereinafter also denoted as \mathbb{E}) with the *Euclidean metric* $d_{\mathbb{E}}(x, x') = \|x - x'\|_2$ is the simplest example of a metric space. Given as a subset X of \mathbb{E} , we can measure the distances between points x and x' on X using the *restricted Euclidean metric*,

$$d_{\mathbb{E}}|_{X \times X}(x, x') = d_{\mathbb{E}}(x, x')$$

for all x, x' in X .

The restricted Euclidean metric $d_{\mathbb{E}}|_{X \times X}$ is invariant under Euclidean transformations of X , which include translation, rotation, and reflection in \mathbb{E} . In other words, X and its Euclidean transformation $i(X)$ are isometric in the sense of the Euclidean metric. Euclidean isometries are called *congruences*, and two subsets of \mathbb{E} differing up to a Euclidean isometry are said to be *congruent*.

Riemannian Geometry

Manifolds

A Hausdorff space X which is locally homeomorphic to \mathbb{R}^n (i.e., for every x in X , there exists a neighborhood U and a homeomorphism $\alpha : U \rightarrow \mathbb{R}^n$) is called an *n-manifold* or an *n-dimensional manifold*. The function α is called a *chart*. A collection of neighborhoods that cover X together with their charts is called an *atlas* on X . Given two charts α and β with overlapping domains U and V , the map $\beta\alpha^{-1} : \alpha(U \cap V) \rightarrow \beta(U \cap V)$ is called a *transition function*. A manifold whose transition functions are all differentiable is called a *differentiable manifold*. More generally a C^k -manifold has all transition maps k -times continuously differentiable. A C^∞ -manifold is called *smooth*.

A *manifold with boundary* is not a manifold in the strict sense of the above definition. Its *interior points* are locally homeomorphic to \mathbb{R}^n , and every point on the *boundary* ∂X is homeomorphic to $[0, \infty) \times \mathbb{R}^{n-1}$.

Of particular interest for the discussion in this chapter are two-dimensional ($n = 2$) manifolds, which model boundaries of physical objects in the world surrounding us. Such manifolds are also called *surfaces*. In the following, when referring to shapes and objects, the terms manifold, surface, and shape will be used synonymously.

Differential Structures

Locally, a manifold can be represented as a linear space, in the following way. Let $\alpha : U \rightarrow \mathbb{R}^n$ be a chart on a neighborhood of x and $\gamma : (-1, 1) \rightarrow X$ be a differentiable curve passing through $x = \gamma(0)$. The derivative of the curve $\frac{d}{dt}(\alpha \circ \gamma)(0)$ is called a *tangent vector* at x . The set of all equivalence classes of tangent vectors at x forming an n -dimensional real vector space is called the *tangent space* $T_x X$ at x .

A family of inner products $\langle \cdot, \cdot \rangle_x : T_x X \times T_x X \rightarrow \mathbb{R}$ depending smoothly on x is called *Riemannian metric tensor*. A manifold X with a Riemannian metric tensor is called a *Riemannian manifold*.

The Riemannian metric allows to define local length structures and differential calculus on the manifold. Given a differentiable scalar-valued function $f : X \rightarrow \mathbb{R}$, the *exterior derivative (differential)* is a form $df = \langle \nabla f, \cdot \rangle$ on the tangent space TX . For a tangent vector $\mathbf{v} \in T_x X$, $df(x)\mathbf{v} = \langle \nabla f(x), \mathbf{v} \rangle_x$. ∇f is called the *gradient* of f at x and is a natural generalization of the notion of the gradient in vector spaces to manifolds. Similarly to the definition of Laplacian satisfying

$$\int_X \langle \nabla f, \nabla h \rangle_x d\mu(x) = \int_X h \Delta_X f d\mu(x)$$

for differentiable scalar-valued functions f and h , the operator Δ_X is called the *Laplace–Beltrami operator*, a generalization of the Laplacian. Here, μ denotes the measure associated with the n -dimensional *volume element (area element)* for $n = 2$. The Laplace–Beltrami operator is (Li) symmetric ($\int_X h \Delta_X f d\mu(x) = \int_X f \Delta_X x d\mu(x)$), (Lii) of local action ($\Delta_X f(x)$ is independent of the value of $f(x')$ for $x' \neq x$), and (Liii) positive semi-definite ($\int_X f \Delta_X f d\mu(x) \geq 0$) (in many references, the Laplace–Beltrami is defined as a negative semi-definite operator) and (Liv) coincides with the Laplacian on Euclidean domains, such that $\Delta_X f = 0$ if f is a linear function and X is Euclidean.

Geodesics

Another important use of the Riemannian metric tensor is to measure the length of paths on the manifold. Given a continuously differentiable curve $\gamma : [a, b] \rightarrow X$, its length is given by

$$\ell(\gamma) = \int_a^b \langle \gamma'(t), \gamma'(t) \rangle_{\gamma(t)}^{1/2} dt.$$

For the set of all continuously differentiable curves $\Gamma(x, x')$ between the points x, x' ,

$$d_X(x, x') = \inf_{\gamma \in \Gamma(x, x')} \ell(\gamma) \tag{1}$$

defines a metric on X referred to as *length* or *geodesic metric*. If the manifold is compact, for any pair of points x and x' , there exists a curve $\gamma \in \Gamma(x, x')$ called a *minimum geodesic* such that $\ell(\gamma) = d_X(x, x')$.

Embedded Manifolds

A particular realization of a Riemannian manifold called *embedded manifold* (or *embedded surface* for $n = 2$) is a smooth submanifold of \mathbb{R}^m ($m > n$). In this case, the tangent space is an n -dimensional hyperplane in \mathbb{R}^m , and the Riemannian metric

is defined as the restriction of the Euclidean inner product to the tangent space, $\langle \cdot, \cdot \rangle_{\mathbb{R}^m}|_{TX}$.

The length of a curve $\gamma : [a, b] \rightarrow X \subset \mathbb{R}^m$ on an embedded manifold is expressed through the Euclidean metric,

$$\ell(\gamma) = \int_a^b (\langle \gamma'(t), \gamma'(t) \rangle_{\mathbb{R}^m}|_{T_{\gamma(t)}X})^{1/2} dt, = \int_a^b \|\gamma'(t)\|_{\mathbb{R}^m} dt \quad (2)$$

and the geodesic metric d_X defined according to (1) is said to be *induced* by $d_{\mathbb{R}^m}$. (Repeating the process, one obtains that the metric induced by d_X is equal to d_X . For this reason, d_X is referred to as *intrinsic metric* [34].)

Though apparently embedded manifolds are a particular case of a more general notion of Riemannian manifolds, it appears that any Riemannian manifold can be realized as an embedded manifold. This is a consequence of the *Nash embedding theorem* [84], showing that a C^k ($k \geq 3$) Riemannian manifold can be isometrically embedded in a Euclidean space of dimension $m = n^2 + 5n + 3$. In other words, any smooth Riemannian manifold can be defined as a metric space which is isometric to a smooth submanifold of a Euclidean space with the induced metric.

Rigidity

Riemannian manifolds do not have a unique realization as embedded manifolds. One obvious degree of freedom is the set of all Euclidean isometries: two congruent embedded manifolds are isometric and thus are realizations of the same Riemannian manifold. However, a Riemannian manifold may have two realizations which are isometric but incongruent. Such manifolds are called *nonrigid*. If, on the other hand, a manifold's only isometries are congruences, it is called *rigid*.

Diffusion Geometry

Another type of metric geometry arises from the analysis of heat propagation on manifolds. This geometry is called *diffusion* and is also intrinsic. We start by reviewing properties of diffusion operators.

Diffusion Operators

A function $k : X \times X \rightarrow \mathbb{R}$ is called a *diffusion kernel* if it satisfies the following properties: (Ki) *nonnegativity*: $k(x, x) \geq 0$; (Kii) *symmetry*: $k(x, y) = k(y, x)$; (Kiii) *positive-semidefiniteness*: for every bounded f ,

$$\int \int k(x, y) f(x) f(y) d\mu(x) d\mu(y) \geq 0;$$

(Kiv) *square integrability*: $\int \int k^2(x, y) d\mu(x) d\mu(y) < \infty$; and (Kv) *conservation*: $\int k(x, y) d\mu(y) = 1$. The value of $k(x, y)$ can be interpreted as a transition probability from x to y by one step of a random walk on X .

Diffusion kernel defines a linear operator

$$\mathbf{K}f = \int k(x, y)f(y)d\mu(y), \quad (3)$$

which is known to be self-adjoint. Because of (Kiv), \mathbf{K} has a finite Hilbert norm and therefore is compact. As the result, it admits a discrete eigendecomposition $\mathbf{K}\psi_i = \alpha_i \psi_i$ with some eigenfunctions $\{\psi_i\}_{i=0}^{\infty}$ and eigenvalues $\{\alpha_i\}_{i=0}^{\infty}$. $\alpha_i \geq 0$ by virtue of property (Kii), and $\alpha_i \leq 1$ by virtue of (Kv) and consequence of the Perron–Frobenius theorem.

By the spectral theorem, the diffusion kernel can be presented as $k(x, y) = \sum_{i=0}^{\infty} \alpha_i \psi_i(x)\psi_i(y)$. Since $\{\psi_i\}_{i=1}^{\infty}$ form an orthonormal basis of $L^2(X)$,

$$\int \int k^2(x, y)d\mu(x)d\mu(y) = \sum_{i=0}^{\infty} \alpha_i^2, \quad (4)$$

a fact sometimes referred to as Parseval's theorem. Using these results, properties (Kiii–Kv) can be rewritten in the spectral form as $0 \leq \alpha_i \leq 1$ and $\sum_{i=0}^{\infty} \alpha_i^2 < \infty$.

An important property of diffusion operators is the fact that for every $t \geq 0$, the operator \mathbf{K}^t is also a diffusion operator with the eigenbasis of \mathbf{K} and corresponding eigenvalues $\{\alpha_i^t\}_{i=0}^{\infty}$. The kernel of \mathbf{K}^t expresses the transition probability by random walk of t steps. This allows to define a scale space of kernels, $\{k_t(x, y)\}_{t \in T}$, with the scale parameter t .

There exist a large variety of possibilities to define a diffusion kernel and the related diffusion operator. Here, we restrict our attention to operators describing *heat diffusion*. Heat diffusion on surfaces is governed by the *heat equation*

$$\left(\Delta_X + \frac{\partial}{\partial t} \right) u(x, t) = 0; \quad u(x, 0) = u_0(x), \quad (5)$$

where $u(x, t)$ is the distribution of heat on the surface at point x in time t , u_0 is the initial heat distribution, and Δ_X is the positive-semidefinite Laplace–Beltrami operator, a generalization of the second-order Laplacian differential operator Δ to non-Euclidean domains. (If X has a boundary, *boundary conditions* should be added.)

On Euclidean domains ($X = \mathbb{R}^m$), the classical approach to the solution of the heat equation is by representing the solution as a product of temporal and spatial components. The spatial component is expressed in the Fourier domain, based on the observation that the Fourier basis is the eigenbasis of the Laplacian Δ , and the corresponding eigenvalues are the frequencies of the Fourier harmonics. A particular solution for a point initial heat distribution $u_0(x) = \delta(x - y)$ is called the *heat*

kernel $h_t(x - y) = \frac{1}{(4\pi t)^{m/2}} e^{-\|x-y\|^2/4t}$, which is shift invariant in the Euclidean case. A general solution for any initial condition u_0 is given by convolution $\mathbf{H}^t u_0 = \int_{\mathbb{R}^m} h_t(x - y) u_0(y) dy$, where \mathbf{H}^t is referred to as *heat operator*.

In the non-Euclidean case, the eigenfunctions of the Laplace–Beltrami operator $\Delta_X \phi_i = \lambda_i \phi_i$ can be regarded as a “Fourier basis” and the eigenvalues given the “frequency” interpretation. The heat kernel is not shift invariant but can be expressed as $h_t(x, y) = \sum_{i=0}^{\infty} e^{-t\lambda_i} \phi_i(x) \phi_i(y)$.

It can be shown that the heat operator is related to the Laplace–Beltrami operator as $\mathbf{H}^t = e^{-t\Delta}$, and as a result, it has the same eigenfunctions ϕ_i and corresponding eigenvalues $e^{-t\lambda_i}$. It can be thus seen as a particular instance of a more general family of diffusion operators \mathbf{K} diagonalized by the eigenbasis of the Laplace–Beltrami operator, namely, \mathbf{K} ’s as defined in the previous section but restricted to have the eigenfunctions $\psi_i = \phi_i$. The corresponding diffusion kernels can be expressed as

$$k(x, y) = \sum_{i=0}^{\infty} K(\lambda_i) \phi_i(x) \phi_i(y), \quad (6)$$

where $K(\lambda)$ is some function such that $\alpha_i = K(\lambda_i)$ (in the case of \mathbf{H}_t , $K(\lambda) = e^{-t\lambda}$). Since the Laplace–Beltrami eigenvalues can be interpreted as frequency, $K(\lambda)$ can be thought of as the *transfer function* of a low-pass filter. Using this signal processing analogy, the kernel $k(x, y)$ can be interpreted as the point spread function at a point y , and the action of the diffusion operator $\mathbf{K}f$ on a function f on X can be thought of as the application of the point spread function by means of a non shift-invariant version of convolution. The transfer function of the diffusion operator \mathbf{K}^t is $K^t(\lambda)$, which can be interpreted as multiple applications of the filter $K(\lambda)$. Such multiple applications decrease the effective bandwidth of the filter and, consequently, increase its effective support in space. Because of this duality, both $k(x, y)$ and $K(\lambda)$ are often referred to as diffusion kernels.

Diffusion Distances

Since a diffusion kernel $k(x, y)$ measures the degree of proximity between x and y , it can be used to define a metric

$$d^2(x, y) = \|k(x, \cdot) - k(y, \cdot)\|_{L^2(X)}^2, \quad (7)$$

on X , which was first constructed by Berard et al. in [*] and dubbed as the *diffusion distance* by Coifman and Lafon [40]. Another way to interpret the latter distance is by considering the embedding $\Psi : x \mapsto L^2(X)$ by which each point x on X is mapped to the function $\Psi(x) = k(x, \cdot)$. The embedding Ψ is an isometry between X equipped with diffusion distance and $L^2(X)$ equipped with the standard L^2 metric, since $d(x, y) = \|\Psi(x) - \Psi(y)\|_{L^2(X)}$. Because of spectral duality, the diffusion distance can also be written as

$$d^2(x, y) = \sum_{i=0}^{\infty} K^2(\lambda_i)(\phi_i(x) - \phi_i(y))^2. \quad (8)$$

Here as well we can define an isometric embedding $\Phi : x \mapsto \ell^2$ with $\Phi(x) = \{K(\lambda_i)\phi_i(x)\}_{i=0}^{\infty}$, termed as the *diffusion map* by Lafon. The diffusion distance can be cast as $d(x, y) = \|\Phi(x) - \Phi(y)\|_{\ell^2}$.

The same way a diffusion operator \mathbf{K}^t defines a scale space, a family of diffusion metrics can be defined for $t \geq 0$ as

$$\begin{aligned} d_t^2(x, y) &= \|\Phi_t(x) - \Phi_t(y)\|_{\ell^2}^2 \\ &= \sum_{i=0}^{\infty} K^{2t}(\lambda_i)(\phi_i(x) - \phi_i(y))^2, \end{aligned} \quad (9)$$

where $\Phi_t(x) = \{K^t(\lambda_i)\phi_i(x)\}_{i=0}^{\infty}$. Interpreting diffusion processes as random walks, d_t can be related to the “connectivity” of points x and y by walks of length t (the more such walks exist, the smaller is the distance).

The described framework is very generic, leading to numerous potentially useful diffusion geometries parametrized by the selection of the transfer function $K(\lambda)$. Two particular choices are frequent in shape analysis, the first one being the *heat kernel*, $K_t(\lambda) = e^{-t\lambda}$, and the second one being the *commute time kernel*, $K(\lambda) = \frac{1}{\sqrt{\lambda}}$, resulting in the *heat diffusion* and *commute time* metrics, respectively. While the former kernel involves a scale parameter, typically tuned by hand, the latter one is *scale invariant*, meaning that neither the kernel nor the diffusion metric it induces changes under uniform scaling of the embedding coordinates of the shape.

3 Shape Discretization

In order to allow storage and processing of a shape by a digital computer, it has to be *discretized*. This section reviews different notions in the discrete representation of shapes.

Sampling

Sampling is the reduction of the continuous surface X representing a shape into a finite discrete set of representative points $\hat{X} = \{x_1, \dots, x_N\}$. The number of points $|\hat{X}| = N$ is called the *size* of the sampling. The *radius* of the sampling refers to the smallest positive scalar r for which \hat{X} is an r -covering of X , i.e.,

$$r(\hat{X}) = \max_{x \in X} \min_{x_i \in \hat{X}} d_X(x, x_i). \quad (10)$$

The sampling is called *s-separated* if $d_X(x_i, x_j) \geq s$ for every distinct $x_i, x_j \in \hat{X}$.

Sampling partitions the continuous surface into a set of disjoint regions,

$$V_i = \{x \in X : d_X(x, x_i) < d_X(x, x_j), x_j \neq i \in \hat{X}\}, \quad (11)$$

called the *Voronoi regions* [7] (Fig. 2). A Voronoi region V_i contains all the points on X that are closer to x_i than to any other x_j . That the sampling is said to induce a *Voronoi tessellation* (Unlike in the Euclidean case where every sampling induces a valid tessellation (cell complex), samplings of curved surfaces may result in Voronoi regions that are not valid cells, i.e., are not homeomorphic to a disk. In [66], Leibon and Letscher showed that an r -separated sampling of radius r with r smaller than $\frac{1}{5}$ of the convexity radius of the shape is guaranteed to induce a valid tessellation.) which we denote by $V(\hat{X}) = \{V_1, \dots, V_n\}$.

Sampling can be regarded as a *quantization* process in which a point x on the continuous surface is represented by the closest x_i in the sampling [51]. Such a process can be expressed as a function mapping each V_i to the corresponding (Points on the boundary of the Voronoi regions are equidistant from at least two sample points and therefore can be mapped arbitrarily to any of them.) sample x_i . Intuitively, the smaller are the Voronoi regions, the better is the sampling. Sampling quality is quantified using an *error function*. For example,

$$\epsilon_\infty(\hat{X}) = \max_{x \in X} d_X(x, \hat{X}) = \max_{x \in X} \min_{x_i \in \hat{X}} d_X(x, x_i) \quad (12)$$

determines the maximum size of the Voronoi regions. If the shape is further equipped with a measure (e.g., the standard area measure), other error functions can be defined, e.g.,

$$\epsilon_p(\hat{X}) = \sum_i \int_{V_i} d_X^p(x, x_i) d\mu(x). \quad (13)$$

In what follows, we will show sampling procedures optimal or nearly optimal in terms of these criteria.

Farthest Point Sampling

Farthest point sampling (FPS) is a greedy procedure constructing a sequence of samplings $\hat{X}_1, \hat{X}_2, \dots$. A sampling \hat{X}_{N+1} is constructed from \hat{X}_N by adding the *farthest point*

$$x_{N+1} = \arg \max_{x \in X} d_X(x, \hat{X}_N) = \arg \max_{x \in X} \min_{x_i \in \hat{X}_N} d_X(x, x_i). \quad (14)$$

The sequence $\{r_N\}$ of the sampling radii associated with $\{\hat{X}_N\}$ is nonincreasing, and, furthermore, each \hat{X}_N is also r_N -separated. The starting point x_1 is usually picked up at random, and the stopping condition can be either the sampling size or radius.

Fig. 2 Voronoi decomposition of a surface with a non-Euclidean metric

Though FPS does not strictly minimize any of the error criteria defined in the previous section, in terms of ϵ_∞ , it is no more than twice inferior to the optimal sampling of the same size [59]. In other words, for \hat{X} produced using FPS,

$$\epsilon_\infty(\hat{X}) \leq 2 \min_{|\hat{X}'|=|\hat{X}|} \epsilon_\infty(\hat{X}'). \quad (15)$$

This result is remarkable, as finding the optimal sampling is known to be an NP-hard problem.

Centroidal Voronoi Sampling

In order for a sampling to be ϵ_2 -optimal, each sample x_i has to minimize

$$\int_{V_i} d_X^2(x, x_i) d\mu(x). \quad (16)$$

A point minimizing the latter quantity is referred to as the *centroid* of V_i . Therefore, an ϵ_2 -optimal sampling induces a so-called *centroidal Voronoi tessellation* (CVT), in which the centroid of each Voronoi region coincides with the sample point inducing it [45, 90]. Such a tessellation and the corresponding *centroidal Voronoi sampling* are generally not unique.

A numerical procedure for the computation of a CVT of a shape is known as the Lloyd–Max algorithm [68, 73]. Given some initial sampling \hat{X}^1 of size N (produced, e.g., using FPS), the Voronoi tessellation induced by it is computed. The centroids of each Voronoi region are computed, yielding a new sampling \hat{X}^2 of size N .

The process is repeated iteratively until the change of \hat{X}^k becomes insignificant. While producing high-quality samplings in practice, the Lloyd–Max procedure is guaranteed to converge only to a local minimum of ϵ_2 . For computational aspects of CVTs on meshes, the reader is referred to [90].

Shape Representation

Once the shape is sampled, it has to be represented in a way allowing computation of discrete geometric quantities associate with it.

Simplicial Complexes

The simplest representation of a shape is obtained by considering the points of the sampling as points in the ambient Euclidean space. Such a representation is usually referred to as a *point cloud*. Points in the cloud are called *vertices* and denoted by $\mathbf{X} = \{x_1, \dots, x_N\}$. The notion of a point cloud can be generalized using the formalism of simplicial complexes. For our purpose, an abstract *k-simplex* is a set of cardinality $k + 1$. A subset of a simplex is called a *face*. A set K of simplices is said to be an abstract *simplicial complex* if any face of $\sigma \in K$ is also in K , and the intersection of any two simplices $\sigma_1, \sigma_2 \in K$ is a face of both σ_1 and σ_2 . A simplicial *k*-complex is a simplicial complex in which the largest dimension of any simplex is *k*. A simplicial *k*-complex is said to be *homogeneous* if every simplex of dimension less than *k* is the face of some *k*-simplex. A *topological realization* \bar{K} of a simplicial complex K maps K to a simplicial complex in \mathbb{R}^n , in which vertices are identified with the canonical basis of \mathbb{R}^n , and each simplex in K is represented as the convex hull of the corresponding points $\{\mathbf{e}_i\}$. A *geometric realization* $\phi_{\mathbf{X}}(\bar{K})$ is a map of the simplicial complex \bar{K} to \mathbb{R}^3 defined by associating the standard basis vectors $\mathbf{e}_i \in \mathbb{R}^n$ with the vertex positions x_i .

In this terminology, a point cloud is a simplicial 0-complex having a *discrete topology*. Introducing the notion of neighborhood, we can define a subset $E \subset \mathbf{X} \times \mathbf{X}$ of pairs of vertices that are *adjacent*. Pairs of adjacent vertices are called *edges*, and the simplicial 1-complex $\mathbf{X} \cup E$ has a *graph topology*, i.e., the set of vertices \mathbf{X} forms an *undirected graph* with the set of edges E . A simplicial 2-complex consisting of vertices, edges, and triangular faces built upon triples of vertices and edges is called a *triangular mesh*. The mesh is called *topologically valid* if it is homeomorphic to the underlying continuous surface X . This usually implies that the mesh has to be a two manifold. A mesh is called *geometrically valid* if it does not contain self-intersecting triangles, which happens if and only if the geometric realization $\phi_{\mathbf{X}}(\bar{K})$ of the mesh is bijective. Consequently, any point \mathbf{x} on a geometrically valid mesh can be uniquely represented as $\mathbf{x} = \varphi_{\mathbf{X}}(\mathbf{u})$. The vector \mathbf{u} is called the *barycentric coordinates* of \mathbf{x} and has at most three nonzero elements. If the point coincides with a vertex, \mathbf{u} is a canonical basis vector; if the point lies on an edge, \mathbf{u} has two nonzero elements; otherwise, \mathbf{u} has three nonzero elements and \mathbf{x} lies on a triangular face.

A particular way of constructing a triangular mesh stems from the Voronoi tessellation induced by the sampling. We define the simplicial 3-complex as

$$\mathbf{X} \cup \{(x_i, x_j) : \partial V_i \cap \partial V_j \neq \emptyset\} \cup \{(x_i, x_j, x_k) : \partial V_i \cap \partial V_j \cap \partial V_k \neq \emptyset\}, \quad (17)$$

in which a pair of vertices spans an edge and a triple of vertices spans a face if the corresponding Voronoi regions are adjacent. A mesh defined in this way is called a *Delaunay mesh*. (Unlike in the Euclidean case where every sampling induces a valid Delaunay triangulation, an invalid Voronoi tessellation results in a topologically invalid Delaunay mesh. In [66], Leibon and Letscher showed that under the same conditions sufficient for the existence of a valid Voronoi tessellation, the Delaunay mesh is also topologically valid.)

Parametric Surfaces

Shapes homeomorphic to a disk can be parametrized using a single global chart, e.g., on the unit square, $x : [0, 1]^2 \rightarrow \mathbb{R}^3$. (Manifolds with more complex topology can still be parametrized in this way by introducing cuts that open the shape into a topological disk.) Such surfaces are called *parametric* and can be sampled directly in the parametrization domain. For example, if the parametrization domain is sampled on a regular Cartesian grid, the shape can be represented as three $N \times N$ arrays of x , y , and z values. Such a completely regular structure is called a *geometry image* [56, 69, 99] and can be thought indeed as a three-channel image that can undergo standard image processing such as compression. Geometry images are ideally suitable for processing by vector and parallel hardware.

Implicit Surfaces

Another way of representing a shape is by considering the isosurfaces $\{x : \Phi(x) = 0\}$ of some function Φ defined on a region of \mathbb{R}^3 . Such a representation is called *implicit*, and it often arises in medical imaging applications, where shapes are two-dimensional boundaries created by discontinuities in volumetric data. Implicit representation can be naturally processed using level-set-based algorithms, and it easily handles arbitrary topology. A disadvantage is the bigger amount of storage commonly required for such representations.

4 Metric Discretization

Next step in the discrete representation of shapes is the discretization of the metric.

Shortest Paths on Graphs

The most straightforward approach to metric discretization arises from considering the shape as a graph in which neighbor vertices are connected. A path in the graph between vertices x_i, x_j is an ordered set of connected edges

$$\Gamma(x_i, x_j) = \{(x_{i_1}, x_{i_2}), (x_{i_2}, x_{i_3}), \dots, (x_{i_k}, x_{i_{k+1}})\} \subset E, \quad (18)$$

where $x_{i_1} = x_i$ and $x_{i_{k+1}} = x_j$. The length of path Γ is the sum of its constituent edge lengths,

$$L(\Gamma(x_i, x_j)) = \sum_{n=1}^k \|x_{i_n} - x_{i_{n+1}}\|. \quad (19)$$

A minimum geodesic in a graph is the shortest path between the vertices,

$$\Gamma^*(x_i, x_j) = \arg \min_{\Gamma(x_i, x_j)} L(\Gamma(x_i, x_j)). \quad (20)$$

We can use $d_L(x_i, x_j) = L(\Gamma^*(x_i, x_j))$ as a discrete approximation to the geodesic metric $d_X(x_i, x_j)$.

According to the *Bellman optimality principle* [10], given $\Gamma^*(x_i, x_j)$ a shortest path between x_i and x_j and x_k a point on the path, the sub-paths $\Gamma^*(x_i, x_k)$ and $\Gamma^*(x_k, x_j)$ are the shortest paths between x_i, x_k and x_k, x_j , respectively. The length of the shortest path in the graph can be thus expressed by the following recursive equation:

$$d_L(x_i, x_j) = \min_{x_k : (x_k, x_j) \in E} \{d_L(x_i, x_k) + \|x_k - x_j\|\}. \quad (21)$$

Dijkstra's Algorithm

A famous algorithm for the solution of the recursion (21) was proposed by Dijkstra. Dijkstra's algorithm measures the *distance map* $d(x_k) = d_L(x_i, x_k)$ from the source vertex x_i to all the vertices in the graph.

Initialize $d(x_i) = 0$, $d(x_k) = \infty$ for all $k \neq i$; queue of unprocessed vertices $Q = \{x_1, \dots, x_N\}$.

while Q is non-empty **do**

Find vertex with smallest value of d in the queue

$$x = \arg \min_{x \in Q} d(x)$$

for all unprocessed adjacent vertices $x' \in Q : (x, x') \in E$ **do**

$$d(x') = \min \{d(x'), d(x) + \|x - x'\|\}$$

end for

Remove x from Q .

end while

Every vertex in Dijkstra's algorithm is processed exactly once; hence, Nn outer iterations are performed. Extraction of vertex with smallest d is straightforward with $\mathcal{O}(N)$ complexity and can be reduced to $\mathcal{O}(\log N)$ using efficient data structures such as *Fibonacci heap*. In the inner loop, updating adjacent vertices in our case, since the graph is sparsely connected, is $\mathcal{O}(1)$. The resulting overall complexity is $\mathcal{O}(N \log N)$.

Metrication Errors and Sampling Theorem

Unfortunately, the graph distance d_L is an inconsistent approximation of d_X , in the sense that d_L usually does not converge to d_X when the sampling becomes infinitely dense. This phenomenon is called *metrication error*, and the reason is that the graph induces a metric inconsistent with d_X (Fig. 3). While metrication errors make in general the use of d_L an approximation of d_X disadvantageous, the Bernstein–de Silva–Langford–Tenenbaum theorem [14] states that under certain conditions, the graph metric d_L can be made as close as desired to the geodesic metric d_X . The theorem is formulated as a bound of the form

$$1 - \lambda_1 \leq \frac{d_L}{d_X} \leq 1 + \lambda_2, \quad (22)$$

where λ_1, λ_2 depend on shape properties, sampling quality, and graph connectivity. In order for d_L to represent d_X accurately, the sampling must be sufficiently dense, length of edges in the graph bounded, and sufficiently close vertices must be connected, usually in a non-regular manner.

Fast Marching

Eikonal Equation

An alternative to computation of a discrete metric on a discretized surface is the discretization of the metric itself. The distance map $d(x) = d_X(x_0, x)$ (Fig. 4) on the manifold can be associated with the time of arrival of a propagating front traveling with unit speed (illustratively, imagine a fire starting at point x_0 at time $t = 0$ and propagating from the source). Such a propagation obeys the *Fermat principle of least action* (the propagating front chooses the quickest path to travel, which coincides with the definition of the geodesic distance) and is governed by the *eikonal equation*

$$\|\nabla_X d\|_2 = 1, \quad (23)$$

where ∇_X is the intrinsic gradient on the surface X . Eikonal equation is a hyperbolic PDE with boundary conditions $d(x_0) = 0$; minimum geodesics are its characteristics. Propagation direction is the direction of the steepest increase of d and is perpendicular to geodesics.

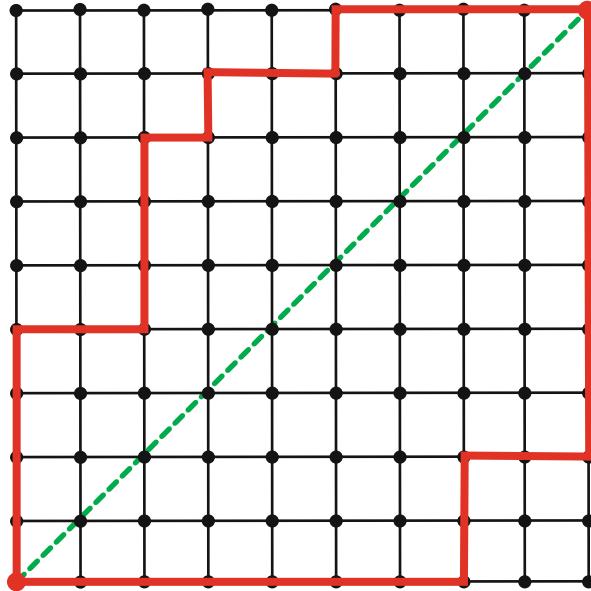

Fig. 3 Shortest paths measured by Dijkstra’s algorithm (*solid bold lines*) do not converge to the true shortest path (*dashed diagonal*), no matter how much the grid is refined (Reproduced from [25])

Since the distance map is not everywhere differentiable (in particular, at the source point), no solution to the eikonal equation exists in the classical sense, while there exist many non \mathcal{C}^1 functions satisfying the equation and the boundary conditions. Among such functions, the largest d satisfying the boundary conditions and the inequality

$$\|\nabla_X d\|_2 \leq 1 \quad (24)$$

at every point where $\nabla_X d$ exists is called the *viscosity solution* [42]. The viscosity solution of the eikonal equation always exists and is unique, and its value at a point x coincides with $d_X(x, x_0)$. It is known to be monotonous, i.e., not having local maxima.

Triangular Meshes

A family of algorithms for finding the viscosity solution of the discretized eikonal equation by simulated wavefront propagation is called *fast marching methods* [63, 100, 112]. Fast marching algorithms can be thought of as continuous variants of Dijkstra’s algorithm, with the notable difference that they consistently approximate the geodesic metric d_X on the surface.

Fig. 4 Distance map measured on a curved surface. Equidistant contours from the source located at the right hand are shown
(Reproduced from [25])

Initialize $d(x_0) = 0$ and mark x_0 as *processed*; for all $k \neq 0$ set $d(x_k) = \infty$ and mark x_k as *unprocessed*.

while there exist *unprocessed* vertices **do**

Mark *unprocessed* neighbors of *processed* vertices as *interface*.

for all *interface* vertices x and all incident triangles (x, x_1, x_2) with $x_1, x_2 \neq$ *unprocessed* **do**

Update $d(x)$ from $d(x_1)$ and $d(x_2)$.

end for

Mark *interface* vertex with the smallest value of d as *processed*.

end while

The general structure of fast marching closely resembles that of Dijkstra's algorithm with the main difference lying in the update step. Unlike the graph case where shortest paths are restricted to pass through the graph edges, the continuous approximation allows paths passing anywhere in the simplicial complex. For that reason, the value of $d(x)$ has to be computed from the values of the distance map at two other vertices forming a triangle with x . In order to guarantee consistency of the solution, all such triangles must have an acute angle at x . Obtuse triangles are split at a preprocessing stage by adding virtual connections to nonadjacent vertices.

Given a triangle (x, x_1, x_2) with known values of $d(x_1)$ and $d(x_2)$, the goal of the update step is to compute $d(x)$. The majority of fast marching algorithms do so by simulating the propagation of a planar wavefront in the triangle. The wavefront arrival time to x_1 and x_2 is set to $d(x_1)$ and $d(x_2)$, from which the parameters of the wave source are estimated. Generally, there exist two solutions for $d(x)$ consistent with the input, the smallest corresponding to the wavefront first arriving to x and

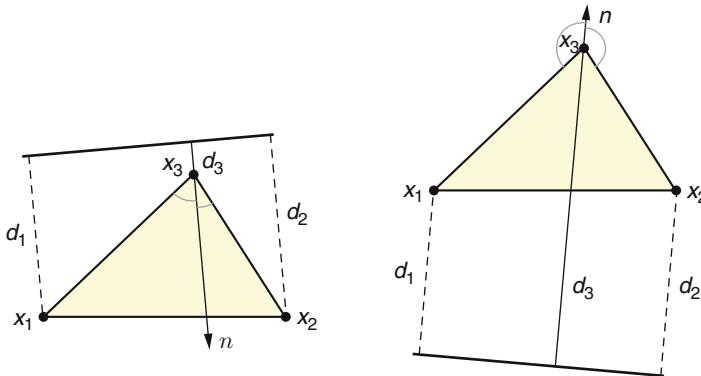

Fig. 5 Fast marching updates the triangle (x_1, x_2, x_3) by estimating the planar wavefront direction n and origin p based on d_1 at x_1 and d_2 at x_2 and propagating it further to x_3 . d_3 has two possible solutions: the one shown on the left is inconsistent, since $d_3 < d_1, d_2$. The solution on the right is consistent, since $d_3 > d_1, d_2$. Geometrically, in order to be consistent, the update direction n has to form obtuse angles with the triangle edges (x_3, x_1) and (x_3, x_2) (Reproduced from [25])

then to x_1 and x_2 and the largest corresponding to the inverse situation. In order to guarantee monotonicity of the solution, the largest solution is always chosen (Fig. 5).

Computationally, fast marching has the $\mathcal{O}(N \log N)$ complexity of Dijkstra, perhaps with a slightly larger constant.

Parametric Surfaces

For surfaces admitting a global parametrization $x : U \rightarrow \mathbb{R}^3$, the eikonal equation can be expressed entirely in the parametrization domain as [104]

$$\nabla^T d G^{-1} \nabla d = 1, \quad (25)$$

where $d(u)$ is the distance map in the parametrization domain, ∇d is its gradient with respect to the standard basis in \mathbb{R}^2 , and G are the coefficients of the first fundamental form in parametrization coordinates. The fast marching update step can be therefore performed on U . Moreover, since only G is involved in the equation, the knowledge of the actual vertex coordinates is not required. This property is useful when the surface is reconstructed from some indirect measurements, e.g., normals or gradients, as it allows to avoid surface reconstruction for metric computation.

Parallel Marching

The main disadvantage of all Dijkstra-type algorithms based on a heap structure in general and fast marching in particular is the fact that they are inherently sequential. Moreover, as the order in which the vertices are visited is unknown in advance, they typically suffer from inefficient access to memory. Working with well-structured parametric surfaces such as geometry images allows to circumvent these

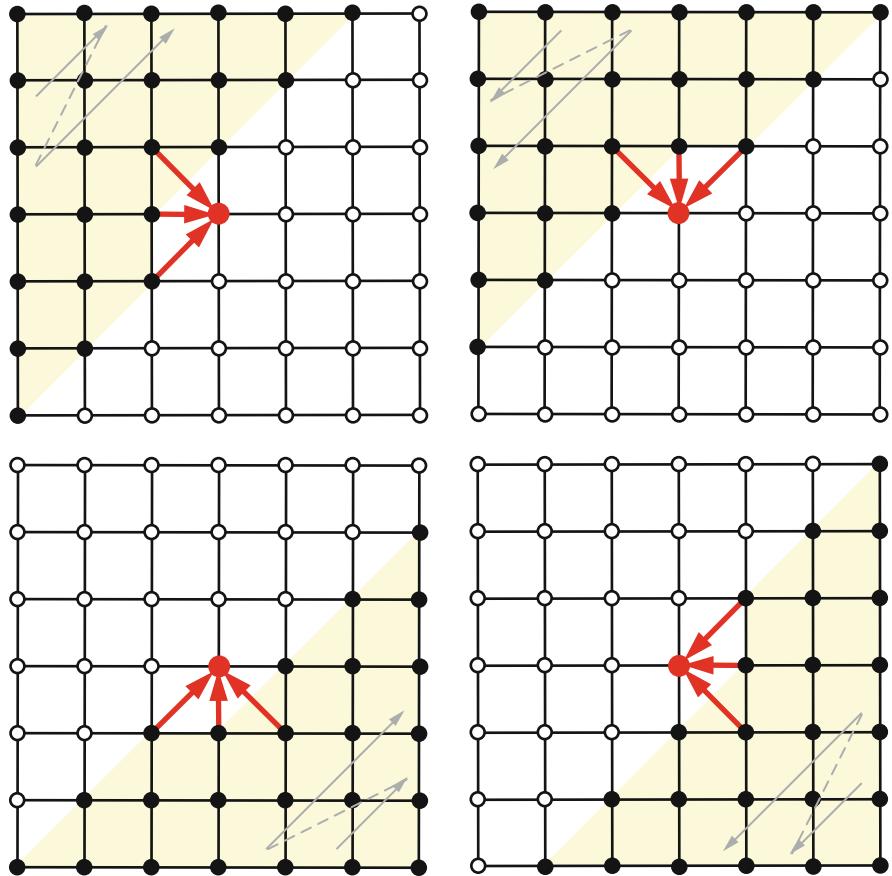

Fig. 6 Raster scan grid traversals rotated by 45° (Reproduced from [116])

disadvantages by replacing the heap-based update by the regular raster scan update. Such family of algorithms is usually called *parallel marching* [117] or *fast sweeping* [111, 121].

In parallel marching, vertices of the geometry image are visited in a raster scan order, and for each vertex, the standard fast marching update is applied using already updated (causal) vertices as the supporting vertices for the following update. Four raster scans in alternating left-to-right top-to-bottom, right-to-left top-to-bottom, left-to-right bottom-to-top, and right-to-left bottom-to-top directions are applied (in practice, it is advantageous to rotate the scan directions by 45° , as shown in Fig. 6). For a Euclidean domain, such four scans are sufficient to consistently approximate the metric; for non-Euclidean shapes, several repetitions of the four scans are required. The algorithm stops when the distance map stops changing significantly from one repetition to another. The exact number of repetitions required depends on the metric and the parametrization, but is practically very small.

Parallel marching algorithms map well on modern vector and parallel architectures and in particular on graphics hardware [117].

Implicit Surfaces and Point Clouds

Two-dimensional manifolds represented in the implicit form $X = \{\Phi(x) = 0\} \subset \mathbb{R}^3$ can be approximated with arbitrary precision as the union of Euclidean balls of radius $h > 0$ around X ,

$$B_h(X) = \bigcup_{x \in X} B_h^{\mathbb{R}^3}(x). \quad (26)$$

$B_h(X)$ is a three-dimensional Euclidean submanifold, which for $h < 1 / \max \kappa_2$ has a smooth boundary. For every $x, x' \in X$, the shortest path in $B_h(X)$ is no longer than the corresponding shortest path on X . Mémoli and Sapiro [77] showed that as $h \rightarrow 0$, shortest paths in $B_h(X)$ converge to those on X and the corresponding geodesic distances $d_{B_h(X)}|_{X \times X}$ converge uniformly to d_X . This result allows to cast the computation of a distance map on a curved two-dimensional space as the computation of a distance map on a three-dimensional Euclidean submanifold. The latter can be done using fast marching or parallel marching on orthogonal grid restricted to a *narrow band* around X [76].

A similar methodology can be used for the computation of distance maps on point clouds [76]. The union of Euclidean balls centered at each vertex of the cloud creates a three-dimensional Euclidean manifold, on which the distance map is computed using fast marching or parallel marching.

Diffusion Distance

The diffusion distance is expressed through the spectral decomposition of the Laplace–Beltrami operator, and its discretization involves the discretization of the Laplace–Beltrami operator and the computation of its eigenfunctions.

Discretized Laplace–Beltrami Operator

A discrete approximation of the Laplace–Beltrami on the mesh \hat{X} has the following generic form

$$(\Delta_{\hat{X}} f)_i = \frac{1}{a_i} \sum_j w_{ij} (f_i - f_j), \quad (27)$$

where $f = (f_1, \dots, f_N)$ is a scalar function defined on the mesh \hat{X} , w_{ij} are weights, and a_i are normalization coefficients. In matrix notation, Eq. (27) can be written as

$$\Delta_{\hat{X}} f = A^{-1} L f, \quad (28)$$

where $A = \text{diag}(a_i)$ and $L = \text{diag}\left(\sum_{l \neq i} w_{il}\right) - (w_{ij})$.

Different discretizations of the Laplace–Beltrami operator lead to different choice of A and W . In general, it is common to distinguish between *discrete* and *discretized* Laplace–Beltrami operator, the former being a combinatorial construction and the latter a discretization trying to preserve some of the properties (Li)–(Liv) of the continuous counterpart. In addition to these properties, it is important that the discrete Laplace–Beltrami operator converges to the continuous one, in the sense that the solution of the continuous heat equation with Δ_X converges to the discrete solution of the discrete heat equation with $\Delta_{\hat{X}}$ as the number of samples grows to infinity.

Purely combinatorial approximations such as the *umbrella operator* ($w_{ij} = 1$ if x_i and x_j are connected by an edge and zero otherwise) [120] and the *Tutte Laplacian* ($w_{ij} = d_i^{-1}$, where d_i is the valence of vertex x_i) [113] are not geometric, violate property (Liv), and do not converge to the continuous Laplace–Beltrami operator. One of the most widely used discretizations is the *cotangent weight scheme* [91] and its variants [79] ($w_{ij} = \cot \alpha_{ij} + \cot \beta_{ij}$ if x_i and x_j are connected, where α_{ij} and β_{ij} are the two angles opposite to the edge between vertices x_i and x_j in the two triangles sharing the edge and a_i is proportional to the sum of the areas of the triangles sharing x_i). It preserves properties (Li)–(Liv) as well as satisfies the convergence property under certain mild conditions [116].

Computation of Eigenfunctions and Eigenvalues

By solving the *generalized eigendecomposition* problem [67],

$$A\Phi = \Lambda L\Phi,$$

where Φ is an $N \times (k + 1)$ matrix whose columns are discretized eigenfunctions ϕ_0, \dots, ϕ_k and Λ is the diagonal matrix of the corresponding eigenvalues $\lambda_0, \dots, \lambda_k$ of the discretized Laplace–Beltrami operator are computed. ϕ_{il} approximates the value of the l th eigenfunction at the point x_i .

A different approach to the computation of eigenfunction is based on the *finite element method* (FEM). Using the Green formula, the Laplace–Beltrami eigenvalue problem $\Delta_X \phi = \lambda \phi$ can be expressed in the *weak form* as

$$\langle \Delta_X \phi, \alpha \rangle_{L_2(X)} = \lambda \langle \phi, \alpha \rangle_{L_2(X)} \quad (29)$$

for any smooth α . Given a finite basis $\{\alpha_1, \dots, \alpha_K\}$ spanning a subspace of $L_2(X)$, the solution ϕ can be expanded as $\phi(x) \approx u_1 \alpha_1(x) + \dots + u_K \alpha_K(x)$. Substituting this expansion into (29) results in a system of equations

$$\sum_{j=1}^K u_j \langle \Delta_X \alpha_j, \alpha_k \rangle_{L_2(X)} = \lambda \sum_{j=1}^K u_j \langle \alpha_j, \alpha_k \rangle_{L_2(X)}, \quad k = 1, \dots, K,$$

which, in turn, is posed as a generalized eigenvalue problem

$$Au = \lambda Bu. \quad (30)$$

(here A and B are $K \times K$ matrices with elements $a_{kj} = \langle \Delta_X \alpha_j, \alpha_k \rangle_{L_2(X)}$ and $b_{kj} = \langle \alpha_j, \alpha_k \rangle_{L_2(X)}$). Solution of (30) gives eigenvalues λ and eigenfunctions $\phi = u_1 \alpha_1 + \dots + u_K \alpha_K$ of Δ_X .

As the basis, linear, quadratic, or cubic polynomials defined on the mesh can be used. Since the inner products are computed on the surface, the method is less sensitive to shape discretization compared to the direct approach based on the discretization of the Laplace–Beltrami operator. This is confirmed by numerical studies performed by Reuter et al. [94].

Discretization of Diffusion Distances

Using the discretized eigenfunctions, a discrete diffusion kernel is approximated as

$$K(x_i, x_j) \approx \sum_{l=0}^k K(\lambda_l) \phi_{il} \phi_{jl},$$

and can be represented as an $N \times N$ matrix. The corresponding diffusion distance is approximated as

$$d_{X,i}(x_i, x_j) \approx \left(\sum_{l=1}^k K^2(\lambda_i) (\phi_{il} - \phi_{jl})^2 \right)^{1/2}.$$

5 Invariant Shape Similarity

Let us denote by \mathbb{X} the space of all shapes equipped with some metric, i.e., a point in \mathbb{X} is a metric space (X, d_X) . Let \mathcal{T} be a group of shape *transformations*, i.e., a collection of operators $\tau : \mathbb{X} \rightarrow \mathbb{X}$ with the function composition. Two shapes differing by a transformation $\tau \in \mathcal{T}$ are said to be *equivalent up to \mathcal{T}* . The equivalence relation induces the *quotient space* \mathbb{X}/\mathcal{T} in which each point is an *equivalence class* of shapes that differ by a transformation in \mathcal{T} . A particular instance of \mathcal{T} is the group of *isometries*, i.e., such transformations that acting on X leave d_X unchanged. The exact structure of such the isometry group depends on the choice of the metric with which the shapes are equipped. For example, if the Euclidean metric $d_X = d_{\mathbb{E}}|_{X \times X}$ is used, the isometry group coincides with the group of Euclidean congruences (rotations, translations, and reflections).

A function $d : \mathbb{X} \times \mathbb{X} \rightarrow \mathbb{R}$ that associates a pair of shapes with a nonnegative scalar is called a *distance* or *dissimilarity* function. We will say that the dissimilarity d is \mathcal{T} -*invariant* if it defines a *metric* on the quotient space \mathbb{X}/\mathcal{T} . In particular,

this means that $d(X, \tau(X)) = 0$ and $d(\tau(X) \times \sigma(Y)) = d(X, Y)$ for every $\tau, \sigma \in \mathcal{T}$ and $X, Y \in \mathbb{X}$. In particular, for \mathcal{T} being the isometry group, a \mathcal{T} -invariant dissimilarity is an *isometry-invariant* metric between shapes. The exact type of invariance depends on the structure of the isometry group and, hence, again on the choice of the metric with which the shapes are equipped.

As a consequence from the metric axioms, an isometry-invariant dissimilarity $d(X, Y)$ between two shapes X and Y equals to zeros if and only if X and Y are isometric. However, since exact isometry is an ideal rather than practical notion, it is desirable to extend this property to *similar* (almost isometric) rather than strictly equivalent (isometric) shapes. We will therefore require that (Ii) two ϵ -isometric shapes X and Y satisfy $d(X, Y) \leq c_1\epsilon + b_1$, and vice versa (Iii) if $d(X, Y) \leq \epsilon$, then X and Y are $(c_2\epsilon + b_2)$ -isometric, where c_1, c_2, b_1 , and b_2 are some nonnegative constants. In what follows, we will focus on the construction of such dissimilarities and their approximation and show how different choices of the metric yield different classes of invariance.

Rigid Similarity

Equipping shapes with the restriction of the Euclidean metric in \mathbb{E} allows to consider them as subsets of a bigger common metric space, \mathbb{E} equipped with the standard Euclidean metric. We will therefore examine dissimilarity functions allowing to compare between two subsets of the same metric space.

Hausdorff Distance

For two sets X and Y , a subset $R \subseteq X \times Y$ is said to be a *correspondence between X and Y* if (1) for every $x \in X$ there exists at least one $y \in Y$ such that $(x, y) \in R$ and (2) for every $y \in Y$ there exists at least one $x \in X$ such that $(x, y) \in R$. We will denote by $\mathcal{R}(X, Y)$ the set of all possible correspondences between X and Y .

Using the notion of correspondence, we can define the *Hausdorff distance* [58] between the two subsets of some metric space $(\mathbb{Z}, d_{\mathbb{Z}})$ as

$$d_{\mathbb{H}}^{\mathbb{Z}}(X, Y) = \min_{R \in \mathcal{R}(X, Y)} \max_{(x, y) \in R} d_{\mathbb{Z}}(x, y). \quad (31)$$

In other words, Hausdorff distance is the smallest nonnegative radius r for which $B_r(X) = \bigcup_{x \in X} B_r(x) \subseteq Y$ and $B_r(Y) \subseteq X$, i.e.,

$$d_{\mathbb{H}}^{\mathbb{Z}}(X, Y) = \max \left\{ \max_{x \in X} \min_{y \in Y} d_{\mathbb{Z}}(x, y), \max_{y \in Y} \min_{x \in X} d_{\mathbb{Z}}(x, y) \right\}. \quad (32)$$

Hausdorff distance is a metric on the set of all compact nonempty sets in \mathbb{Z} . However, it is not isometry invariant, i.e., for a nontrivial $\tau \in \text{Iso}(\mathbb{Z})$, generally $d_{\mathbb{H}}^{\mathbb{Z}}(X, \tau(X)) \neq 0$. The isometry-invariant Hausdorff metric is constructed as the minimum of $d_{\mathbb{H}}^{\mathbb{Z}}$ over all isometries in \mathbb{Z} ,

$$d_{\text{H}}^{\mathbb{Z}/\text{Iso}(\mathbb{Z})}(X, Y) = \min_{\tau \in \text{Iso}(\mathbb{Z})} d_{\text{H}}^{\mathbb{Z}}(X, \tau(Y)). \quad (33)$$

In the particular case of $(\mathbb{Z}, d_{\mathbb{Z}})$ being $(\mathbb{E}, d_{\mathbb{E}})$, the isometry-invariant Hausdorff metric can be used to quantify similarity between rigid shapes measuring to which extent they are *congruent* (isometric in the Euclidean sense) to each other. The metric assumes the form

$$d_{\text{H}}^{\mathbb{E}/\text{Iso}(\mathbb{E})}(X, Y) = \min_{R,t} d_{\text{H}}^{\mathbb{E}}(X, RY + t), \quad (34)$$

where an orthogonal (rotation or, sometimes, rotation and reflection) matrix R and a translation vector $t \in \mathbb{E}$ are used to parametrize the Euclidean isometry group.

Iterative Closest Point Algorithms

Denoting by

$$\text{cp}_Y(x) = \min_{y \in Y} d_{\mathbb{E}}(x, y) \quad (35)$$

the *closest point* to x in Y , the Euclidean isometry-invariant Hausdorff metric can be expressed as

$$\begin{aligned} d_{\text{H}}^{\mathbb{E}/\text{Iso}(\mathbb{E})}(X, Y) &= \max \left\{ \min_{R,t} \max_{x \in X} d_{\mathbb{E}}(x, RY + t), \min_{R,t} \max_{y \in Y} d_{\mathbb{E}}(y, RX + t) \right\} \\ &= \min_{R,t} \max \left\{ \max_{x \in X} \|x - \text{cp}_{RY+t}(x)\|_2, \max_{y \in Y} \|y - \text{cp}_{R^{-1}(X-t)}(y)\|_2 \right\}. \end{aligned} \quad (36)$$

Such a formulation lends itself to numerical computation. A family of algorithms referred to as *iterative closest point* (ICP) [15, 36] first established the closest point correspondences between X and Y ; once the correspondence is available, the Euclidean isometry (R, t) minimizing $\max_{x \in X} \|x - \text{cp}_{RY+t}(x)\|_2$ and $\max_{y \in Y} \|y - \text{cp}_{R^{-1}(X-t)}(y)\|_2$ is found and applied to Y . This, however, is likely to change the correspondence, so the process is repeated until convergence. For practical reasons, more robust variants of the Hausdorff distance are used [81].

Shape Distributions

A disadvantage of the ICP algorithms is that the underlying optimization problem becomes computationally intractable in high-dimensional spaces. A different approach for isometry-invariant comparison of rigid shapes, proposed by Osada et al. [85] and referred to as *shape distribution*, compares the distributions (histograms) of distances defined on the shape. Two isometric shapes obviously have identical shape distributions, which makes the approach isometry invariant. Shape distributions can be computed in a space of any dimension, are computationally efficient, and are not limited to a specific metric. A notable disadvantage of shape distribution

distance is that it does not satisfy our axioms (II)–(III), as there may be two non-isometric shapes with equal shape distributions; therefore, it is not a metric.

Wasserstein Distances

Let the sets X and Y be further equipped with measures μ_X and μ_Y , respectively. (It is required that $\text{supp}(\mu_X) = X$ and $\text{supp}(\mu_Y) = Y$.) We will say that a measure μ on $X \times Y$ is a coupling of μ_X and μ_Y if (i) $\mu(X' \times Y) = \mu_X(X')$ and (ii) $\mu(X \times Y') = \mu_Y(Y')$ for all Borel sets $X' \subseteq X$ and $Y' \subseteq Y$. We will denote by $\mathcal{M}(\mu_X, \mu_Y)$ the set of all possible couplings of μ_X and μ_Y . The *support* $\text{supp}(\mu)$ of the measure μ is the minimum closed subset $R \subset X \times Y$ such that $\mu(R^c) = 0$. The support of each $\mu \in \mathcal{M}(\mu_X, \mu_Y)$ defines a correspondence; measure coupling can be therefore interpreted as a “soft” or “fuzzy” correspondence between two sets.

The family of distances

$$d_{W,p}^{\mathbb{Z}}(\mu_X, \mu_Y) = \min_{\mu \in \mathcal{M}(\mu_X, \mu_Y)} \left(\int_{X \times Y} d_{\mathbb{Z}}^p(x, y) d\mu(x, y) \right)^{\frac{1}{p}} \quad (37)$$

for $1 \leq p < \infty$, and

$$d_{W,\infty}^{\mathbb{Z}}(\mu_X, \mu_Y) = \min_{\mu \in \mathcal{M}(\mu_X, \mu_Y)} \max_{(x,y) \in \text{supp}(\mu)} d_{\mathbb{Z}}(x, y) \quad (38)$$

for $p = \infty$ is called the *Wasserstein* or *Earth mover’s distances* [97]. Wasserstein distances are metrics on the space of distributions (finite measures) on \mathbb{Z} . For convenience, we will sometimes write $d_{W,p}^{\mathbb{Z}}(X, Y)$ implying $d_{W,p}^{\mathbb{Z}}(\mu_X, \mu_Y)$.

Exactly like in the case of the Hausdorff distance, Wasserstein distances can be transformed into isometry-invariant metrics by considering the quotient with all isometries of \mathbb{Z} ,

$$d_{W,p}^{\mathbb{Z}/\text{Iso}(\mathbb{Z})}(X, Y) = \min_{\tau \in \text{Iso}(\mathbb{Z})} d_{W,p}^{\mathbb{Z}}(X, \tau(Y)). \quad (39)$$

Wasserstein distances are intimately related to *Monge–Kantorovich optimal transportation problems*. Informally, if the measures μ_X and μ_Y are interpreted as two ways of piling up a certain amount of dirt over the regions X and Y , respectively, and the cost of transporting dirt from point x to point y is quantified by $d_{\mathbb{Z}}^p(x, y)$, then the Wasserstein distance $d_{W,p}^{\mathbb{Z}}$ expresses the minimum cost of turning one pile into the other. On discrete domains, the Wasserstein distance can be cast as an optimal *assignment problem* and solved using the *Hungarian algorithm* or *linear programming* [97]. Several approximations have also been proposed in [60, 102].

Canonical Forms

The Hausdorff distance allows comparing shapes equipped with the restricted Euclidean metric, i.e., considered as subsets of the Euclidean space. If other metrics

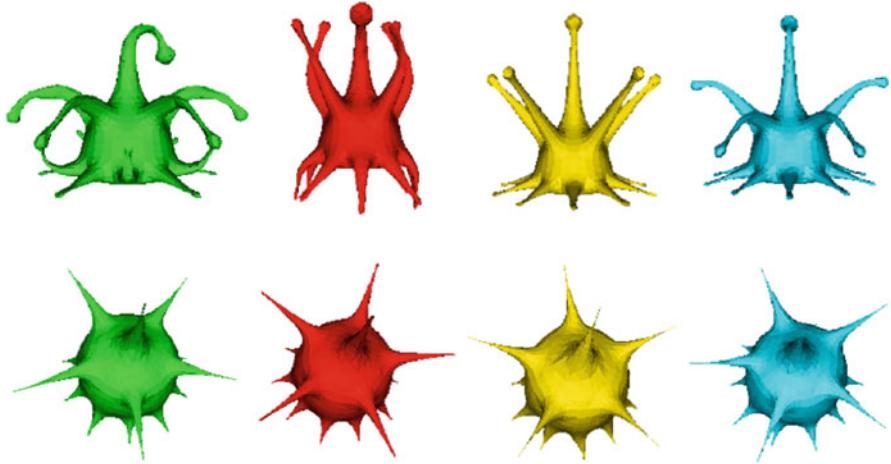

Fig. 7 Nearly isometric deformations of a shape (*top row*) and their canonical forms in \mathbb{R}^3 (*bottom row*)

are used, we have a more difficult problem of comparison of two different metric spaces. Elad and Kimmel [47, 48] proposed an approximate solution to this problem, reducing it to the comparison of Euclidean subspaces by means of *minimum-distortion embedding*. Given a shape X with some metric d (e.g., geodesic or diffusion), it can be represented as a subset of the Euclidean space by means of an *embedding* $\varphi : X \rightarrow \mathbb{R}^m$. If the embedding is isometric ($d_{\mathbb{E}}|_{\varphi(X) \times \varphi(X)} \circ \varphi = d$), the Euclidean representation $(\varphi(X), d_{\mathbb{E}}|_{\varphi(X) \times \varphi(X)})$ called the *canonical form* of X can be used equivalently instead of (X, d) (Fig. 7). Given a Euclidean isometry $i \in \mathbb{E}$, if φ is isometric, then $\varphi \circ i$ is also isometric. In other words, the canonical form is defined up to an isometry. In a more general setting, an arbitrary metric space $(\mathbb{Z}, d_{\mathbb{Z}})$ is used instead of \mathbb{E} for the computation of the canonical form.

The advantage of using canonical forms is that it brings the problem of shape comparison to the comparison of subsets of the Euclidean space, using, e.g., the Hausdorff distance. Given two shapes (X, d) and (Y, δ) , their canonical forms $\varphi(X)$ and $\psi(Y)$ in \mathbb{Z} are computed. In order to compensate for ambiguity in the definition of the canonical forms, an isometry-invariance distance between subsets of \mathbb{Z} must be used, e.g., $d_{\mathbb{H}}^{\mathbb{Z}/\text{Iso}(\mathbb{Z})}(\varphi(X), \psi(Y))$. In the particular case of Euclidean canonical forms, $d_{\mathbb{H}}^{\mathbb{E}/\text{Iso}(\mathbb{E})}(\varphi(X), \psi(Y))$ can be computed using ICP.

Multidimensional Scaling

Unfortunately, in most cases, there exists no isometric embedding of X into some predefined metric space. The right choice of \mathbb{Z} can decrease the embedding distortion, but cannot make it zero [21, 114]. Instead, one can find an embedding with minimal distortion,

$$\min_{\varphi : (X, d) \rightarrow (\mathbb{Z}, d_{\mathbb{Z}})} \text{dis}(\varphi).$$

In this case, $d_{\mathbb{Z}}|_{\varphi(X) \times \varphi(X)} \circ \varphi \approx d$, and thus the canonical form is only an approximate representation of the shape X in the space \mathbb{Z} .

In the discrete setting and $\mathbb{Z} = \mathbb{R}^m$, given the discretized shape $\{x_1, \dots, x_N\}$ with the discretized metric $d_{ij} = d(x_i, x_j)$, the minimum-distortion embedding can be computed by solving the *multidimensional scaling* (MDS) problem [17, 41],

$$\min_{\{z_1, \dots, z_N\} \subset \mathbb{R}^m} \max_{i, j=1, \dots, N} |d_{ij} - \|z_i - z_j\||, \quad (40)$$

where $z_i = \varphi(x_i)$.

In practical applications, other norms (e.g., L_2) are used in the MDS problem (40). The MDS objective function is usually referred to as *stress* in MDS literature. For the L_2 MDS problem (also known as *least squares* or LS-MDS), an efficient algorithm based on *iterative majorization* (commonly referred to as *scaling by majorizing a complicated function* or SMACOF) exists [44]. Denoting by Z the $N \times m$ matrix of the embedding coordinates of $\{x_1, \dots, x_N\}$ in \mathbb{R}^m , the SMACOF algorithm can be summarized as follows:

Initialize embedding coordinate $Z^{(0)}$.

for $k = 1, 2, \dots$ **do**

 Perform multiplicative update

$$Z^{(k)} = \frac{1}{N} B(Z^{(k-1)}) Z^{(k-1)},$$

where $B(Z)$ is an $N \times N$ matrix-valued function with elements

$$b_{ij}(Z) = \begin{cases} \frac{d_X(x_i, x_j)}{\|z_i - z_j\|} & i \neq j \text{ and } \|z_i - z_j\| \neq 0, \\ 0 & i \neq j \text{ and } \|z_i - z_j\| = 0, \\ -\sum_{k \neq i} b_{ik} & i = j. \end{cases}$$

end for

SMACOF iteration is equivalent to a weighted steepest descent with constant step size [32], but due to a special structure of the problem, it guarantees monotonous decrease of the stress function [17]. Other L_p formulations can be solved using iteratively reweighted least-squares (IRLS) techniques [16]. Acceleration of convergence is possible using multiscale and multigrid methods [32] as well as vector extrapolation techniques [96].

Eigenmaps

In the specific case when the shape is equipped with the diffusion distance ($d = d_{X,t}$), the canonical form can be computed by observing the fact that the map $\Phi_{X,t}(x) = (e^{-\lambda_0 t} \phi_0(x), e^{-\lambda_1 t} \phi_1(x), \dots)$ defined by the eigenvalues and eigenvectors of Laplace–Beltrami operator Δ_X satisfies $d_{X,t}(x, x') = \|\Phi_t(x) - \Phi_t(x')\|_2$.

In other words, $\Phi_{X,t}$ is an *isometric embedding* of $(X, d_{X,t})$ into an infinite-dimensional Euclidean space and can be thought of as an infinite-dimensional canonical form [13, 72]. $\Phi_{X,t}$ is termed *Laplacian eigenmap* [9] or *diffusion map* [40]. Another eigenmap given by $\Psi_X(x) = (\lambda_1^{-1/2}\phi_1(x), \lambda_2^{-1/2}\phi_2(x), \dots)$, referred to as the *global point signature* (GPS) [98], is an isometric embedding of the commute time metric c_X .

Unlike Elad–Kimmel canonical forms computed by MDS, the eigenmap is uniquely defined (i.e., there are no degrees of freedom related to the isometry in the embedding space) if the Laplace–Beltrami operator has no eigenvalues of multiplicity greater than one. Otherwise, the ambiguity in the definition of the eigenmap is up to switching between the eigenfunction corresponding to the eigenvalues with multiplicity and changes in their signs. More ambiguities arise in cases of symmetric shapes [86]. In general, two eigenmaps may differ by a permutation of coordinates corresponding to simple eigenvalues or by a roto-reflection in the eigensubspaces corresponding to eigenvalues with multiplicities.

For practical comparison of eigenmaps, a finite number k of eigenvectors is used, $\tilde{\Phi}_{X,t} = (e^{-\lambda_0 t}\phi_0, \dots, e^{-\lambda_k t}\phi_k)$. The Euclidean distance on the eigenmap $\tilde{\Phi}_{X,t}$ is thus a numerical approximation to the diffusion metric $d_{X,t}$ using k eigenfunctions of the Laplace–Beltrami operator (similarly, $\tilde{\Psi}_X$ approximates the commute time). For small k , eigenmaps can be compared using ICP. The problem of coordinate permutations must be addressed if eigenvalues of multiplicity greater than one are present. Such an approach is impractical for $k \gg 1$.

As an alternative, Rustamov [98] proposed using shape distributions to compare eigenmaps. This method overcomes the aforementioned problem, but lacks the metric properties of a true isometry-invariant metric.

Gromov–Hausdorff Distance

The source of inaccuracy of Elad–Kimmel canonical forms is that it is generally impossible to select a common metric space $(\mathbb{Z}, d_{\mathbb{Z}})$ in which the geometry of any shape can be accurately represented. However, for given two shapes X and Y , the space $(\mathbb{Z}, d_{\mathbb{Z}})$ can be selected in such a way that (X, d) and (Y, δ) can be isometrically embedded into it, the simplest example being the disjoint union $\mathbb{Z} = X \sqcup Y$ of X and Y , with the metric $d_{\mathbb{Z}}|_{X \times X} = d$ and $d_{\mathbb{Z}}|_{Y \times Y} = \delta$. $d_{\mathbb{Z}}|_{X \times Y}$ is defined to minimize the Hausdorff distance between X and Y in $(\mathbb{Z}, d_{\mathbb{Z}})$, resulting in a distance,

$$d_{\text{GH}}(X, Y) = \inf_{d_{\mathbb{Z}}} d_{\text{H}}^{\mathbb{Z}}(X, Y), \quad (41)$$

called the *Gromov–Hausdorff distance*. The Gromov–Hausdorff distance was first proposed by Gromov [55] as a distance between metric spaces and a generalization of the Hausdorff distance and brought into shape recognition by Mémoli and Sapiro [78].

The Gromov–Hausdorff distance satisfies axioms (Ii)–(Iii) with $c_1 = c_2 = 2$ and $b_1 = b_2 = 0$, such that $d_{\text{GH}}(X, Y) = 0$ if and only if X and Y are isometric. More generally, if $d_{\text{GH}}(X, Y) \leq \epsilon$, then X and Y are 2ϵ -isometric, and, conversely, if X and Y are ϵ -isometric, then $d_{\text{GH}}(X, Y) \leq 2\epsilon$ [34].

The Gromov–Hausdorff distance is a generic distance between metric spaces and, in particular, can be used to measure similarity between subsets of the Euclidean metric space, $(X, d_{\mathbb{E}}|_{X \times X})$ and $(Y, d_{\mathbb{E}}|_{Y \times Y})$. In [75], Mémoli showed that the Gromov–Hausdorff distance in the Euclidean space is equivalent to the ICP distance,

$$c \cdot d_{\text{H}}^{\mathbb{E}/\text{Iso}(\mathbb{E})}(X, Y) \leq d_{\text{GH}}((X, d_{\mathbb{E}}|_{X \times X}), (Y, d_{\mathbb{E}}|_{Y \times Y})) \leq d_{\text{H}}^{\mathbb{E}/\text{Iso}(\mathbb{E})}(X, Y),$$

in the sense of equivalence of metrics ($c > 0$ is a constant). (Metric equivalence should not be confused with equality: for example, L_1 and L_2 metrics are equivalent but not equal.) Consequently, (1) if $d_{\text{H}}^{\mathbb{E}/\text{Iso}(\mathbb{E})}(X, Y) \leq \epsilon$, then $(X, d_{\mathbb{E}}|_{X \times X})$ and $(Y, d_{\mathbb{E}}|_{Y \times Y})$ are 2ϵ -isometric; and (2) if $(X, d_{\mathbb{E}}|_{X \times X})$ and $(Y, d_{\mathbb{E}}|_{Y \times Y})$ are ϵ -isometric, then $d_{\text{H}}^{\mathbb{E}/\text{Iso}(\mathbb{E})}(X, Y) \leq c\sqrt{\epsilon}$.

Using the Gromov–Hausdorff distance to compare shapes equipped with diffusion metric allows to benefit from the advantage of the diffusion metric over geodesic one, such as lesser sensitivity to topological noise [28].

Generalized Multidimensional Scaling

For compact metric spaces, the Gromov–Hausdorff distance can also be expressed as

$$d_{\text{GH}}(X, Y) = \frac{1}{2} \inf_C \text{dis}(C), \quad (42)$$

where the infimum is taken over all correspondence C and $\text{dis}(C)$. The two expressions (41) and (42) are equivalent [34].

The advantage of this formulation is that it allows to reduce the computation of the Gromov–Hausdorff distance to finding a minimum-distortion embedding, similarly to the computation of canonical forms by means of MDS. In the discrete setting, given two triangular meshes \hat{X} and \hat{Y} representing the shapes X, Y , let us fix two sufficiently dense finite samplings $P = \{p_1, \dots, p_m\}$ and $Q = \{q_1, \dots, q_n\}$ of \hat{X} and \hat{Y} , respectively. A discrete correspondence between the shapes is defined as $C = (P \times Q') \cup (Q \times P')$, where $P' = \{p'_1, \dots, p'_n\}$ and $Q' = \{q'_1, \dots, q'_m\}$ are some (different) sets of samples on \hat{X} and \hat{Y} corresponding to Q and P , respectively. One can represent C as the union of the graphs of two discrete functions $\varphi : P \rightarrow \hat{Y}$ and $\psi : Q \rightarrow \hat{X}$, parametrizing the class of all discrete correspondences.

Given two sets P and P' on \hat{X} , we can construct an $m \times n$ distance matrix $D(P, P')$, whose elements are the distances $\hat{d}_{\hat{X}}(p_i, p'_j)$ (e.g., geodesic or diffusion). In these terms, the distortion of the correspondence C can be written as

$$\text{dis}(C) = \left\| \begin{pmatrix} D(P, P) & D(P, P') \\ D(P, P')^T & D(P', P') \end{pmatrix} - \begin{pmatrix} D(Q', Q') & D(Q', Q) \\ D(Q', Q)^T & D(Q, Q) \end{pmatrix} \right\|,$$

where $\|\cdot\|$ is some norm on the space of $(m+n) \times (m+n)$ matrices. The selection of the infinity norm $\|D\|_\infty = \max_{i,j} |d_{ij}|$ is consistent with the Gromov–Hausdorff distance; however, in practice more robust norms like the Frobenius norm $\|D\|_F^2 = \text{trace}(DD^T)$ are often preferable (see [23, 74, 78] for discussions on the regularization of the infinity norm in the Gromov–Hausdorff framework by other l_p norms).

The discretization of $\text{dis}(C)$ leads directly to a discretized approximation of the Gromov–Hausdorff distance between shapes, which can be expressed as

$$\hat{d}_{\text{GH}}(\hat{X}, \hat{Y}) := \frac{1}{2} \min_{P', Q'} \text{dis}(C).$$

Note that only P' and Q' participate as continuous minimization variables, while P and Q are constants (given samples on the respective shapes). The above minimization problem is solved using a numerical procedure resembling MDS, first introduced in [23, 24] under the name *generalized MDS* (GMDS).

We use barycentric coordinates to represent points on \hat{X} and \hat{Y} . In these coordinates, a point p_i lying in a triangle t_i on \hat{X} is represented as a convex combination of the triangle vertices (corresponding to the indices t_i^1 , t_i^2 , and t_i^3) with the weights $u_i = (u_i^1, u_i^2, u_i^3)^T$. We will denote by $T = (t_1, \dots, t_m)^T$ the vector of triangle indices and by $U = (u_1, \dots, u_m)$ the $3 \times m$ matrix of coordinates corresponding to the sampling P . Similarly, the samplings P' , Q , and Q' are represented as (T', U') , (S, V) , and (S', V') . For the sake of notation simplicity, we are going to use these interchangeably.

It was shown in [26] that a first-order approximation of a geodesic distance between p'_i and p'_j on \hat{X} can be expressed as the quadratic form

$$D_{ij}(P', P') \approx u_i^T \begin{pmatrix} D_{t_i^1, t_j^1}(P, P) & D_{t_i^1, t_j^2}(P, P) & D_{t_i^1, t_j^3}(P, P) \\ D_{t_i^2, t_j^1}(P, P) & D_{t_i^2, t_j^2}(P, P) & D_{t_i^2, t_j^3}(P, P) \\ D_{t_i^3, t_j^1}(P, P) & D_{t_i^3, t_j^2}(P, P) & D_{t_i^3, t_j^3}(P, P) \end{pmatrix} u_j.$$

Other distance terms are expressed similarly. Using tensor notation, we can write

$$\text{dis}(C) \approx \| (U, U') \mathcal{D}_{\hat{X}}(T, T')(U, U') - (V, V') \mathcal{D}_{\hat{Y}}(S, S')(V, V') \|_F^2,$$

where $\mathcal{D}_{\hat{X}}(T, T')$ is a rank four tensor whose ij -th elements are defined as the 3×3 distance matrices above, and $\mathcal{D}_{\hat{Y}}(S, S')$ is defined in a similar way.

The resulting objective function $\text{dis}(C)$ is a fourth-order polynomial with respect to the continuous coordinates U', V' , also depending on the discrete index variables T' and S' . However, when all indices and all

coordinate vectors except one, say, u'_i , are fixed, the function becomes convex and quadratic with respect to u'_i . A closed-form minimizer of $\text{dis}(u'_i)$ is found under the constraints $u'_i \geq 0$ and $u'^1_i + u'^2_i + u'^3_i = 1$, guaranteeing that the point p'_i remains within the triangle t'_i . The GMDS minimization algorithm proceeds iteratively by selecting u'_i or v'_i corresponding to the largest gradient of the objective function, updating it according to the closed-form minimizer, and updating the corresponding triangle index to a neighboring one in case the solution is found on the boundary of the triangle. The reader is referred to [26] for further implementation details.

Graph-Based Methods

The minimum-distortion correspondence problem can be formulated as a *binary labeling* problem with uniqueness constraints [110] in a graph with vertices defined as pairs of points and edges defined as quadruplets. Let $\mathcal{V} = \{(x, y) : x \in X, y \in Y\} = X \times Y$ be the set of pairs of points from X and Y , and let $\mathcal{E} = \{((x, y), (x', y')) \in \mathcal{V} \times \mathcal{V} \text{ and } (x, y) \neq (x', y')\}$. A correspondence $C \subset X \times Y$ can be represented as binary labeling $u \in \{0, 1\}^{\mathcal{V}}$ of the graph $(\mathcal{V}, \mathcal{E})$, as follows: $u_{x,y} = 1$ iff $(x, y) \in C$ and 0 otherwise. When using L_2 distortions, the correspondence problem can be reformulated as

$$\begin{aligned} \min_{u \in \{0,1\}^{\mathcal{V}}} \quad & \sum_{((x,y),(x',y')) \in \mathcal{E}} u_{x,y} u_{x',y'} |d_X(x, x') - d_Y(y, y')|^2 \\ \text{s.t.} \quad & \sum_y u_{x,y} \leq 1 \quad \forall x \in X; \quad \sum_x u_{x,y} \leq 1 \quad \forall y \in Y. \end{aligned} \quad (43)$$

In general, optimization of this energy is NP-hard [53]. One possible approximation of (43) is by relaxing the labels to be in $[0, 1]$. This formulation leads to a non-convex quadratic program with linear constraints [46, 74]. Alternatively, instead of minimizing directly the energy (43), it is possible to maximize a lower bound on it by solving the dual to the linear programming (LP) relaxation of (43), a technique known as *dual decomposition* [110]. This approaches demonstrate good global convergence behavior [65].

Probabilistic Gromov–Hausdorff Distance

The Gromov–Hausdorff framework can be extended to a setting in which pairwise distances are replaced by *distributions* of distances, modeling the intra-class variability shapes (e.g., the fact that different humans have legs of different length) [115]. The pairwise metric difference terms in the correspondence distortion are replaced by probabilities, and the problem is posed as likelihood maximization.

Gromov–Wasserstein Distances

The same way as the Gromov–Hausdorff extends the Hausdorff distance by taking a minimum over all possible metric spaces, $d_{\text{GH}} = \min_{d_{\mathbb{Z}}} d_{\mathbb{H}}^{\mathbb{Z}}$, an extension for the Wasserstein distance of the form

$$\begin{aligned} d_{\text{GW},p}(X, Y) &= \min_{d_{\mathbb{Z}}} d_{\text{W},p}^{\mathbb{Z}}(X, Y) \\ &= \min_{d_{\mathbb{Z}}} \min_{\mu \in \mathcal{M}(\mu_X, \mu_Y)} \left(\int_{X \times Y} d_{\mathbb{Z}}^p(x, y) d\mu(x, y) \right)^{\frac{1}{p}}, \end{aligned} \quad (44)$$

referred to as *Gromov–Wasserstein distance*, was proposed by Mémoli [74]. Here, it is assumed that X and Y are metric measure spaces with metrics d_X, d_Y and measures μ_X, μ_Y . The analogy between the Gromov–Hausdorff and the Gromov–Wasserstein distances is very close: the Hausdorff distance is a distance between subsets of a metric measure space, and the Gromov–Hausdorff distance is a distance between metric spaces. The Wasserstein distance is a distance between subsets of a metric space, and the Gromov–Wasserstein distance is a distance between metric measure spaces.

Numerical Computation

In [74], Mémoli showed that (44) can be alternatively formulated as

$$\begin{aligned} d_{\text{GW},p}(X, Y) &= \\ &\min_{\mu \in \mathcal{M}(\mu_X, \mu_Y)} \left(\int_{X \times Y} \int_{X \times Y} |d_X(x, x') - d_Y(y, y')|^p d\mu(x, y) d\mu(x', y') \right)^{\frac{1}{p}}. \end{aligned} \quad (45)$$

This formulation has an advantage in numerical implementation. Given discrete surfaces $\{x_1, \dots, x_N\}$ and $\{y_1, \dots, y_M\}$ with discretized metrics $d_X(x_i, x_{i'})$, $d_Y(y_j, y_{j'})$ and measures $\mu_X(x_i), \mu_Y(y_j)$ (for $i, i' = 1, \dots, N$ and $j = 1, \dots, M$), problem (45) can be posed as an optimization problem with NM variables and $N + M$ linear constraints:

$$\begin{aligned} \min_{\mu} \quad & \sum_{i,i'=1}^N \sum_{j,j'=1}^M \mu_{ij} \mu_{i'j'} |d_X(x_i, x_{i'}) - d_Y(y_j, y_{j'})|^p \\ \text{s.t.} \quad & \mu_{ij} \in [0, 1] \\ & \sum_{i=1}^N \mu_{ij} = \mu_Y(y_j) \\ & \sum_{j=1}^M \mu_{ij} = \mu_X(x_i). \end{aligned}$$

Shape DNA

Reuter et al. [95] proposed using the Laplace–Beltrami *spectrum* (i.e., eigenvalues $\lambda_0, \lambda_1, \dots$ of Δ_X) as shape descriptors, referred to as *shape DNA*. Laplace–Beltrami spectrum is isometry invariant; however, there may exist shapes which are *isospectral* (have equal eigenvalues) but non-isometric. This fact was first conjectured by Kac [62] and shown by example in [54]. Thus, the equivalence class of isospectral shapes to which the shape DNA approach is invariant is wider than the class of isometries. The exact relations between these classes are currently unknown.

6 Partial Similarity

In many situations, it happens that while two objects are not similar, some of their parts are. Such a situation is common, for example, in the face recognition application, where the quality of facial images (or surfaces in the case of 3D face recognition) can be degraded by acquisition imperfections, occlusions, and the presence of facial hair. Semantically, we can say that two objects are partially similar if they have significant similar parts. If one is able to detect such parts, the degree of partial similarity can be evaluated.

We define a part of a shape (X, d_X) simply as its subset $X' \subset X$ equipped with the restricted metric $d_X|_{X' \times X'}$. According to this definition, every part of a shape is also a shape. We will denote by $\Sigma(X) \subset 2^X$ the set of all admissible parts, satisfying (1) $\Sigma(X)$ is nonempty; (2) $\Sigma(X)$ is closed under complement, i.e., if $X' \in \Sigma(X)$, then $X \setminus X' \in \Sigma(X)$; and (3) $\Sigma(X)$ is closed under countable unions, i.e., any countable union of parts from $\Sigma(X)$ is also an admissible part in $\Sigma(X)$. Formally, the set of all parts of X is a σ -algebra. An equivalent representation of a part is by means of a binary indicator function, $p : X \rightarrow \{0, 1\}$, assuming the value of one for each $x \in X'$ and zero otherwise. We will see the utility of such a definition in the sequel.

Significance

The *significance* of a part is a function on $\Sigma(X)$ assigning each part a number quantifying its “importance.” We denote significance by σ and demand that (1) σ is nonnegative; (2) $\sigma(\emptyset) = 0$; and (3) σ is countably additive, i.e., $\sigma(\bigcup_i X'_i) = \sum_i \sigma(X'_i)$ for every countable union of parts in $\Sigma(X)$. Formally, significance is a finite *measure* on X . As in the case of similarity, the notion of significance is application dependent. The most straightforward way to define significance is by identifying it with the *area*

$$\sigma(X') = \int_{X'} da$$

or the *normalized area*

$$\sigma(X') = \frac{\int_{X'} da}{\int_X da}.$$

of the part. However, such a definition might deem equally important a large flat region and a region rich in features if they have the same area, while it is clear that the latter one would usually be more informative. A better approach is to interpret significance as the amount of information about the entire shape contained in its part, quantified, e.g., as the ability to discriminate the shape from a given corpus of other shapes given only its part. Such a definition leads to a weighted area measure, where the weighting reflects the *discriminativity density* of each point and is constructed similarly to the term frequency-inverse document frequency (TF-IDF) weighting commonly used in text retrieval [2].

Regularity

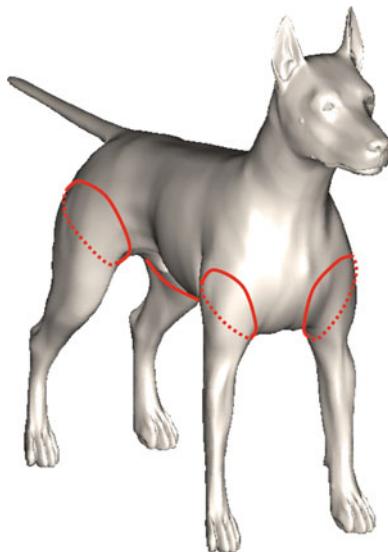

Another quantity characterizing the importance of a part is its *regularity*, which we model as a scalar function $\rho : \Sigma(X) \rightarrow \mathbb{R}$ [18, 19]. In general, we would like the part to be simple, i.e., if two parts contain the same amount of information (are equally significant), we would prefer the simpler one, following Ockham's *pluralitas non est ponenda sine necessitate* principle. What is exactly meant by "regular" and "simple" is again application dependent. In many applications, an acceptable definition of regularity is the deviation of a shape from some perfectly regular one. For example, in image processing and computer vision, regularity is commonly expressed using the *shape factor*

$$\rho(X') = \frac{4\pi \int_{X'} da}{\left(\int_{\partial X'} ds \right)^2},$$

or the ratio between the area of X' and the squared length of its boundary. Because of the isoperimetric inequality in the plane, this ratio is always less or equal to one, with the equality achieved by a circle, which is arguably a very regular shape. Shape factor can be readily extended to non-Euclidean shapes, where, however, there is no straightforward analogy of the isoperimetric inequality. Consequently, two equally regular shapes might have completely different topology, e.g., one might have numerous disconnected components, while the other having only one (Fig. 8).

A remedy can be in regarding regularity as a purely topological property, counting, for example, the number of disconnected components of a part. Topological

Fig. 8 Large shape factor does not necessarily imply regularity in non-Euclidean shapes. Here, the upper body of the dog and the four legs have the same area and the same boundary length (*red contours*) and, hence, the same shape factor. However, the upper body is arguably more regular than the four disconnected legs
(Reproduced from [26])

regularity can be expressed in terms of the *Euler characteristic*, which using the Gauss–Bonnet identity becomes

$$\rho(X') = 2\pi\chi(X') = \int_{X'} K da + \int_{\partial X'} k_g ds,$$

where K is the Gaussian curvature of X and k_g is the geodesic curvature of $\partial X'$.

Partial Similarity Criterion

In this terminology, the problem of partial similarity of two shapes X and Y can be thought finding two parts $X' \in \Sigma(X)$ and $Y' \in \Sigma(Y)$ simultaneously maximizing regularity, significance, and similarity. Since a part of a shape is also a shape, the latter can be quantified using any shape similarity (Since we use *dissimilarity*, we will maximize $-d(X', Y')$.) criterion appropriate for the application, e.g., the Gromov–Hausdorff distance. This can be written as the following multi-criterion optimization problem [18, 19, 27]

$$\max_{\substack{X' \in \Sigma(X) \\ Y' \in \Sigma(Y)}} (\rho(X'), \rho(Y'), \sigma(X'), \sigma(Y'), -d(X', Y')),$$

where maximum is understood as a point in the criterion space, such that no other point has all the criteria larger simultaneously. Such a maximum is said to be *Pareto efficient* and is not unique. The solution of this multi-criterion maximization problem can be interpreted as a *set-valued* partial similarity criterion. Since such

criteria are not mutually comparable, the problem should be converted into a scalar maximization problem

$$\max_{\substack{X' \in \Sigma(X) \\ Y' \in \Sigma(Y)}} \lambda_r(\rho(X') + \rho(Y')) + \lambda_s(\sigma(X') + \sigma(Y')) - d(X', Y'), \quad (46)$$

where λ_r and λ_s are positive scalars reflecting the tradeoff between regularity, significance, and dissimilarity.

Computational Considerations

Direct solution of problem (46) involves searching over the space of all parts of X and Y , which has combinatorial complexity. However, the problem can be relaxed to maximization in continuous variables if binary parts are allowed to be *fuzzy*. Formally, a fuzzy part is obtained by letting the binary indicator functions assume values on the interval $[0, 1]$. Such functions are called *membership functions* in the fuzzy set theory terminology. The optimization problem becomes [28]

$$\max_{\substack{p: X \rightarrow [0,1] \\ q: Y \rightarrow [0,1]}} \lambda_r(\rho(p) + \rho(q)) + \lambda_s(\sigma(p) + \sigma(q)) - d(p, q),$$

where $\rho(p)$, $\sigma(p)$ and $d(p, q)$ are the fuzzy counterparts of the regularity, significance, and dissimilarity terms. The significance of a fuzzy part p is simply

$$\sigma(p) = \int_X p \, d\sigma.$$

The regularity term is somewhat more involved as it involves integration along the part boundary, which does not exist in case of a fuzzy part. However, the following relaxation is available [35]

$$\rho(p) = \frac{4\pi \int_X p \, da}{\left(\int_X \|\nabla p\| \delta(p - \frac{1}{2}) \, da \right)^2},$$

with δ being the Dirac delta function. This fuzzy version of the shape factor converges to the original definition when p approaches a binary indicator function. The dissimilarity term needs to be modified to involve the membership function. The most straightforward way to do so is by defining a weighted dissimilarity between the entire shapes X and Y with p and q serving as the weights. For example, using $p(x)da(x)$ and $q(y)da(y)$ as the respective measures on X and Y , the Wasserstein distance incorporates the weights in a natural way.

7 Self-Similarity and Symmetry

An important particular case of shape similarity is the similarity of shape with itself, which is commonly referred to as *symmetry*. The latter notion is intimately related with that of invariance.

Rigid Symmetry

Computation of exact and approximate symmetries has been extensively studied in the Euclidean sense [3, 6, 83, 118]. A shape X is said to be symmetric if there exists a nontrivial Euclidean isometry $f \in \text{Iso}(\mathbb{R}^3)$ to which it is invariant, i.e., $f(X) = X$. Such an isometry is called a symmetry of X . True symmetries, like true isometries, are a mere idealization not existing in practice. In real applications, we might still find approximate symmetries. The degree of asymmetry of a Euclidean isometry f can be quantified as a distance between X and $f(X)$ in \mathbb{R}^3 , e.g.,

$$\text{asym}(f) = d_{\text{H}}^{\mathbb{R}^3}(X, f(X)).$$

Intrinsic Symmetry

A symmetry f restricted to X defines a *self-isometry* of X , i.e., $f|_X \in \text{Iso}(X)$. Therefore, an alternative definition of an approximate symmetry could be an ϵ -isometry, with the distortion quantifying the degree of asymmetry. Such a definition requires approximate symmetries to be automorphisms of X , yet its main advantage is the fact that it can be extended beyond the Euclidean case (Fig. 9). In fact, identifying the symmetry group with the isometry group $\text{Iso}(X, d_X)$ of the shape X with some intrinsic (e.g., geodesic or diffusion) metric d_X , a nonrigid equivalent of symmetries is defined, while setting $d_X = d_E|_{X \times X}$ the standard Euclidean symmetries are obtained [92]. Approximate symmetries with respect to any metric can be computed as local minima of the distortion function in embedding X into itself. Computationally, the process can be carried out using GMDS.

Spectral Symmetry

An alternative to this potentially heavy computation is due to Ovsjanikov et al. [87] and is based on the elegant observation that for any simple (A simple eigenfunction is one corresponding an eigenvalues with multiplicity one.) eigenfunction ϕ_i of the Laplace–Beltrami operator, a reflection symmetry f satisfies $\phi_i \circ f = \pm \phi_i$. This allows parametrize reflection symmetries by *sign sequences* $\mathbf{s} = \{s_1, s_2, \dots\}$, $s_i \in \{\pm 1\}$, such that $\phi_i \circ f = s_i \phi_i$.

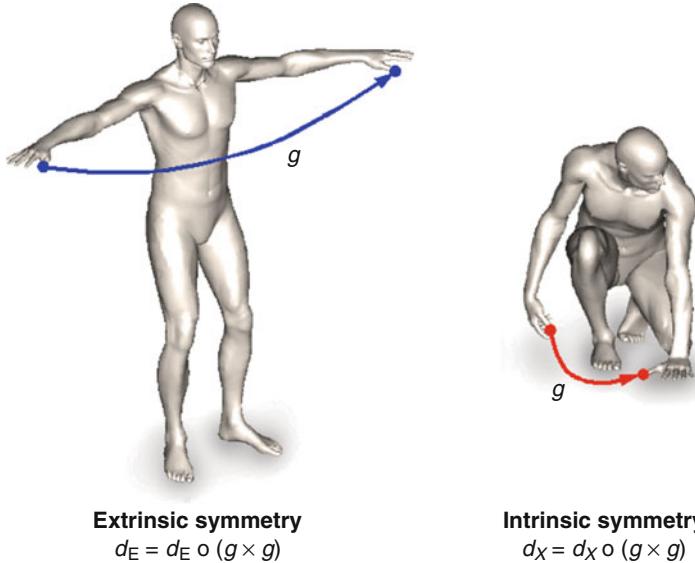

Fig. 9 Symmetry defined as a metric-preserving automorphism (self-isometry) of X allows extending the standard notion of Euclidean symmetry to nonrigid shapes (Reproduced from [92])

Given a sign sequence, the eigenmap $\Phi_s(x) = \{s_1\lambda_1^{-1/2}\phi_1(x), s_2\lambda_2^{-1/2}\phi_2(x), \dots\}$ is defined. Symmetries are detected by evaluating the asymmetry

$$\text{asym}(s) = \max_{x \in X} \min_{x' \in X} \|\Phi_s(x') - \Phi(x)\|$$

of different sign sequences and keeping those having $\text{asym} \leq \epsilon$. The symmetry itself corresponding to a sequence s is recovered as

$$f(x) = \arg \min_{x' \in X} \|\Phi_s(x') - \Phi(x)\|,$$

and is an ϵ self-isometry of X in the sense of the commute time metric. While it can be made relatively computationally simple, this method is limited to global reflection symmetries only.

Partial Symmetry

In many cases, a shape does not have symmetries as a whole, yet possesses parts that are symmetric. Adopting the notion of partial similarity defined in Sect. 6, one can think of a part $X' \subset X$ and a *partial symmetry* $f : X' \times X'$ as of a Pareto-efficient tradeoff between asymmetry $\text{asym}(f)$, part significance $\sigma(X')$,

and regularity $\rho(X')$. Partial symmetries are found similarly to the computation of partial similarity of two distinct shapes.

Repeating Structure

Another important particular case of self-similarity is repeating *regular structure*. Shapes possessing regular structure can be divided into self-similar patches (*structural elements*) forming some regular patterns, e.g., a grid. State-of-the-art methods [89, 108?] can detect structured repetitions in extrinsic geometry if the Euclidean transformations between repeated patches exhibit group-like behavior. In case of nonrigid and deformable shapes, however, the problem is challenging since no apparent structure is visible to simple Euclidean probes in the absence of repetitive Euclidean transformations to describe the shape. A general solution for the detection of intrinsic regular structure is still missing, though particular cases have been recently addressed in [29].

8 Feature-Based Methods

Another class of methods, referred to as *feature based*, uses local information to describe the shape, perform matching, or compute similarity. The popularity of these methods has increased following the success of the scale-invariant feature transform (SIFT) [70] and similar algorithms [8, 71] in image analysis and computer vision application.

Feature Descriptors

In essence, feature-based methods try to represent the shape as a collection of local *feature descriptors*. This is typically done in two steps first, selecting robust and representative points (*feature detection*) and computing the local shape representation at these points (*feature description*).

Feature Detection

One of the main requirements on a feature detector is that the points it selects are (1) *repeatable*, i.e., in two instances of a shape, ideally the same set of corresponding points is detected, and (2) *informative*, i.e., the information contained in these points is sufficient to, e.g., distinguish the shape from others.

In the most trivial case, no feature detection is performed and the feature descriptor is computed at all the points of the shape or at some regularly sampled subset thereof. The descriptor in this case is usually termed *dense*. Dense descriptors bypass the problem of repeatability at the price of increased computational cost and potentially introducing many unimportant points that clutter the shape representation.

Many geometric feature detection paradigms come from the image analysis community, such as finding points with high derivatives (e.g., the *Harris operator* [30, 52, 57]) or local maxima in a scale space (e.g., *difference of Gaussians* (DOG) [119] or local maxima of the heat kernel [49]).

Feature Description

Given a set of feature points (or, in the case of a dense descriptor, all the points on the shape), a local descriptor is then computed. An ideal feature descriptor should be (1) invariant under the class of transformations a shape can undergo and (2) informative. One of the most known feature descriptors is *spin image* [4, 5, 61], describing the neighborhood of a point by fitting an oriented coordinate system at the point. Belongie and Malik introduced the *shape context descriptor* [11], describing the structure of the shape as relations between a point to the rest of the point. Given the coordinates of a point x on the shape, the shape context descriptor is constructed as a histogram of the direction vectors from x to the rest of the point, $y - x$. Typically, a log-polar histogram is used. Because of dependence on the embedding coordinates, such a descriptor is not deformation invariant. Other descriptors exist based on local patches [82], local moments [38] and volume descriptors [50], spherical harmonics [101], and contour and edge structures [64, 88]. Zaharescu et al. [119] proposed using as a local descriptor the histogram of gradients of a function (e.g., Gaussian curvature) defined in a neighborhood of a point, similarly to the *histogram of gradients* (HOG) [43] and SIFT [70] techniques used in computer vision.

Because considering local geometry, feature descriptors are usually not very susceptible to nonrigid deformations of the shape. Nevertheless, there exist several geometric descriptors which are invariant to isometric deformations by construction. Examples include descriptors based on histograms of local geodesic distances [27], conformal factors [12], and heat kernels [106], described in the following in more details.

Heat Kernel Signatures

Sun et al. [106] proposed the *heat kernel signature* (HKS), defined as the diagonal of the heat kernel. Given some fixed time values t_1, \dots, t_n , for each point x on the shape, the HKS is an n -dimensional descriptor vector

$$p(x) = (K_{t_1}(x, x), \dots, K_{t_n}(x, x)). \quad (47)$$

The HKS descriptor is deformation invariant, captures local geometric information at multiple scales, is insensitive to topological noise, is informative (if the Laplace–Beltrami operator of a shape is non-degenerate, then any continuous map that preserves the HKS at every point must be an isometry), and is easily computed across different shape representations solving the eigenproblem described in section “Diffusion Distance.”

Scale-Invariant Heat Kernel Signatures

A disadvantage of the HKS is its dependence on the global scale of the shape. If X is globally scaled by β , the corresponding HKS is $\beta^{-2} K_{\beta^{-2} t}(x, x)$. In some cases, it is possible to remove this dependence by *global* normalization of the shape. A *scale-invariant HKS* (SI-HKS) based on *local* normalization was proposed in [33]. By using a logarithmic scale-space $t = \alpha^\tau$, the scaling of X by β results in HKS amplitude scaling and shift by $2 \log_\alpha \beta$. This effect is undone by the following sequence of transformations,

$$\begin{aligned} p_{dif}(x) &= (\log K_{\alpha^{\tau_2}}(x, x) - \log K_{\alpha^{\tau_1}}(x, x), \dots, \log K_{\alpha^{\tau_m}}(x, x) \\ &\quad - \log K_{\alpha^{\tau_{m-1}}}(x, x)), \hat{p}(x) = |(\mathcal{F}p_{dif}(x))(\omega_1, \dots, \omega_n)|, \end{aligned} \quad (48)$$

where \mathcal{F} is the discrete Fourier transform and $\omega_1, \dots, \omega_n$ denotes a set of frequencies at which the transformed vector is sampled. Taking differences of logarithms removes the scaling constant, and the Fourier transform converts the scale-space shift into a complex phase, which is removed by taking the absolute value.

Bags of Features

One of the notable advantages of feature-based approaches is the possibility of representing a shape as a collection of primitive elements (“geometric words”) and using the well-developed methods from text search such as the *bag of features* (BOF) (or *bag of words*) paradigm [37, 103]. Such approaches are widely used in image retrieval and have been introduced more recently to shape analysis [29, 109]. The bag of features representation is usually compact and easy to store and compare, which makes such approaches suitable for large-scale shape retrieval.

The construction of a bag of features is usually performed in a few steps, depicted in Fig. 10. First, the shape is represented as a collection of local feature descriptors (either dense or computed at a set of stable points following an optional stage of feature detection). Second, the descriptors are represented by *geometric words* from a *geometric vocabulary* using vector quantization. The geometric vocabulary is a set of representative descriptors, precomputed in advance. This way, each descriptor is replaced by the index of the closest geometric word in the vocabulary. Computing the histogram of the frequency of occurrence of geometric words gives the bag of features. Alternatively, a two-dimensional histogram of co-occurrences of pairs of geometric words (*geometric expressions*) can be used [29]. Shape similarity is computed as a distance between the corresponding bags of features.

Combining Global and Local Information

Another use of local descriptors is in combination with global (metric) information, in an extension of the Gromov–Hausdorff framework. Given two shapes X, Y with

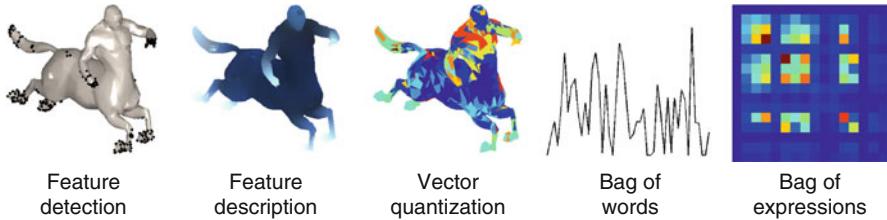

Fig. 10 Feature-based shape analysis algorithm (Reproduced from [29])

metrics d_X, d_Y and descriptors p_X, p_Y , the quality of correspondence $C \subseteq X \times Y$ is measured using global geometric distortion as well as local matching of descriptors,

$$\text{dis}(C) = \sup_{(x,y),(x',y') \in C} |d_X(x, x') - d_Y(y, y')| + \beta \sup_{(x,y) \in C} \|p_X(x) - p_Y(y)\|,$$

where $\beta > 0$ is some parameter. This L_∞ formulation can be replaced by a more robust L_2 version. As the descriptors, texture [105, 107] or geometric information [46, 115] can be used.

The minimum-distortion correspondence can be found by an extension of the GMDS algorithm described in section ‘‘Generalized Multidimensional Scaling’’ [107] or graph labeling [105, 110, 115] described in section ‘‘Graph-Based Methods.’’ The probabilistic extension of the Gromov–Hausdorff distance can be applied to this formulation as well [115].

9 Conclusion

In this chapter, the problem of invariant shape similarity was presented through the prism of metric geometry. It was shown that by representing shapes as metric spaces allows to reduce the similarity problem to isometry-invariant comparison of metric spaces. The particular choice of the metric results in different isometry groups and, hence, different invariance classes. The construction of Euclidean, geodesic, and diffusion metrics was presented, and their theoretical properties were highlighted in Sect. 2. Based on these notions, different shape similarity criteria and distances were presented in Sect. 5, fitting well under the metric umbrella. Computational aspects related to shape and metric discretization were discussed in Sects. 3 and 4, and computation of full and partial similarity was discussed in Sects. 5 and 6. In Sect. 8, feature-based methods were discussed. For further detailed discussion of these and related subjects, the reader is referred to the book [25].

1 Introduction

Image Analysis and Prior Knowledge

Image segmentation is among the most studied problems in image understanding and computer vision. The goal of image segmentation is to partition the image plane into a set of meaningful regions. Here *meaningful* typically refers to a semantic partitioning where the computed regions correspond to individual objects in the observed scene. Unfortunately, generic purely low-level segmentation algorithms often do not provide the desired segmentation results, because the traditional low-level assumptions like intensity or texture homogeneity and strong edge contrast are not sufficient to separate objects in a scene.

To overcome these limitations, researchers have proposed to impose prior knowledge into low-level segmentation methods. In the following, we will review methods which allow to impose knowledge about the *shape* of objects of interest into segmentation processes.

In the literature there exist various definitions of the term *shape*, from the very broad notion of shape of Kendall [54] and Bookstein [5] where shape is whatever remains of an object when similarity transformations are factored out (i.e., a geometrically normalized version of a gray value image) to more specific notions of shape referring to the geometric outline of an object in 2D or 3D. In this work, we will adopt the latter view and refer to an object's silhouette or boundary as its shape. Intentionally we will leave the exact mathematical definition until later, as different representations of geometry actually imply different definitions of the term *shape*.

One can distinguish various kinds of shape knowledge:

- Low-level shape priors which typically simply favor shorter boundary length, i.e., curves with shorter boundary have lower shape energy, where boundary length can be measured in various ways [4, 6, 49, 53, 69].
- Mid-level shape priors which favor, for example, thin and elongated structures, thereby facilitating the segmentation of roads in satellite imagery or of blood vessels in medical imagery [44, 70, 78].
- High-level shape priors which favor similarity to previously observed shapes, such as hand shapes [22, 36, 50], silhouettes of humans [26, 29], or medical organs like the heart, the prostate, the lungs, or the cerebellum [58, 82, 84, 99].

There exists a wealth of works on shape priors for image segmentation. It is beyond the scope of this article to provide a complete overview of existing work. Instead, we will present a range of representative works – with many of the examples taken from the author’s own work – and discuss their advantages and shortcomings. Some of these works are formulated in a probabilistic setting where the challenge is to infer the most likely shape given an image and a set of training shapes. Typically the segmentation is formulated as an optimization problem.

One can distinguish two important challenges:

1. The modeling challenge: How do we formalize distances between shapes? What probability distributions do we impose? What energies should we minimize?
2. The algorithmic challenge: How do we minimize the arising cost function? Are the computed solutions globally optimal? If they are not globally optimal, how sensitive are solutions with respect to the initialization?

Explicit Versus Implicit Shape Representation

A central question in the modeling of shape similarity is that of how to represent a shape. Typically one can distinguish between *explicit* and *implicit* representations. In the former case, the boundary of the shape is represented explicitly – in a spatially continuous setting, this could be a polygon or a spline curve. In a spatially discrete setting this could be a set of edges (edge elements) forming a regular grid. Alternatively, shapes can be represented implicitly in the sense that one labels all points in space as being part of the interior or the exterior of the object. In the spatially continuous setting, the optimization of such implicit shape representations is solved by means of partial differential equations. Among the most popular representatives are the level set method [39, 72] or alternative convex relaxation techniques [11]. In the spatially discrete setting, implicit representations have become popular through the graph cut methods [7, 49]. More recently, researchers have also advocated hybrid representations where objects are represented both explicitly and implicitly [90]. Table 1 provides an overview of a few representative works on image segmentation based on explicit and implicit representations of shape.

Figure 1 shows examples of shape representations using an explicit parametric representation by spline curves (spline control points are marked as black boxes), implicit representations by a signed distance function or a binary indicator function, and an explicit discrete representation (4th image).

As we shall see in the following, the choice of shape representation has important consequences on the class of objects that can be modeled, the type of energy that can be minimized, and the optimality guarantees that can be obtained. Among the goals of this article is to put in contrast various shape representations and discuss their advantages and limitations. In general one observes that:

Table 1 Shapes can be represented explicitly or implicitly, in a spatially continuous or a spatially discrete setting. More recently, researchers have adopted hybrid representations [90], where objects are represented both in terms of their interior (implicitly) and in terms of their boundary (explicitly)

| | Spatially continuous | Spatially discrete | |
|----------|--|--|---------------------------------------|
| Explicit | Polygons [22, 102], splines [3, 36, 53] | Edgel labeling and dyn. progr. [1, 74, 80, 87, 89] | Hybrid repres. and LP relaxation [90] |
| Implicit | Level set methods [39, 72], convex relaxation [11, 31] | Graph cut methods [6, 49] | |

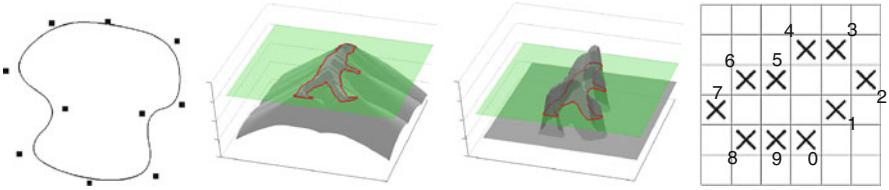

Fig. 1 Examples of shape representations by means of a parametric spline curve (1st image), a signed distance function (2nd image), a binary indicator function (3rd image), and an explicit discrete representation (4th image)

- Implicit representations are easily generalized to shapes in arbitrary dimension. Respective algorithms (level set methods, graph cuts, convex relaxation techniques) straightforwardly extend to three or more dimensions. Instead, the extension of explicit shape representations to higher dimensions is by no means straightforward: The notion of arc-length parameterization of curves does not extend to surfaces. Moreover, the discrete polynomial-time shortest-path algorithms [1, 85, 89] which allow to optimally identify pairwise correspondence of points on either shape do not directly extend to minimal-surface algorithms.
- Implicit representations are easily generalized to arbitrary shape topology. Since the implicit representation merely relies on a labeling of space (as being inside or outside the object), the topology of the shape is not constrained. Both level set and graph cut algorithms can therefore easily handle objects of arbitrary topology. Instead, for spatially continuous parametric curves, modeling the transition from a single closed curve to a multiply connected object boundary requires sophisticated splitting and merging techniques [38, 60, 61, 65]. Similarly, discrete polynomial-time algorithms are typically constrained to finding open [1, 20, 23] or closed curves [86, 89].
- Explicit boundary representations allow to capture the notion of *point correspondence* [47, 85, 89]. The correspondence between points on either of two shapes and the underlying correspondence of semantic parts is of central importance to human notions of shape similarity. The determination of optimal point correspondences, however, is an important combinatorial challenge, especially in higher dimensions.
- For explicit representations, the modeling of shape similarity is often more straightforward and intuitive. For example, for two shapes parameterized as spline curves, the linear interpolation of these shapes also gives rise to a spline curve and often captures the human intuition of an *intermediate shape*. Instead, the linear interpolation of implicit representations is generally not straightforward: Convex combinations of binary-valued functions are no longer binary-valued. And convex combinations of signed distance functions are generally no longer a signed distance function. Figure 2 shows examples of a linear interpolations of spline curves and a linear interpolations of signed distance functions. Note that the linear interpolation of signed distance functions may give rise to intermediate silhouettes of varying topology.

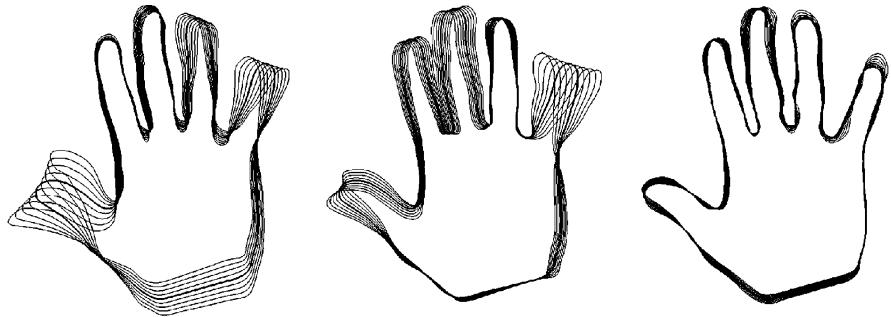

Fig. 2 The linear interpolation of spline-based curves (shown here along the first three eigenmodes of a shape distribution) gives rise to a families of intermediate shapes

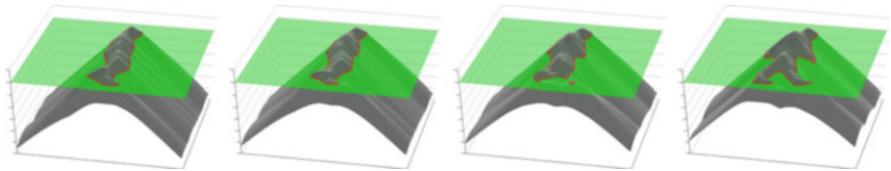

Fig. 3 This figure shows the linear interpolation of the signed distance functions associated with two human silhouettes. The interpolation gives rise to intermediate shapes and allows changes of the shape topology. Yet, the linear combination of two signed distance functions is generally no longer a signed distance function

In the following, we will give an overview over some of the developments in the domain of shape priors for image segmentation. In Sect. 2, we will review a formulation of image segmentation by means of Bayesian inference which allows the fusion of input data and shape knowledge in a single energy minimization framework (Fig. 3). In Sect. 3, we will discuss a framework to impose statistical shape priors in a spatially continuous parametric representation. In Sect. 4, we discuss methods to impose statistical shape priors in level set based image segmentation. In Sect. 5, we discuss statistical models which allow to represent the temporal evolution of shapes and can serve as dynamical priors for image sequence segmentation. And lastly, in Sect. 6, we will present recent developments to impose elastic shape priors in a manner which allows to compute globally optimal shape-consistent segmentations in polynomial time.

2 Image Segmentation via Bayesian Inference

Over the last decades Bayesian inference has become an established paradigm to tackle data analysis problems – see [30, 105] for example. Given an input image $I : \Omega \rightarrow \mathbb{R}$ on a domain $\Omega \subset \mathbb{R}^2$, a segmentation \mathcal{C} of the image plane Ω can be computed by maximizing the posterior probability:

$$\mathcal{P}(\mathcal{C} | I) = \frac{\mathcal{P}(I | \mathcal{C}) \mathcal{P}(\mathcal{C})}{\mathcal{P}(I)}, \quad (1)$$

where $\mathcal{P}(I | \mathcal{C})$ denotes the data likelihood for a given segmentation \mathcal{C} and $\mathcal{P}(\mathcal{C})$ denotes the prior probability which allows to impose knowledge about which segmentations are a priori more or less likely.

Maximizing the posterior distribution can be performed equivalently by minimizing the negative logarithm of (1) which gives rise to an energy or cost function of the form

$$E(\mathcal{C}) = E_{\text{data}}(\mathcal{C}) + E_{\text{shape}}(\mathcal{C}), \quad (2)$$

where $E_{\text{data}}(\mathcal{C}) = -\log \mathcal{P}(I | \mathcal{C})$ and $E_{\text{shape}}(\mathcal{C}) = -\log \mathcal{P}(\mathcal{C})$ are typically referred to as *data fidelity term* and *regularizer* or *shape prior*. By maximizing the posterior, one aims at computing the most likely solution given data and prior. Of course there exist alternative strategies of either computing solutions corresponding to the mean of the distribution rather than its mode or of retaining the entire posterior distribution in order to propagate multiple hypotheses over time, as done, for example, in the context of particle filtering [3].

Over the years various data terms have been proposed. In the following, we will simply use a piecewise-constant approximation of the input intensity I [69]:

$$E_{\text{data}}(\mathcal{C}) = \sum_{i=1}^k \int_{\Omega_i} (I(x) - \mu_i)^2 dx, \quad (3)$$

where the regions $\Omega_1, \dots, \Omega_k$ are pairwise disjoint regions separated by the boundary \mathcal{C} and μ_i denotes the average of I over the region Ω_i :

$$\mu_i = \frac{1}{|\Omega_i|} \int_{\Omega_i} I(x) dx. \quad (4)$$

More sophisticated data terms based on color likelihoods [8, 57, 103] or texture likelihoods [2, 30] are conceivable.

A glance into the literature indicates that the most prominent image segmentation methods rely on a rather simple geometric shape prior E_{shape} which energetically favors shapes with shorter boundary length [4, 53, 69], a penalizer which – in a spatially discrete setting – dates back at least as far as the Ising model for ferromagnetism [52]. There are several reasons for the popularity of length constraints in image segmentation. Firstly, solid objects in our world indeed tend to be spatially compact. Secondly, such length constraints are mathematically well studied. They give rise to well-behaved models and algorithms – mean curvature motion in a continuous setting and low-order Markov random fields and submodular cost functions in the discrete setting.

Nevertheless, the preference for a shorter boundary is clearly a very simplistic shape prior. In many applications the user may have a more specific knowledge about what kinds of shapes are likely to arise in a given segmentation task. For example, in biology one may want to segment cells that all have a rather specific size and shape. In medical imaging one may want to segment organs that all have a rather unique shape – up to a certain variability – and preserve a specific spatial relationship with respect to other organs. In satellite imagery one may be most interested in segmenting thin and elongated roads, or in the analysis of traffic scenes from a driving vehicle, the predominant objects may be cars and pedestrians. In the following sections, we will discuss ways to impose such *higher-level* shape knowledge into image segmentation methods.

3 Statistical Shape Priors for Parametric Shape Representations

Among the most straightforward ways to represent a shape is to model its outline as a parametric curve. An example is a simple closed spline curve $\mathcal{C} \in \mathcal{C}^k(\mathbb{S}^1, \Omega)$ of the form

$$\mathcal{C}(s) = \sum_{i=1}^n p_i B_i(s), \quad (5)$$

where $p_i \in \mathbb{R}^2$ denote a set of spline control points and B_i a set of spline basis functions of degree k [19, 36, 43, 66]. In the special case of linear basis functions, we simply have a polygonal shape, used, for example, in [102]. With increasing number of control points, we obtain a more and more detailed shape representation – see Fig. 4. It shows one of the nice properties of parametric shape representations: The representation is quite *compact* in the sense that very detailed silhouettes can be represented by a few real-valued variables.

Given a family of m shapes, each represented by a spline curve of a fixed number of n control points, we can think of these training shapes as a set $\{z_1, \dots, z_m\}$ of control point vectors:

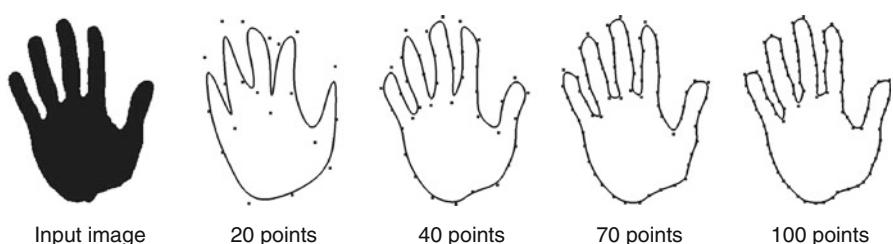

Fig. 4 Spline representation of a hand shape (*left*) with increasing resolution

$$z_i = (p_{i1}, \dots, p_{in}) \in \mathbb{R}^{2n}, \quad (6)$$

where we assume that all control point vectors are normalized with respect to translation, rotation, and scaling [41].

With this contour representation, the image segmentation problem boils down to computing an optimal spline control point vector $z \in \mathbb{R}^{2n}$ for a given image. The segmentation process can be constrained to familiar shapes by imposing a statistical shape prior computed from the set of training shapes.

Linear Gaussian Shape Priors

Among the most popular shape prior is based on the assumption that the training shapes are Gaussian distributed – see for example [22, 36, 55]. There are several reasons for the popularity of Gaussian distributions. Firstly, according to the central limit theorem, the average of a large number of i.i.d. random variables is approximately Gaussian distributed – so if the observed variations of shape were created by independent processes, then one could expect the overall distribution to be approximately Gaussian. Secondly, the Gaussian distribution can be seen as a second-order approximation of the true distribution. And thirdly, the Gaussian distribution gives rise to a convex quadratic cost function that allows for easy minimization.

In practice, the number of training shapes m is often much smaller than the number of dimensions $2n$. Therefore, the estimated covariance matrix Σ is degenerate with many zero eigenvalues and thus not invertible. As introduced in [36], a regularized covariance matrix is given by

$$\Sigma_{\perp} = \Sigma + \lambda_{\perp} (I - V V^t), \quad (7)$$

where V is the matrix of eigenvectors of Σ . In this way, we replace all zero eigenvalues of the sample covariance matrix Σ by a constant $\lambda_{\perp} \in [0, \lambda_r]$, where λ_r denotes the smallest nonzero eigenvalue of Σ . (Note that the inverse Σ_{\perp}^{-1} of the regularized covariance matrix defined in (7) fundamentally differs from the pseudoinverse, the former scaling components in degenerate directions by λ_{\perp}^{-1} while the latter scaling them by 0.) In [68] it was shown that λ_{\perp} can be computed from the true covariance matrix by minimizing the Kullback–Leibler divergence between the exact and the approximated distribution. Yet, since we do not have the exact covariance matrix but merely a *sample* covariance matrix, the reasoning for determining λ_{\perp} suggested in [68] is not justified.

The Gaussian shape prior is then given by

$$\mathcal{P}(z) = \frac{1}{|2\pi\Sigma_{\perp}|^{1/2}} \exp\left(-\frac{1}{2} (z - \bar{z})^t \Sigma_{\perp}^{-1} (z - \bar{z})\right), \quad (8)$$

where \bar{z} denotes the mean control point vector.

Based on the Gaussian shape prior, we can define a shape energy that is invariant to similarity transformations (translation, rotation, and scaling) by

$$E_{\text{shape}}(z) = -\log \mathcal{P}(\hat{z}), \quad (9)$$

where \hat{z} is the shape vector upon similarity alignment with respect to the training shapes:

$$\hat{z} = \frac{R(z - z_0)}{|R(z - z_0)|}, \quad (10)$$

where the optimal translation z_0 and rotation R can be written as functions of z [36]. As a consequence, we can minimize the overall energy

$$E(z) = E_{\text{data}}(C(z)) + E_{\text{shape}}(z) \quad (11)$$

using gradient descent in z . For details on the numerical minimization, we refer to [25, 36].

Figure 5 shows several intermediate steps in a gradient descent evolution on the energy (2) combining the piecewise constant intensity model (3) with a Gaussian shape prior constructed from a set of sample hand shapes. Note how the similarity-

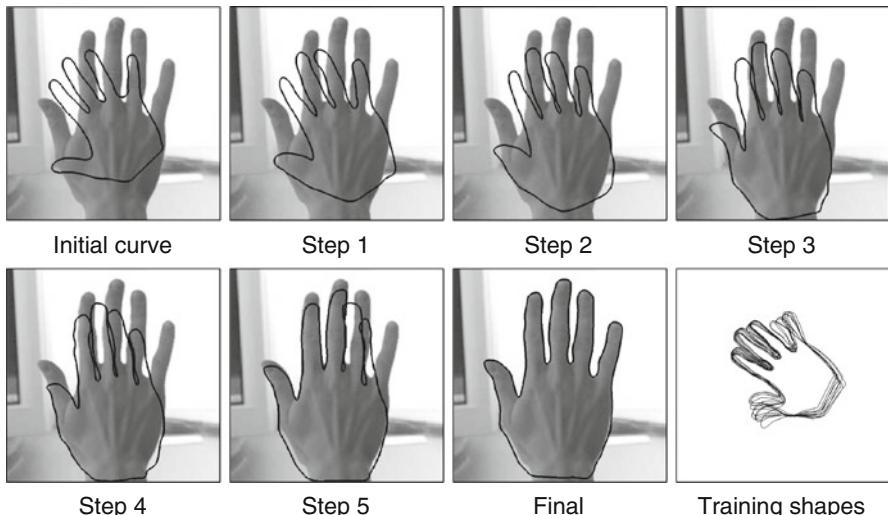

Fig. 5 Evolution of a parametric spline curve during gradient descent on the energy (2) combining the piecewise constant intensity model (3) with a Gaussian shape prior constructed from a set of sample hand shapes (*lower right*). Note that the shape prior is by construction invariant to similarity transformations. As a consequence, the contour easily undergoes translation, rotation, and scaling as these do not affect the energy

Fig. 6 Gradient descent evolution of a parametric curve from initial to final with similarity-invariant shape prior. The statistical shape prior permits a reconstruction of the hand silhouette in places where it is occluded

invariant shape prior (9) constrains the evolving contour to hand-like shapes without constraining its translation, rotation, or scaling.

Figure 6 shows the gradient descent evolution with the same shape prior for an input image of a partially occluded hand. Here the missing part of the silhouette is recovered through the statistical shape prior. These evolutions demonstrate that the curve converges to the correct segmentation over rather large spatial distance, an aspect which is characteristic for region-based cost functions like (3).

Nonlinear Statistical Shape Priors

The shape prior (9) was based on the assumption that the training shapes are Gaussian distributed. For collections of real-world shapes, this is generally not the case. For example, the various silhouettes of a rigid 3D object obviously form a three-dimensional manifold (given that there are only three degrees of freedom in the observation process). Similarly, the various silhouettes of a walking person essentially correspond to a one-dimensional manifold (up to small fluctuations). Furthermore, the manifold of shapes representing deformable objects like human persons are typically very low-dimensional, given that the observed 3D structure only has a small number of joints.

Rather than learning the underlying low-dimensional representation (using principal surfaces or other manifold learning techniques), we can simply estimate arbitrary shape distributions by reverting to nonlinear density estimators – *nonlinear* in the sense that the permissible shapes are not simply given by a weighted sum of eigenmodes. Classical approaches for estimating nonlinear distributions are the Gaussian mixture model or the Parzen–Rosenblatt kernel density estimator – see Sect. 4.

An alternative technique is to adapt recent kernel learning methods to the problem of density estimation [28]. To this end, we approximate the training shapes by a Gaussian distribution, not in the input space but rather upon transformation $\psi : \mathbb{R}^{2n} \rightarrow Y$ to some generally higher-dimensional *feature space* Y :

$$\mathcal{P}_\psi(z) \propto \exp\left(-\frac{1}{2} (\psi(z) - \psi_0)^t \Sigma_\psi^{-1} (\psi(z) - \psi_0)\right). \quad (12)$$

As before, we can define the corresponding shape energy as

$$E(z) = -\log \mathcal{P}_\psi(\hat{z}), \quad (13)$$

with \hat{z} being the similarity-normalized shape given in (10). Here ψ_0 and Σ_ψ denote the mean and covariance matrix computed for the transformed shapes:

$$\psi_0 = \frac{1}{m} \sum_{i=1}^m \psi(z_i), \quad \Sigma_\psi = \frac{1}{m} \sum_{i=1}^m (\psi(z_i) - \psi_0)(\psi(z_i) - \psi_0)^\top, \quad (14)$$

where Σ_ψ is again regularized as in (7).

As shown in [28], the energy $E(z)$ in (13) can be evaluated without explicitly specifying the nonlinear transformation ψ . It suffices to define the corresponding Mercer kernel [24, 67]:

$$k(x, y) := \langle \psi(x), \psi(y) \rangle, \quad \forall x, y \in \mathbb{R}^{2n}, \quad (15)$$

representing the scalar product of pairs of transformed points $\psi(x)$ and $\psi(y)$. In the following, we simply chose a Gaussian kernel function of width σ :

$$k(x, y) = \frac{1}{(2\pi\sigma^2)^{\frac{n}{2}}} \exp\left(-\frac{\|x - y\|^2}{2\sigma^2}\right). \quad (16)$$

It was shown in [28] that the resulting energy can be seen as a generalization of the classical Parzen–Rosenblatt estimators. In particular, the Gaussian distribution in feature space Y is fundamentally different from the previously presented Gaussian distribution in the input space \mathbb{R}^{2n} . Figure 7 shows the level lines of constant shape energy computed from a set of left- and right-hand silhouettes, displayed

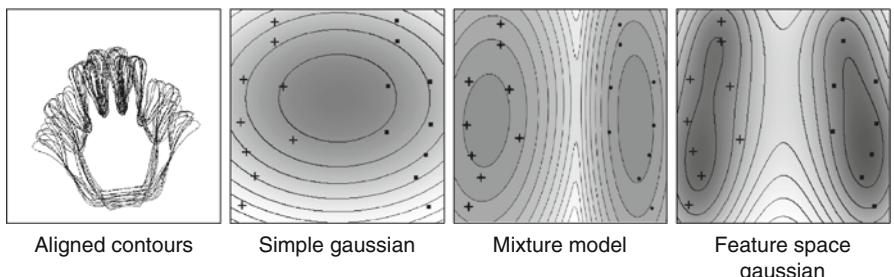

Fig. 7 Model comparison. Density estimates for a set of left (\bullet) and right ($+$) hands, projected onto the first two principal components. From *left to right*: aligned contours, simple Gaussian, mixture of Gaussians, and Gaussian in feature space (13). In contrast to the mixture model, the Gaussian in feature space does not require an iterative (sometimes suboptimal) fitting procedure

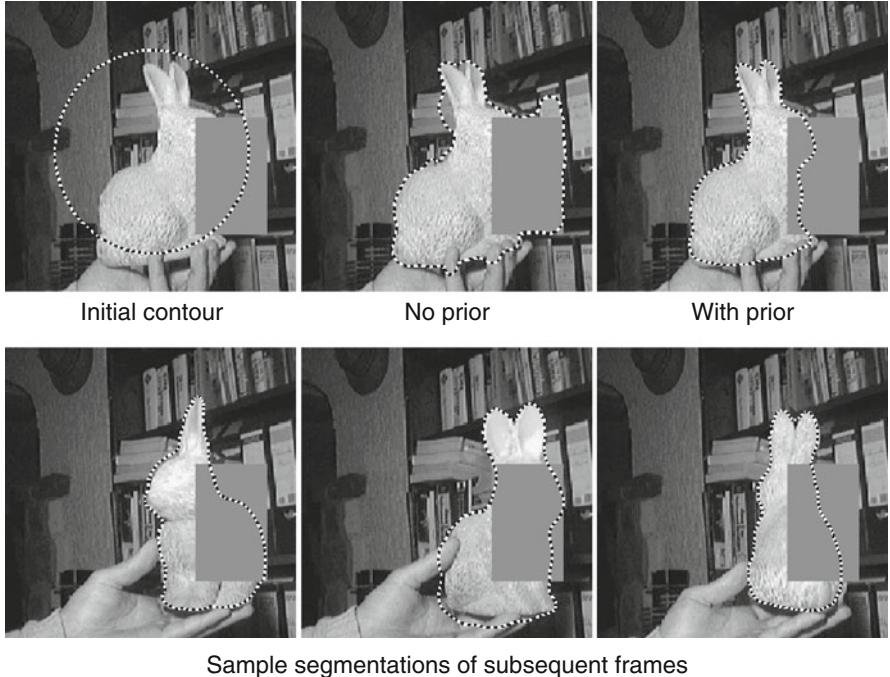

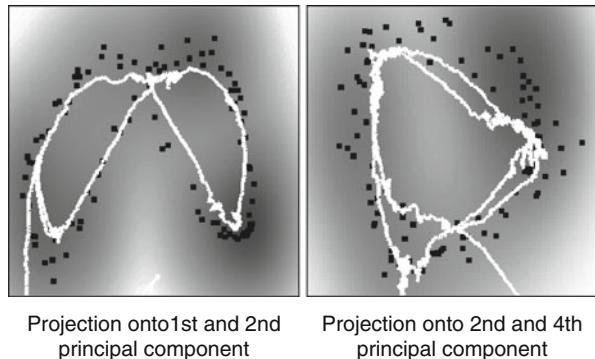

Fig. 8 Tracking a familiar object over a long image sequence with a nonlinear statistical shape prior. A single shape prior constructed from a set of sample silhouettes allows the emergence of a multitude of familiar shapes, permitting the segmentation process to cope with background clutter and partial occlusions

in a projection onto the first two eigenmodes of the distribution. While the linear Gaussian model gives rise to elliptical level lines, the Gaussian mixture and the nonlinear Gaussian allow for more general non-elliptical level lines. In contrast to the mixture model, however, the nonlinear Gaussian does not require an iterative parameter estimation process, nor does it require or assume a specific number of Gaussians.

Figure 8 shows screenshots of contours computed for an image sequence by gradient descent on the energy (11) with the nonlinear shape energy (13) computed from a set of 100 training silhouettes. Throughout the entire sequence, the object of interest was occluded by an artificially introduced rectangle. Again, the shape prior allows to cope with spurious background clutter and to restore the missing parts of the object's silhouette. Two-dimensional projections of the training data and evolving contour onto the first principal components, shown in Fig. 9, demonstrate how the nonlinear shape energy constrains the evolving shape to remain close to the training shapes.

Fig. 9 Tracking sequence from Fig. 8 visualized. Training data (\bullet), estimated energy density (shaded), and the contour evolution (white curve) in appropriate 2D projections. The evolving contour – see Fig. 8 – is constrained to the domains of low energy induced by the training data

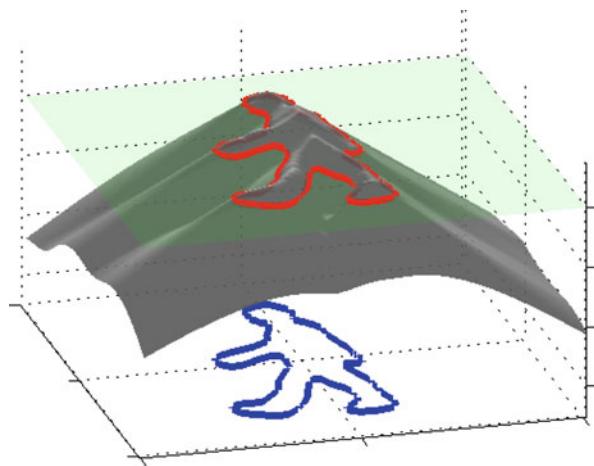

4 Statistical Priors for Level Set Representations

Parametric representations of shape as those presented above have numerous favorable properties; in particular, they allow to represent rather complex shapes with a few parameters, resulting in low memory requirements and low computation time. Nevertheless, the explicit representation of shape has several drawbacks:

- The representation of explicit shapes typically depends on a specific choice of representation. To factor out this dependency in the representation and in respective algorithms gives rise to computationally challenging problems. Determining point correspondences, for example, becomes particularly difficult for shapes in higher dimensions (e.g., surfaces in 3D).
- In particular, the evolution of explicit shape representations requires sophisticated numerical regridding procedures to assure an equidistant spacing of control points and prevent control point overlap.
- Parametric representations are difficult to adapt to varying topology of the represented shape. Numerically, topology changes require sophisticated splitting and remerging procedures.
- A number of recent publications [11, 49, 59] indicate that in contrast to explicit shape representations, the implicit representation of shape allows to compute *globally optimal* solutions to shape inference for large classes of commonly used energy functionals.

A mathematical representation of shape which is independent of parameterization was pioneered in the analysis of random shapes by Fréchet [45] and in the school of mathematical morphology founded by Matheron and Serra [64, 94]. The level set method [39, 72] provides a means of propagating contours \mathcal{C} (independent of parameterization) by evolving associated embedding functions ϕ via partial differential equations – see Fig. 10 for a visualization of the level set function associated with a human silhouette. It has been adapted to segment images based on numerous low-level criteria such as edge consistency [10, 56, 63], intensity

Fig. 10 The level set method is based on representing shapes implicitly as the zero level set of a higher-dimensional embedding function

homogeneity [12, 101], texture information [9, 51, 73, 81], and motion information [33].

In this section, we will give a brief insight into shape modeling and shape priors for implicit level set representations. Parts of the following text were adopted from [34, 35, 82].

Shape Distances for Level Sets

The first step in deriving a shape prior is to define a distance or dissimilarity measure for two shapes encoded by the level set functions ϕ_1 and ϕ_2 . We shall briefly discuss three solutions to this problem. In order to guarantee a unique correspondence between a given shape and its embedding function ϕ , we will in the following assume that ϕ is a *signed distance function*, i.e., $\phi > 0$ inside the shape, $\phi < 0$ outside, and $|\nabla\phi| = 1$ almost everywhere. A method to project a given embedding function onto the space of signed distance functions was introduced in [98].

Given two shapes encoded by their signed distance functions ϕ_1 and ϕ_2 , a simple measure of their dissimilarity is given by their L₂-distance in Ω [62]:

$$\int_{\Omega} (\phi_1 - \phi_2)^2 dx. \quad (17)$$

This measure has the drawback that it depends on the domain of integration Ω . The shape dissimilarity will generally grow if the image domain is increased – even if the relative position of the two shapes remains the same. Various remedies to this problem have been proposed. We refer to [32] for a detailed discussion.

An alternative dissimilarity measure between two implicitly represented shapes represented by the embedding functions ϕ_1 and ϕ_2 is given by the area of the

symmetric difference [14, 15, 77]:

$$d^2(\phi_1, \phi_2) = \int_{\Omega} (H\phi_1(x) - H\phi_2(x))^2 dx. \quad (18)$$

In the present work, we will define the distance between two shapes based on this measure, because it has several favorable properties. Beyond being independent of the image size Ω , measure (18) defines a distance on the set of shapes: it is nonnegative, symmetric, and fulfills the triangle inequality. Moreover, it is more consistent with the philosophy of the level set method in that it only depends on the *sign* of the embedding function. In practice, this means that one does not need to constrain the two level set functions to the space of signed distance functions. It can be shown [15] that L^∞ and $W^{1,2}$ norms on the signed distance functions induce equivalent topologies as the metric (18).

Since the distance (18) is not differentiable, we will in practice consider an approximation of the Heaviside function H by a smooth (differentiable) version H_ϵ . Moreover, we will only consider gradients of energies with respect to the L_2 norm on the level set function, because they are easy to compute and because variations in the signed distance function correspond to respective variations of the implicitly represented curve. In general, however, these do not coincide with the so-called shape gradients – see [46] for a recent work on this topic.

Invariance by Intrinsic Alignment

One can make use of the shape distance (18) in a segmentation process by adding it as a shape prior $E_{\text{shape}}(\phi) = d^2(\phi, \phi_0)$ in a weighted sum to the data term, which we will assume to be the two-phase version of (3) introduced in [13]:

$$E_{\text{data}}(\phi) = \int_{\Omega} (I - u_+)^2 H\phi(x) dx + \int_{\Omega} (I - u_-)^2 (1 - H\phi(x)) dx + \nu \int_{\Omega} |\nabla H\phi| dx, \quad (19)$$

Minimizing the total energy

$$E_{\text{total}}(\phi) = E_{\text{data}}(\phi) + \alpha E_{\text{shape}}(\phi) = E_{\text{data}}(\phi) + \alpha d^2(\phi, \phi_0), \quad (20)$$

with a weight $\alpha > 0$, induces an additional driving term which aims at maximizing the similarity of the evolving shape with a given template shape encoded by the function ϕ_0 .

By construction this shape prior is not invariant with respect to certain transformations such as translation, rotation, and scaling of the shape represented by ϕ .

A common approach to introduce invariance (cf. [17, 35, 83]) is to enhance the prior by a set of explicit parameters to account for translation by μ , rotation by an angle θ , and scaling by σ of the shape:

$$d^2(\phi, \phi_0, \mu, \theta, \sigma) = \int_{\Omega} (H(\phi(\sigma R_\theta(x - \mu))) - H\phi_0(x))^2 dx. \quad (21)$$

This approach to estimate the appropriate transformation parameters has several drawbacks:

- Optimization of the shape energy (21) is done by local gradient descent. In particular, this implies that one needs to determine an appropriate time step for each parameter, chosen so as to guarantee stability of resulting evolution. In numerical experiments, we found that balancing these parameters requires a careful tuning process.
- The optimization of μ , θ , σ , and ϕ is done simultaneously. In practice, however, it is unclear how to alternate between the updates of the respective parameters. How often should one iterate one or the other gradient descent equation? In experiments, we found that the final solution depends on the selected scheme of optimization.
- The optimal values for the transformation parameters will depend on the embedding function ϕ . An accurate shape gradient should therefore take into account this dependency. In other words, the gradient of (21) with respect to ϕ should take into account how the optimal transformation parameters $\mu(\phi)$, $\sigma(\phi)$, and $\theta(\phi)$ vary with ϕ .

Inspired by the normalization for explicit representations introducing in (10), we can eliminate these difficulties associated with the local optimization of explicit transformation parameters by introducing an intrinsic registration process. We will detail this for the cases of translation and scaling. Extensions to rotation and other transformations are conceivable but will not be pursued here.

Translation Invariance by Intrinsic Alignment

Assume that the template shape represented by ϕ_0 is aligned with respect to the shape's centroid. Then we define a shape energy by

$$E_{\text{shape}}(\phi) = d^2(\phi, \phi_0) = \int_{\Omega} (H\phi(x + \mu_\phi) - H\phi_0(x))^2 dx, \quad (22)$$

where the function ϕ is evaluated in coordinates relative to its center of gravity μ_ϕ given by

$$\mu_\phi = \int x h\phi dx, \quad \text{with } h\phi \equiv \frac{H\phi}{\int_{\Omega} H\phi dx}. \quad (23)$$

This intrinsic alignment guarantees that the distance (22) is invariant to the location of the shape ϕ . In contrast to the shape energy (21), we no longer need to iteratively update an estimate of the location of the object of interest.

Translation and Scale Invariance via Alignment

Given a template shape (represented by ϕ_0) which is normalized with respect to translation and scaling, one can extend the above approach to a shape energy which is invariant to translation and scaling:

$$E_{\text{shape}}(\phi) = d^2(\phi, \phi_0) = \int_{\Omega} (H\phi(\sigma_{\phi} x + \mu_{\phi}) - H\phi_0(x))^2 dx, \quad (24)$$

where the level set function ϕ is evaluated in coordinates relative to its center of gravity μ_{ϕ} and in units given by its intrinsic scale σ_{ϕ} defined as

$$\sigma_{\phi} = \left(\int (x - \mu)^2 h\phi dx \right)^{\frac{1}{2}}, \quad \text{where } h\phi = \frac{H\phi}{\int_{\Omega} H\phi dx}. \quad (25)$$

In the following, we will show that functional (24) is invariant with respect to translation and scaling of the shape represented by ϕ . Let ϕ be a level set function representing a shape which is centered and normalized such that $\mu_{\phi} = 0$ and $\sigma_{\phi} = 1$. Let $\tilde{\phi}$ be an (arbitrary) level set function encoding the same shape after scaling by $\sigma \in \mathbb{R}$ and shifting by $\mu \in \mathbb{R}^2$:

$$H\tilde{\phi}(x) = H\phi\left(\frac{x - \mu}{\sigma}\right).$$

Indeed, center and intrinsic scale of the transformed shape are given by

$$\begin{aligned} \mu_{\tilde{\phi}} &= \frac{\int x H\tilde{\phi} dx}{\int H\tilde{\phi} dx} = \frac{\int x H\phi\left(\frac{x - \mu}{\sigma}\right) dx}{\int H\phi\left(\frac{x - \mu}{\sigma}\right) dx} = \frac{\int (\sigma x' + \mu) H\phi(x') \sigma dx'}{\int H\phi(x') \sigma dx'} \\ &= \sigma\mu_{\phi} + \mu = \mu, \\ \sigma_{\tilde{\phi}} &= \left(\frac{\int (x - \mu_{\tilde{\phi}})^2 H\tilde{\phi} dx}{\int H\tilde{\phi} dx} \right)^{\frac{1}{2}} = \left(\frac{\int (x - \mu)^2 H\phi\left(\frac{x - \mu}{\sigma}\right) dx}{\int H\phi\left(\frac{x - \mu}{\sigma}\right) dx} \right)^{\frac{1}{2}} \\ &= \left(\frac{\int (\sigma x')^2 H\phi(x') dx'}{\int H\phi(x') dx'} \right)^{\frac{1}{2}} = \sigma. \end{aligned}$$

The shape energy (21) evaluated for $\tilde{\phi}$ is given by

$$\begin{aligned} E_{\text{shape}}(\tilde{\phi}) &= \int_{\Omega} (H\tilde{\phi}(\sigma_{\tilde{\phi}} x + \mu_{\tilde{\phi}}) - H\phi_0(x))^2 dx \\ &= \int_{\Omega} (H\tilde{\phi}(\sigma x + \mu) - H\phi_0(x))^2 dx \\ &= \int_{\Omega} (H\phi(x) - H\phi_0(x))^2 dx = E_{\text{shape}}(\phi). \end{aligned}$$

Therefore, the above shape dissimilarity measure is invariant with respect to translation and scaling.

Note, however, that while this analytical solution guarantees an invariant shape distance, the transformation parameters μ_ϕ and σ_ϕ are not necessarily the ones which minimize the shape distance (21). Extensions of this approach to a larger class of invariance are conceivable. For example, one could generate invariance with respect to rotation by rotational alignment with respect to the (oriented) principal axis of the shape encoded by ϕ . We will not pursue this here.

Kernel Density Estimation in the Level Set Domain

In the previous sections, we have introduced a translation and scale invariant shape energy and demonstrated its effect on the reconstruction of a corrupted version of a single familiar silhouette the pose of which was unknown. In many practical problems, however, we do not have the exact silhouette of the object of interest. There may be several reasons for this:

- The object of interest may be three-dimensional. Rather than trying to reconstruct the three-dimensional object (which generally requires multiple images and the estimation of correspondence), one may learn the two-dimensional appearance from a set of sample views. A meaningful shape dissimilarity measure should then measure the dissimilarity with respect to this set of projections – see the example in Fig. 8.
- The object of interest may be one object out of a class of similar objects (the class of cars or the class of tree leafs). Given a limited number of training shapes sampled from the class, a useful shape energy should provide the dissimilarity of a particular silhouette with respect to this class.
- Even a single object, observed from a single viewpoint, may exhibit strong shape deformation – the deformation of a gesticulating hand or the deformation which a human silhouette undergoes while walking. In the following, we will assume that one can merely generate a set of stills corresponding to various (randomly sampled) views of the object of interest for different deformations – see Fig. 11. In the following, we will demonstrate that – without constructing a dynamical model of the walking process – one can exploit this set of sample views in order to improve the segmentation of a walking person.

In the above cases, the construction of appropriate shape dissimilarity measures amounts to a problem of density estimation. In the case of explicitly represented boundaries, this has been addressed by modeling the space of familiar shapes by linear subspaces (PCA) [22] and the related Gaussian distribution [36], by mixture models [21] or nonlinear (multimodal) representations via simple models in appropriate feature spaces [27, 28].

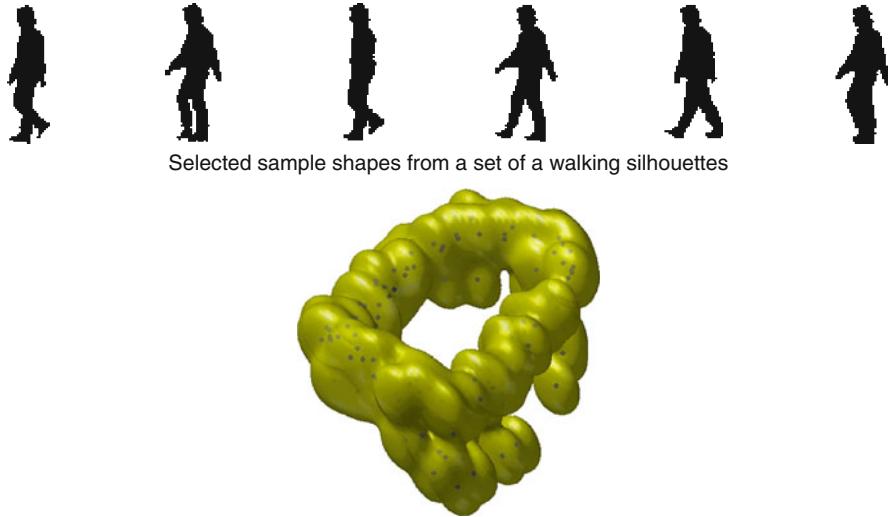

Fig. 11 Density estimated using a kernel density estimator for a projection of 100 silhouettes of a walking person (see above) onto the first three principal components

For level set-based shape representations, it was suggested [62, 84, 100] to fit a linear subspace to the sampled signed distance functions. Alternatively, it was suggested to represent familiar shapes by the level set function encoding the mean shape and a (spatially independent) Gaussian fluctuation at each image location [83]. These approaches were shown to capture some shape variability. Yet, they exhibit two limitations: Firstly, they rely on the assumption of a Gaussian distribution which is not well suited to approximate shape distributions encoding more complex shape variation. Secondly, they work under the assumption that shapes are represented by signed distance functions. Yet, the space of signed distance functions is not a linear space. Therefore, in general, neither the mean nor the linear combination of a set of signed distance functions will correspond to a signed distance function.

In the following, we will propose an alternative approach to generate a statistical shape dissimilarity measure for level set based shape representations. It is based on classical methods of (so-called nonparametric) kernel density estimation and overcomes the above limitations.

Given a set of training shapes $\{\phi_i\}_{i=1 \dots N}$ – such as those shown in Fig. 11 – we define a probability density on the space of signed distance functions by integrating the shape distances (22) or (24) in a Parzen–Rosenblatt kernel density estimator [75, 79]:

$$\mathcal{P}(\phi) \propto \frac{1}{N} \sum_{i=1}^N \exp \left(-\frac{1}{2\sigma^2} d^2(H\phi, H\phi_i) \right). \quad (26)$$

The kernel density estimator is among the theoretically most studied density estimation methods. It was shown (under fairly mild assumptions) to converge to the true distribution in the limit of infinite samples (and $\sigma \rightarrow 0$); the asymptotic convergence rate was studied for different choices of kernel functions.

It should be pointed out that the theory of classical nonparametric density estimation was developed for the case of finite-dimensional data. It is beyond the scope of this work to develop a general theory of probability distributions and density estimation on infinite-dimensional spaces (including issues of integrability and measurable sets). For a general formalism to model probability densities on infinite-dimensional spaces, we refer the reader to the theory of Gaussian processes [76]. In our case, an extension to infinite-dimensional objects such as level set surfaces $\phi : \Omega \rightarrow \mathbb{R}$ could be tackled by considering discrete (finite-dimensional) approximations $\{\phi_{ij} \in \mathbb{R}\}_{i=1,\dots,N, j=1,\dots,M}$ of these surfaces at increasing levels of spatial resolution and studying the limit of infinitesimal grid size (i.e., $N, M \rightarrow \infty$). Alternatively, given a finite number of samples, one can apply classical density estimation techniques efficiently in the finite-dimensional subspace spanned by the training data [82].

Similarly respective metrics on the space of curves give rise to different kinds of gradient descent flows. Recently researchers have developed rather sophisticated metrics to favor smooth transformations or rigid body motions. We refer the reader to [16, 97] for promising advances in this direction. In the following we will typically limit ourselves to L_2 gradients.

There exist extensive studies on how to optimally choose the kernel width σ based on asymptotic expansions such as the parametric method [37], heuristic estimates [95, 104], or maximum likelihood optimization by cross validation [18, 42]. We refer to [40, 96] for a detailed discussion. For this work, we simply fix σ^2 to be the mean squared nearest-neighbor distance:

$$\sigma^2 = \frac{1}{N} \sum_{i=1}^N \min_{j \neq i} d^2(H\phi_i, H\phi_j). \quad (27)$$

The intuition behind this choice is that the width of the Gaussians is chosen such that on the average the next training shape is within one standard deviation.

Reverting to kernel density estimation resolves the drawbacks of existing approaches to shape models for level set segmentation discussed above. In particular:

- The silhouettes of a rigid 3D object or a deformable object with few degrees of freedom can be expected to form fairly low-dimensional manifolds. The kernel density estimator can capture these without imposing the restrictive assumption of a Gaussian distribution. Figure 11 shows a 3D approximation of our method: We simply projected the embedding functions of 100 silhouettes of a walking person onto the first three eigenmodes of the distribution. The projected silhouette data and the kernel density estimate computed in the 3D

subspace indicate that the underlying distribution is not Gaussian. The estimated distribution (indicated by an isosurface) shows a closed loop which stems from the fact that the silhouettes were drawn from an essentially periodic process.

- Kernel density estimators were shown to converge to the true distribution in the limit of infinite (independent and identically distributed) training samples [40, 96]. In the context of shape representations, this implies that our approach is capable of accurately representing arbitrarily complex shape deformations.
- By not imposing a linear subspace, we circumvent the problem that the space of shapes (and signed distance functions) is not a linear space. In other words, Kernel density estimation allows to estimate distributions on nonlinear (curved) manifolds. In the limit of infinite samples and kernel width σ going to zero, the estimated distribution is more and more constrained to the manifold defined by the shapes.

Gradient Descent Evolution for the Kernel Density Estimator

In the following, we will detail how the statistical distribution (26) can be used to enhance level set based segmentation process. As for the case of parametric curves, we formulate level set segmentation as a problem of Bayesian inference, where the segmentation is obtained by maximizing the conditional probability:

$$\mathcal{P}(\phi | I) = \frac{\mathcal{P}(I | \phi) \mathcal{P}(\phi)}{\mathcal{P}(I)}, \quad (28)$$

with respect to the level set function ϕ , given the input image I . For a given image, this is equivalent to minimizing the negative log-likelihood which is given by a sum of two energies:

$$E(\phi) = E_{\text{data}}(\phi) + E_{\text{shape}}(\phi), \quad (29)$$

with

$$E_{\text{shape}}(\phi) = -\log \mathcal{P}(\phi). \quad (30)$$

Minimizing the energy (29) generates a segmentation process which simultaneously aims at maximizing intensity homogeneity in the separated phases and a similarity of the evolving shape with respect to all the training shapes encoded through the statistical estimator (26).

Gradient descent with respect to the embedding function amounts to the evolution:

$$\frac{\partial \phi}{\partial t} = -\frac{1}{\alpha} \frac{\partial E_{\text{data}}}{\partial \phi} - \frac{\partial E_{\text{shape}}}{\partial \phi}, \quad (31)$$

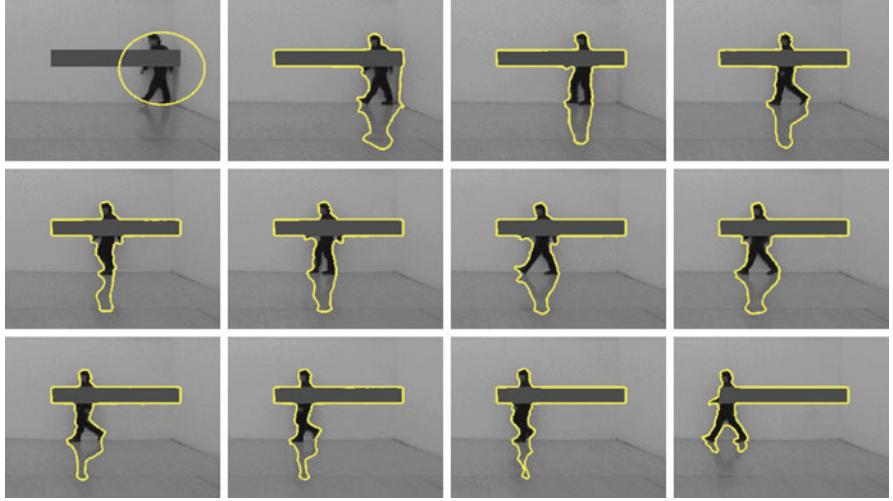

Fig. 12 Purely intensity-based segmentation. Various frames show the segmentation of a partially occluded walking person generated by minimizing the Chan–Vese energy (19). The walking person cannot be separated from the occlusion and darker areas of the background such as the person’s shadow

where the knowledge-driven component is given by

$$\frac{\partial E_{\text{shape}}}{\partial \phi} = \frac{\sum \alpha_i \frac{\partial}{\partial \phi} d^2(H\phi, H\phi_i)}{2\sigma^2 \sum \alpha_i}, \quad (32)$$

which simply induces a force in direction of each training shape ϕ_i weighted by the factor:

$$\alpha_i = \exp\left(-\frac{1}{2\sigma^2} d^2(H\phi, H\phi_i)\right), \quad (33)$$

which decays exponentially with the distance from the training shape ϕ_i .

Nonlinear Shape Priors for Tracking a Walking Person

In the following, we apply the above shape prior to the segmentation of a partially occluded walking person. To this end, a sequence of a walking figure was partially occluded by an artificial bar. Subsequently we minimized energy (19), segmenting each frame of the sequence using the previous segmentation as initialization. Figure 12 shows that this purely image-driven segmentation scheme is not capable of separating the object of interest from the occluding bar and similarly shaded background regions such as the object’s shadow on the floor.

In a second experiment, we manually binarized the images corresponding to the first half of the original sequence (frames 1 through 42) and aligned them to their

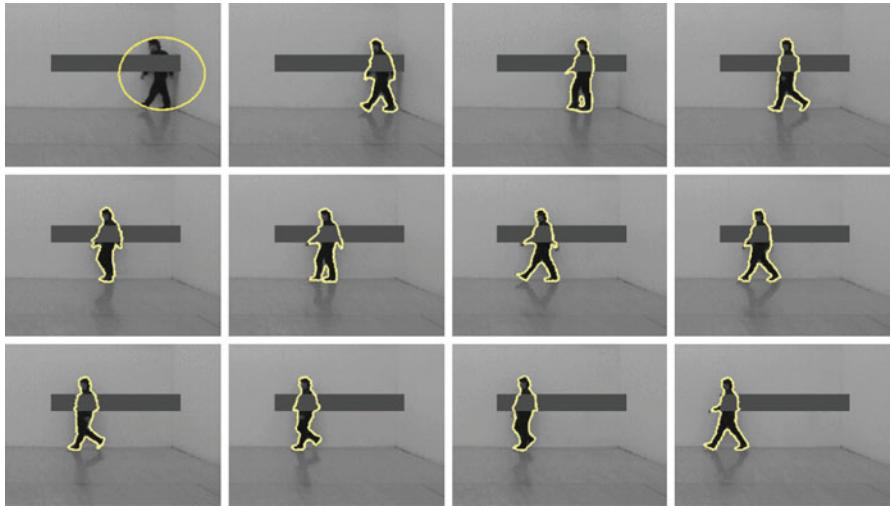

Fig. 13 Segmentation with nonparametric invariant shape prior. Segmentation generated by minimizing energy (29) combining intensity information with the shape prior (26). For every frame in the sequence, the gradient descent equation was iterated (with fixed parameters), using the previous segmentation as initialization. The shape prior permits to separate the walking person from the occlusion and darker areas of the background such as the shadow. The shapes in the second half of the sequence were not part of the training set

respective center of gravity to obtain a set of training shape – see Fig. 11. Then we ran the segmentation process (31) with the shape prior (26). Apart from adding the shape prior, we kept the other parameters constant for comparability.

Figure 13 shows several frames from this knowledge-driven segmentation. A comparison to the corresponding frames in Fig. 12 demonstrates several properties:

- The shape prior permits to accurately reconstruct an entire set of fairly different shapes. Since the shape prior is defined on the level set function ϕ – rather than on the boundary C (cf. [17]) – it can easily handle changing topology.
- The shape prior is invariant to translation such that the object silhouette can be reconstructed in arbitrary locations of the image.
- The statistical nature of the prior allows to also reconstruct silhouettes which were not part of the training set – corresponding to the second half of the images shown (beyond frame 42).

5 Dynamical Shape Priors for Implicit Shapes

Capturing the Temporal Evolution of Shape

In the above works, statistically learned shape information was shown to cope for missing or misleading information in the input images due to noise, clutter, and

occlusion. The shape priors were developed to segment objects of familiar shape in a given image. Although they can be applied to tracking objects in image sequences, they are not well-suited for this task, because they neglect the *temporal coherence of silhouettes* which characterizes many deforming shapes.

When tracking a deformable object over time, clearly not all shapes are equally likely at a given time instance. Regularly sampled images of a walking person, for example, exhibit a typical pattern of consecutive silhouettes. Similarly, the projections of a rigid 3D object rotating at constant speed are generally not independent samples from a statistical shape distribution. Instead, the resulting set of silhouettes can be expected to contain strong temporal correlations.

In the following, we will present temporal statistical shape models for implicitly represented shapes that were first introduced in [26]. In particular, the shape probability at a given time depends on the shapes observed at previous time steps. The integration of such dynamical shape models into the segmentation process can be elegantly formulated within a Bayesian framework for level set based image sequence segmentation. The resulting optimization by gradient descent induces an evolution of the level set function which is driven both by the intensity information of the current image as well as by a dynamical shape prior which relies on the segmentations obtained on the preceding frames. Experimental evaluation demonstrates that the resulting segmentations are not only similar to previously learned shapes, but they are also consistent with the temporal correlations estimated from sample sequences. The resulting segmentation process can cope with large amounts of noise and occlusion because it exploits prior knowledge about *temporal shape consistency* and because it aggregates information from the input images over time (rather than treating each image independently).

Level Set-Based Tracking via Bayesian Inference

Statistical models can be estimated more reliably if the dimensionality of the model and the data are low. We will therefore cast the Bayesian inference in a low-dimensional formulation within the subspace spanned by the largest principal eigenmodes of a set of sample shapes. We exploit the training sequence in a twofold way: Firstly, it serves to define a low-dimensional subspace in which to perform estimation. And secondly, within this subspace we use it to learn dynamical models for implicit shapes. For static shape priors this concept was already used in [82].

Let $\{\phi_1, \dots, \phi_N\}$ be a temporal sequence of training shapes. (We assume that all training shapes ϕ_i are signed distance functions. Yet an arbitrary linear combination of eigenmodes will in general not generate a signed distance function. While the discussed statistical shape models favor shapes which are close to the training shapes (and therefore close to the set of signed distance functions), not all shapes sampled in the considered subspace will correspond to signed distance functions.) Let ϕ_0 denote the mean shape and ψ_1, \dots, ψ_n the n largest eigenmodes with $n \ll N$. We will then approximate each training shape as

$$\phi_i(x) = \phi_0(x) + \sum_{j=1}^n \alpha_{ij} \psi_j(x), \quad (34)$$

where

$$\alpha_{ij} = \langle \phi_i - \phi_0, \psi_j \rangle \equiv \int (\phi_i - \phi_0) \psi_j dx. \quad (35)$$

Such PCA-based representations of level set functions have been successfully applied for the construction of statistical shape priors in [62, 82, 84, 100]. In the following, we will denote the vector of the first n eigenmodes as $\psi = (\psi_1, \dots, \psi_n)$. Each sample shape ϕ_i is therefore approximated by the n -dimensional shape vector $\alpha_i = (\alpha_{i1}, \dots, \alpha_{in})$. Similarly, an arbitrary shape ϕ can be approximated by a shape vector of the form

$$\alpha_\phi = \langle \phi - \phi_0, \psi \rangle. \quad (36)$$

In addition to the deformation parameters α , we introduce transformation parameters θ , and we introduce the notation:

$$\phi_{\alpha, \theta}(x) = \phi_0(T_\theta x) + \alpha^\top \psi(T_\theta x), \quad (37)$$

to denote the embedding function of a shape generated with deformation parameters α and transformed with parameters θ . The transformations T_θ can be translation, rotation, and scaling (depending on the application).

With this notation, the goal of image sequence segmentation within this subspace can be stated as follows: Given consecutive images $I_t : \Omega \rightarrow \mathbb{R}$ from an image sequence and given the segmentations $\hat{\alpha}_{1:t-1}$ and transformations $\hat{\theta}_{1:t-1}$ obtained on the previous images $I_{1:t-1}$, compute the most likely deformation $\hat{\alpha}_t$ and transformation $\hat{\theta}_t$ by maximizing the conditional probability:

$$\mathcal{P}(\alpha_t, \theta_t | I_t, \hat{\alpha}_{1:t-1}, \hat{\theta}_{1:t-1}) = \frac{\mathcal{P}(I_t | \alpha_t, \theta_t) \mathcal{P}(\alpha_t, \theta_t | \hat{\alpha}_{1:t-1}, \hat{\theta}_{1:t-1})}{\mathcal{P}(I_t | \hat{\alpha}_{1:t-1}, \hat{\theta}_{1:t-1})}. \quad (38)$$

The key challenge, addressed in the following, is to model the conditional probability:

$$\mathcal{P}(\alpha_t, \theta_t | \hat{\alpha}_{1:t-1}, \hat{\theta}_{1:t-1}), \quad (39)$$

which constitutes the probability for observing a particular shape α_t and a particular transformation θ_t at time t , conditioned on the parameter estimates for shape and transformation obtained on previous images.

Linear Dynamical Models for Implicit Shapes

For realistic deformable objects, one can expect the deformation parameters α_t and the transformation parameters θ_t to be tightly coupled. Yet, we want to learn dynamical shape models which are invariant to the absolute translation, rotation, etc. To this end, we can make use of the fact that the transformations form a group which implies that the transformation θ_t at time t can be obtained from the previous transformation θ_{t-1} by applying an incremental transformation $\Delta\theta_t$: $T_{\theta_t}x = T_{\Delta\theta_t}T_{\theta_{t-1}}x$. Instead of learning models of the absolute transformation θ_t , we can simply learn models of the update transformations $\Delta\theta_t$ (e.g., the changes in translation and rotation). By construction, such models are invariant with respect to the global pose or location of the modeled shape.

To jointly model transformation and deformation, we simply obtain for each training shape in the learning sequence the deformation parameters α_i and the transformation changes $\Delta\theta_i$ and define the *extended shape vector*:

$$\beta_t := \begin{pmatrix} \alpha_t \\ \Delta\theta_t \end{pmatrix}. \quad (40)$$

We will then impose a linear dynamical model of order k to approximate the temporal evolution of the extended shape vector:

$$\mathcal{P}(\beta_t | \hat{\beta}_{1:t-1}) \propto \exp\left(-\frac{1}{2} v^\top \Sigma^{-1} v\right), \quad (41)$$

where

$$v \equiv \beta_t - \mu - A_1 \hat{\beta}_{t-1} - A_2 \hat{\beta}_{t-2} \dots - A_k \hat{\beta}_{t-k}. \quad (42)$$

Various methods have been proposed in the literature to estimate the model parameters given by the mean μ and the transition and noise matrices A_1, \dots, A_k, Σ . We applied a stepwise least squares algorithm proposed in [71]. Using dynamical models up to an order of 8, we found that according to Schwarz's Bayesian criterion [92], our training sequences were best approximated by an autoregressive model of second order ($k = 2$).

Figure 14 shows a sequence of statistically synthesized embedding functions and the induced contours given by the zero level line of the respective surfaces – for easier visualization, the transformational degrees are neglected. In particular, the implicit representation allows to synthesize shapes of varying topology. The silhouette on the bottom left of Fig. 14, for example, consists of two contours.

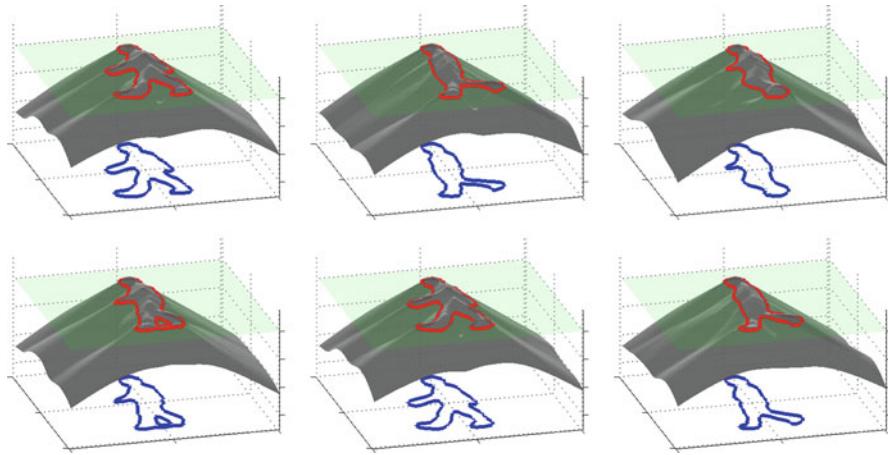

Fig. 14 Synthesis of implicit dynamical shapes. Statistically generated embedding surfaces obtained by sampling from a second-order autoregressive model and the contours given by the zero level lines of the synthesized surfaces. The implicit representation allows the embedded contour to change topology (*bottom left image*)

Variational Segmentation with Dynamical Shape Priors

Given an image I_t from an image sequence and given a set of previously segmented shapes with shape parameters $\hat{\alpha}_{1:t-1}$ and transformation parameters $\hat{\theta}_{1:t-1}$, the goal of tracking is to maximize the conditional probability (38) with respect to shape α_t and transformation θ_t . This can be performed by minimizing its negative logarithm, which is – up to a constant – given by an energy of the form

$$E(\alpha_t, \theta_t) = E_{\text{data}}(\alpha_t, \theta_t) + E_{\text{shape}}(\alpha_t, \theta_t). \quad (43)$$

For the data term we use the model in (3) with independent intensity variances:

$$E_{\text{data}}(\alpha_t, \theta_t) = \int \left(\frac{(I_t - \mu_1)^2}{2\sigma_1^2} + \log \sigma_1 \right) H\phi_{\alpha_t, \theta_t} + \left(\frac{(I_t - \mu_2)^2}{2\sigma_2^2} + \log \sigma_2 \right) (1 - H\phi_{\alpha_t, \theta_t}) dx. \quad (44)$$

Using the autoregressive model (41), the shape energy is given by

$$E_{\text{shape}}(\alpha_t, \theta_t) = \frac{1}{2} \mathbf{v}^\top \Sigma^{-1} \mathbf{v}, \quad (45)$$

with \mathbf{v} defined in (42).

The total energy (43) is easily minimized by gradient descent. For details we refer to [26].

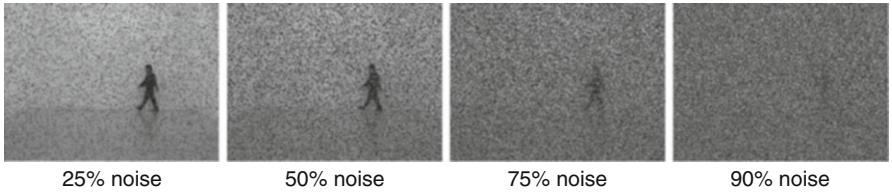

Fig. 15 Images from a sequence with increasing amount of noise

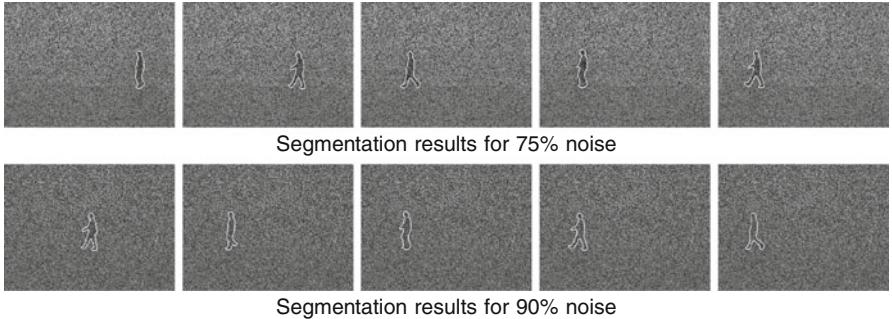

Fig. 16 Variational image sequence segmentation with a dynamical shape prior for various amounts of noise. Ninety percent noise means that nine out of ten intensity values were replaced by a random intensity from a uniform distribution. The statistically learned dynamical model allows for reliable segmentation results despite prominent amounts of noise

Fig. 17 Tracking in the presence of occlusion. The dynamical shape prior allows to reliably segment the walking person despite noise and occlusion

Figure 15 shows images from a sequence that was degraded by increasing amounts of noise.

Figure 16 shows segmentation results obtained by minimizing (43) as presented above. Despite prominent amounts of noise, the segmentation process provides reliable segmentations where human observers fail.

Figure 17 shows the segmentation of an image sequence showing a walking person that was corrupted by noise and an occlusion which completely covers the walking person for several frames. The dynamical shape prior allows for reliable segmentations despite noise and occlusion. For more details and quantitative evaluations, we refer to [26].

6 Parametric Representations Revisited: Combinatorial Solutions for Segmentation with Shape Priors

In previous sections we saw that shape priors allow to improve the segmentation and tracking of familiar deformable objects, biasing the segmentation process to favor familiar shapes or even familiar shape evolution. Unfortunately, these approaches are based on locally minimizing respective energies via gradient descent. Since these energies are generally non-convex, respective solutions are bound to be locally optimal only. As a consequence, they depend on an initialization and are likely to be suboptimal in practice. One exception based on implicit shape representations as binary indicator functions and convex relaxation techniques was proposed in [31]. Yet, the linear interpolation of shapes represented by binary indicator functions does not give rise to plausible intermediate shapes such that respective algorithms require a large number of training shapes.

Moreover, while implicit representations like the level set method circumvent the problem of computing correspondences between points on either of two shapes, it is well-known that the aspect of point correspondences plays a vital role in human notions of shape similarity. For matching planar shapes there is abundant literature on how to solve the arising correspondence problem in polynomial time using dynamic programming techniques [48, 85, 93].

Similar concepts of dynamic programming can be employed to localize deformed template curves in images. Coughlan et al. [23] detected open boundaries by shortest-path algorithms in higher-dimensional graphs. And Felzenszwalb et al. used dynamic programming in chordal graphs to localize shapes, albeit not on a pixel level.

Polynomial-time solutions for localizing deformable closed template curves in images using minimum ratio cycles or shortest circular paths were proposed in [89], with a further generalization presented in [88]. There the problem of determining a segmentation of an image $I : \Omega \rightarrow \mathbb{R}$ that is elastically similar to an observed template $cc : \mathbb{S}^1 \rightarrow \mathbb{R}^2$ by computing minimum ratio cycles

$$\Gamma : \mathbb{S}^1 \rightarrow \Omega \times \mathbb{S}^1 \quad (46)$$

in the product space spanned by the image domain Ω and template domain \mathbb{S}^1 . See Fig. 18 for a schematic visualization. All points along this circular path provide a pair of corresponding template point and image pixel. In this manner, the matching of template points to image pixels is equivalent to the estimation of orientation-preserving cyclic paths, which can be solved in polynomial time using dynamic programming techniques such as ratio cycles [86] or shortest circular paths [91].

Figure 19 shows an example result obtained with this approach: The algorithm determines a deformed version (right) of a template curve (left) in an image (center) in globally optimal manner. An initialization is no longer required and the best conceivable solution is determined in polynomial time.

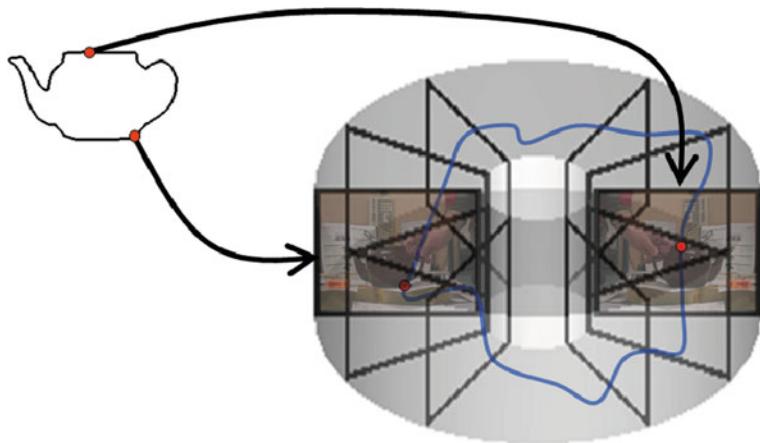

Fig. 18 A polynomial-time solution for matching shapes to images: matching a template curve $C : \mathbb{S}^1 \rightarrow \mathbb{R}^2$ (left) to the image plane $\Omega \subset \mathbb{R}^2$ is equivalent to computing an orientation-preserving cyclic path $\Gamma : \mathbb{S}^1 \rightarrow \Omega \times \mathbb{S}^1$ (blue curve) in the product space spanned by the image domain and the template domain. The latter problem can be solved in polynomial time – see [89] for details

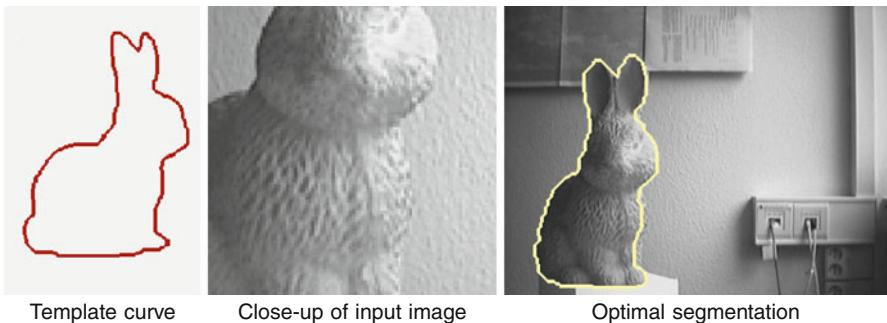

Fig. 19 Segmentation with a single template: despite significant deformation and translation, the initial template curve (red) is accurately matched to the low-contrast input image. The globally optimal correspondence between template points and image pixels is computed in polynomial time by dynamic programming techniques [89]

Figure 20 shows further examples of tracking objects: over long sequences of hundreds of frames, the objects of interest are tracked reliably – despite low contrast, camera shake, bad visibility, and illumination changes. For further details we refer to [89].

7 Conclusion

In the previous sections, we have discussed various ways to impose statistical shape priors into image segmentation methods. We have made several observations:

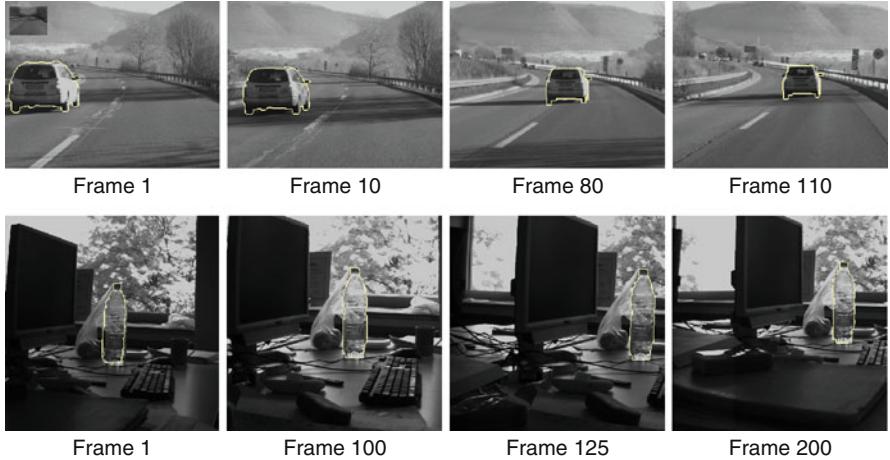

Fig. 20 Tracking of various objects in challenging real-world sequences [89]. Despite bad visibility, camera shake, and substantial lighting changes, the polynomial-time algorithm allows to reliably track objects over hundreds of frames (Image data taken from [89])

- By imposing statistically learned shape information, one can generate segmentation processes which favor the emergence of familiar shapes – where familiarity is based on one or several training shapes.
- Statistical shape information can be elegantly combined with the input image data in the framework of Bayesian maximum a posteriori estimation. Maximizing the posterior distribution is equivalent to minimizing a sum of two energies representing the data term and the shape prior. A further generalization allows to impose dynamical shape priors so as to favor familiar deformations of shape in image sequence segmentation.
- While linear Gaussian shape priors are quite popular, the silhouettes of typical objects in our environment are generally not Gaussian distributed. In contrast to linear Gaussian priors, nonlinear statistical shape priors based on Parzen–Rosenblatt kernel density estimators or based on Gaussian distributions in appropriate feature spaces [28] allow to encode a large variety of rather distinct shapes in a single shape energy.
- Shapes can be represented explicitly (as points on the object’s boundary or surface) or implicitly (as the indicator function of the interior of the object). They can be represented in a spatially discrete or a spatially continuous setting.
- The choice of shape representation has important consequences regarding the question which optimization algorithms are employed and whether respective energies can be minimized locally or globally. Moreover, different shape representations give rise to different notions of shape similarity and shape interpolation. As a result, there is no single ideal representation of shape. Ultimately one may favor hybrid representations such as the one proposed in [90]. It combines explicit and implicit representations allowing cost functions which

represent properties of both the object's interior and its boundary. Subsequent LP relaxation provides minimizers of bounded optimality.

Abstract

Motions of physical objects relative to a camera as observer naturally occur in everyday lives and in many scientific applications. Optical flow represents the corresponding motion induced on the image plane. This paper describes the basic problems and concepts related to optical flow estimation together with mathematical models and computational approaches to solve them. Emphasis is placed on common and different modeling aspects and to relevant research directions from a broader perspective. The state of the art and corresponding deficiencies are reported along with directions of future research. The presentation aims at providing an accessible guide for practitioners as well as stimulating research work in relevant fields of mathematics and computer vision.

1 Introduction

Motivation, Overview

Motion of image data belongs to the crucial features that enable low-level image analysis in natural vision systems and in machine vision systems and the analysis of a major part of stored image data in the format of videos, as documented, for instance, by the fast increasing download rate of YouTube. Accordingly, *image motion analysis* has played a key role from the beginning of research in mathematical and computational approaches to image analysis.

Figure 1 illustrates few application areas of image processing, among many others, where image motion analysis is deeply involved. Mathematical models for analyzing such image sequences boil down to models of a specific instance of the general data analysis task, that is, to fuse prior knowledge with information given by observed image data. While adequate prior knowledge essentially depends on the application area as Fig. 1 indicates, the processing of observed data mainly involves basic principles that apply to *any* image sequence. Correspondingly, the notion of *optical flow*, informally defined as *determining the apparent instantaneous velocity of image structure*, emphasizes the application-independent aspects of this basic image analysis task.

Due to this independency, optical flow algorithms provide a key component for numerous approaches to *applications across different fields*. Major examples include motion compensation for video compression, structure from motion to estimate 3-D scene layouts from image sequences, visual odometry, and incremental construction of mappings of the environment by autonomous systems, estimating vascular wall shear stress from blood flow image sequences for biomedical diagnosis, to name just a few.

This chapter aims at providing a concise and up-to-date account of mathematical models of optical flow estimation. Basic principles are presented along with various

Fig. 1 Some application areas of image processing that essentially rely on image motion analysis. *Left:* scene analysis (depth, independently moving objects) with a camera mounted in a car. *Center:* flow analysis in remote sensing. *Right:* measuring turbulent flows by particle image velocimetry

prior models. Application-specific aspects are only taken into account at a general level of mathematical modeling (e.g., geometric or physical prior knowledge). Model properties favoring a particular direction of modeling are highlighted, while keeping an eye on common aspects and open problems. Conforming to the editor's guidelines, references to the literature are confined to a – subjectively defined – essential minimum.

Organization

Section 2 introduces a dichotomy of models used to present both essential differences and common aspects. These classes of models are presented in Sects. 3 and 4. The former class comprises those algorithms that perform best on current benchmark datasets. The latter class becomes increasingly more important in connection with motion analysis of novel, challenging classes of image sequences and videos. While both classes merely provide different viewpoints on the same subject – optical flow estimation and image motion analysis – distinguishing them facilitates the presentation of various facets of relevant mathematical models in current research. Further relationships, unifying aspects together with some major open problems and research directions, are addressed in Sect. 5.

2 Basic Aspects

Invariance, Correspondence Problem

Image motion computation amounts to define some notion of *invariance* and the recognition in subsequent time frames of *corresponding objects*, defined by local prominent image structure in terms of a feature mapping $g(x)$ whose values are assumed to be conserved during motion. As Fig. 2, left panel, illustrates, invariance only holds approximately due to the imaging process and changes of viewpoint and

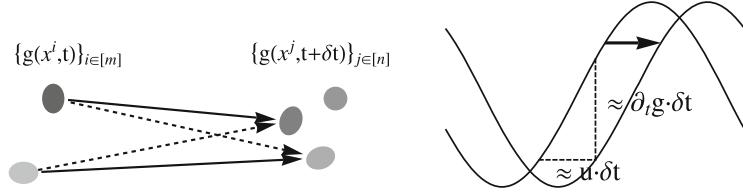

Fig. 2 *Left:* image motion can only be computed by recognizing objects as the same in subsequent time frames, based on some notion of equivalence (invariance) and some distance function. In low-level vision, “object” means some prominent local image structure in terms a feature mapping $g(x, t) \in \mathbb{R}^p$, $p \geq 1$. The correspondence problem amounts to compute a corresponding assignment $\{g(x^i, t)\}_{i \in [m]} \rightarrow \{g(x^j, t + \delta t)\}_{j \in [n]}$. The corresponding objective defines the data term of a variational approach. *Right:* differential approaches to image motion computation are based on smooth feature mappings $g(x, t)$ and aim at solving the assignment problem $g(x(t), t) \rightarrow g(x(t + \delta t), t + \delta t)$. The figure illustrates the basic case of a scalar-valued signal $g(x, t)$ translating with constant speed u and the estimate (14) based on the differential motion approach, as discussed in section “Assignment Approach, Differential Motion Approach”

illumination. Consequently, some *distance function*

$$\rho(g(x^j, t + \delta t) - g(x^i, t)) \quad (1)$$

has to be used in order to compute an *optimal assignment*

$$\{g(x^i, t)\}_{i \in [m]} \rightarrow \{g(x^j, t + \delta t)\}_{j \in [n]}. \quad (2)$$

A vast literature exists on definitions of feature mappings $g(x, t)$, distance functions, and their empirical evaluation in connection with image motion. Possible definitions include

- Image gray value or color,
- Gray value or color gradient,
- Output of analytic band-pass filters (e.g., [1, 2]),
- More complex feature descriptors including SIFT [3] and SURF [4],
- Censor voting, [5], local patches or feature groupings,

together with a corresponding invariance assumption, i.e., that $g(x, t)$ is conserved during motion (cf. Fig. 2, left panel). Figure 3 illustrates the most basic approaches used in the literature. Recent examples adopting a more geometric viewpoint on feature descriptors and studying statistical principles of patch similarity include [6, 7].

For further reference, some basic distance functions $\rho: \mathbb{R}^p \rightarrow \mathbb{R}_+$ are introduced below that are commonly applied in connection with feature mappings $g(x)$ and partly parametrized by $\lambda > 0$ and $0 < \varepsilon \ll 1$. For closely related functions and the nomenclature in computer vision, see, e.g., [8].

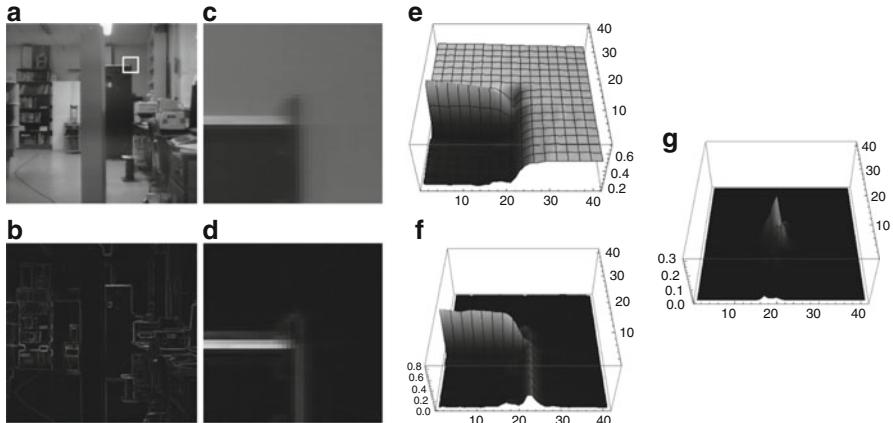

Fig. 3 (a) Lab scene (\circledcirc CMU image database) and (b) gradient magnitude that provides the basis for a range of feature mappings $g(x, t)$. The image section indicated in (a) is shown in (c), and (d) shows the same section extracted from (b). Panels (e) and (f) illustrate these sections as surface plots. Panel (g) shows a feature map responding to crossing gray-value edges. (c), (d), and (g) correspond to the most basic examples of feature mappings $g(x, t)$ used in the literature to compute image motion, based on a corresponding invariance assumption (cf. Fig. 2, left panel) that is plausible for video frame rates

$$\rho_2^2(z) := \|z\|^2 \quad \text{squared } \ell^2 \text{ distance,} \quad (3a)$$

$$\rho_2(z) := \|z\| \quad \ell^2 \text{ distance,} \quad (3b)$$

$$\rho_{2,\varepsilon}(z) := \sqrt{\|z\|^2 + \varepsilon^2} - \varepsilon \quad \text{smoothed } \ell^2 \text{ distance,} \quad (3c)$$

$$\rho_1(z) := \|z\|_1 \quad \ell^1 \text{ distance,} \quad (3d)$$

$$\rho_{1,\varepsilon}(z) := \sum_{i \in [p]} \rho_{2,\varepsilon}(z_i) \quad \text{smoothed } \ell^1 \text{ distance,} \quad (3e)$$

$$\rho_{2,\lambda}(z) := \min\{\|z\|^2, \lambda^2\} \quad \text{truncated squared } \ell^2 \text{ distance,} \quad (3f)$$

$$\rho_{2,\lambda,\varepsilon}(z) := -\varepsilon \log \left(e^{-\|z\|^2/\varepsilon} + e^{-\lambda^2/\varepsilon} \right) \quad \text{smoothed tr. sq. } \ell^2 \text{ distance.} \quad (3g)$$

Figure 4 illustrates these convex and non-convex distance functions. Functions $\rho_{1,\varepsilon}$ and $\rho_{2,\varepsilon}$ constitute specific instances of the general smoothing principle to replace a lower semicontinuous, positively homogeneous, and sublinear function $\rho(z)$ by a smooth proper convex function $\rho_\varepsilon(z)$, with $\lim_{\varepsilon \searrow 0} \rho_\varepsilon(z/\varepsilon) = \rho(z)$ (cf., e.g., [9]). Function $\rho_{2,\lambda,\varepsilon}(z)$ utilizes the log-exponential function [10, Ex. 1.30] to uniformly approximate $\rho_{2,\lambda}$ as $\varepsilon \searrow 0$.

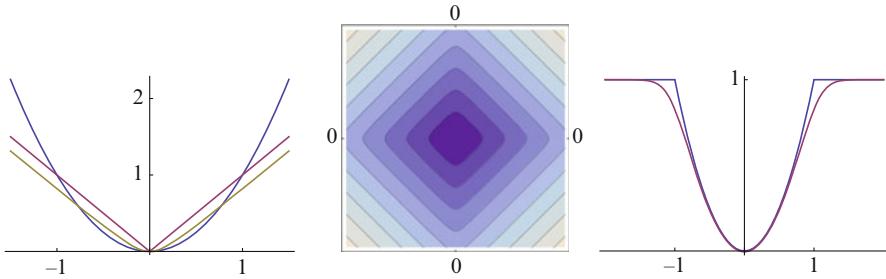

Fig. 4 Left: convex distance functions (3a)–(3c). Center: level lines of the distance function $\rho_{1,\varepsilon}$ (3e). Right: non-convex distance functions (3f) and (3g)

Assignment Approach, Differential Motion Approach

Definitions

Two basic approaches to image motion computation can be distinguished.

Assignment Approach, Assignment Field This approach aims to determine an *assignment* of finite sets of spatially discrete features in subsequent frames of a given image sequence (Fig. 2, left panel). The vector field

$$u(x, t), \quad x^j = x^i + u(x^i, t), \quad (4)$$

representing the assignment in Eq. (2), is called *assignment field*. This approach conforms to the basic fact that image sequences $f(x, t)$, $(x, t) \in \Omega \times [0, T]$ are recorded by *sampling* frames

$$\{f(x, k \cdot \delta t)\}_{k \in \mathbb{N}} \quad (5)$$

along the time axis.

Assignment approaches to image motion will be considered in Sect. 4.

Differential Motion Approach, Optical Flow Starting point of this approach is the *invariance assumption* (section “Invariance, Correspondence Problem”) that observed values of some feature map $g(x, t)$ are conserved during motion,

$$\frac{d}{dt} g(x(t), t) = 0. \quad (6)$$

Evaluating this condition yields information about the trajectory $x(t)$ that represents the motion path of a particular feature value $g(x(t))$. The corresponding vector field

$$\dot{x}(t) = \frac{d}{dt} x(t), \quad x \in \Omega \quad (7)$$

is called *motion field* whose geometric origin will be described in section “Two-View Geometry, Assignment and Motion Fields.” *Estimates*

$$u(x, t) \approx \dot{x}(t), \quad x \in \Omega \quad (8)$$

of the motion field based on some observed time-dependent feature map $g(x, t)$ are called *optical flow fields*.

Differential motion approaches will be considered in Sect. 3.

Common Aspects and Differences

The assignment approach and the differential approach to image motion are closely related. In fact, for small temporal sampling intervals,

$$0 < \delta t \ll 1, \quad (9)$$

one may expect that the optical flow field multiplied by δt , $u(x, t) \cdot \delta t$, closely approximates the corresponding assignment field. The *same* symbol u is therefore used in (4) and (8) to denote the respective vector fields.

A conceptual difference between both approaches is that the ansatz (6) entails the assumption of a spatially differentiable feature mapping $g(x, t)$, whereas the assignment approach requires prior decisions done at a preprocessing stage that localize the feature sets (2) to be assigned. The need for additional processing in the latter case contrasts with the limited applicability of the differential approach: *The highest spatial frequency limits the speed of image motion $\|u\|$ that can be estimated reliably*:

$$\max \{ \|\omega_x\|_\infty, \|u(x)\| \|\omega_x\| : \omega_x \in \text{supp} \hat{g}(\omega), x \in \Omega \} \leq \frac{\pi}{6}. \quad (10)$$

The subsequent section details this bound in the most simple setting for a specific but common filter choice for estimating partial derivatives $\partial_i g$.

Differential Motion Estimation: Case Study (1D)

Consider a scalar signal $g(x, t) = f(x, t)$ moving at constant speed (cf. Fig. 2, right panel),

$$\dot{x}(t) = \dot{x} = u, \quad g(x(t), t) = g(x(0) + ut, t). \quad (11)$$

Note that the two-dimensional function $g(x, t)$ is a very special one generated by motion. Using the shorthands

$$x := x(0), \quad g_0(x) := g(x, 0), \quad (12)$$

$g(x, t)$ corresponds to the translated one-dimensional signal

$$g(x, t) = g_0(x - ut) \quad (13)$$

due to the assumption $g(x(t), t) = g(x(0), 0) = g_0(x)$.

Evaluating (6) at $t = 0$, $x = x(0)$ yields

$$u = -\frac{\partial_t g_0(x)}{\partial_x g_0(x)} \quad \text{if } \partial_x g_0(x) \neq 0. \quad (14)$$

Application and validity of this equation in practice depends on two further aspects: Only sampled values of $g(x, t)$ are given, and the right-hand side has to be computed numerically. Both aspects are discussed next in turn.

1. In practice, samples are observed

$$\{g(k \cdot \delta x, t \delta t)\}_{k,t \in \mathbb{N}} = \{g(k, t)\}_{k,t \in \mathbb{N}}, \quad \delta x = \delta t = 1, \quad (15)$$

with the sampling interval scaled to 1 without loss of generality. The Nyquist-Shannon sampling theorem imposes the constraint

$$\text{supp}|\hat{g}(\omega)| \subset [0, \pi]^2, \quad \omega = (\omega_x, \omega_t)^\top \quad (16)$$

where

$$\hat{g}(\omega) = \mathcal{F}g(\omega) = \int_{\mathbb{R}^2} g(x, t) e^{-i\langle \omega, (x, t) \rangle} dx dt \quad (17)$$

denotes the Fourier transform of $g(x, t)$. Trusting in the sensor, it may be safely assumed that $\text{supp}|\hat{g}_0(\omega_x)| \subset [0, \pi]$. But what about the second coordinate t generated by motion? Does it obey (16) such that the observed samples (15) truly represent the one-dimensional video signal $g(x, t)$?

To answer this question, consider the specific case $g_0(x) = \sin(\omega_x x)$, $\omega_x \in [0, \pi]$ – see Fig. 5. Equation (13) yields $g(x, t) = \sin(\omega_x(x - ut))$. Condition (15) then requires that, for every location x , the one-dimensional time signal $g_x(t) := g(x, t)$ satisfies $\text{supp}|\hat{g}_x(\omega_t)| \subset [0, \pi]$. Applying this to the example yields

$$g_x(t) = \sin(\omega_t t + \varphi_0), \quad \omega_t := -\omega_x u, \quad \varphi_0 := \omega_x x, \quad (18)$$

and hence the condition

$$|\omega_t| \in [0, \pi) \quad \Leftrightarrow \quad |u| < \frac{\pi}{\omega_x}. \quad (19)$$

It implies that Eq. (14) is only valid if, depending on the spatial frequency ω_x , the velocity u is sufficiently small.

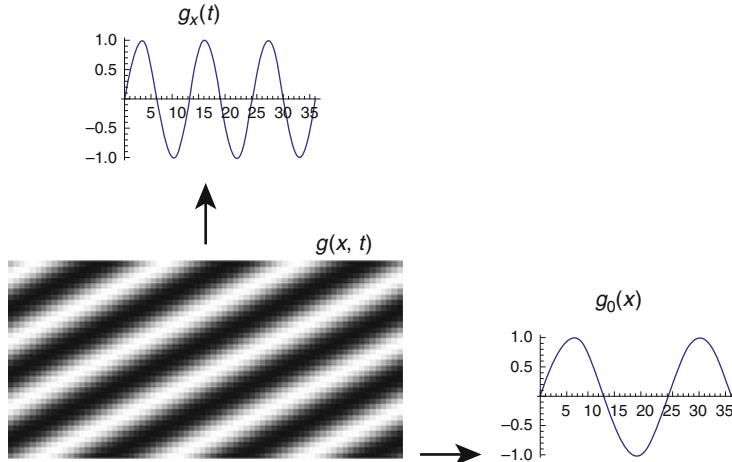

Fig. 5 A sinusoid $g_0(x)$ with angular frequency $\omega_x = \pi/12$, translating with velocity $u = 2$, generates the function $g(x, t)$. The angular frequency of the signal $g_x(t)$ observed at a fixed position x equals $|\omega_t| = u \cdot \omega_x = \pi/6$ due to (18). It meets the upper bound further discussed in connection with Fig. 6 that enables accurate numerical computation of the partial derivatives of $g(x, t)$

This reasoning and the conclusion apply to general functions $g(x, t)$, $x \in \mathbb{R}^d$ in the form of (10), which additionally takes into account the effect of derivative estimation, discussed next.

2. Condition (19) has to be further restricted in practice, depending on how the partial derivatives of the r.h.s. of Eq. (14) are *numerically* computed using the observed samples (15). The Fourier transform

$$\mathcal{F}(\partial^\alpha g)(\omega) = i^{|\alpha|} \omega^\alpha \hat{g}(\omega), \quad \omega \in \mathbb{R}^{d+1} \quad (20)$$

generally shows that taking partial derivatives of order $|\alpha|$ of $g(x, t)$, $x \in \mathbb{R}^d$, corresponds to high-pass filtering that amplifies noise. If $g(x, t)$ is vector valued, then the present discussion applies to the computation of partial derivatives $\partial^\alpha g_i$ of any component $g_i(x, t)$, $i \in [p]$.

To limit the influence of noise, partial derivatives of the *low-pass filtered* feature mapping g are computed. This removes noise and smoothes the signal, and subsequent computation of partial derivatives becomes more accurate. Writing $g(x)$, $x \in \mathbb{R}^{d+1}$, instead of $g(x, t)$, $x \in \mathbb{R}^d$, to simplify the following formulas, low-pass filtering of g with the impulse response $h(x)$ means the convolution

$$g_h(x) := (h * g)(x) = \int_{\mathbb{R}^{d+1}} h(x - y) g(y) dy, \quad \hat{g}_h(\omega) = \hat{h}(\omega) \hat{g}(\omega) \quad (21)$$

whose Fourier transform corresponds to the multiplication of the respective Fourier transforms. Applying (20) yields

$$\mathcal{F}(\partial^\alpha g_h)(\omega) = i^{|\alpha|} \omega^\alpha (\hat{h}(\omega) \hat{g}(\omega)) = (i^{|\alpha|} \omega^\alpha \hat{h}(\omega)) \hat{g}(\omega). \quad (22)$$

Thus, computing the partial derivative of the filtered function g_h can be computed by convolving g with the partial derivative of the impulse response $\partial^\alpha h$. As a result, the approximation of the partial derivative of g reads

$$\partial^\alpha g(x) \approx \partial^\alpha g_h(x) = ((\partial^\alpha h) * g)(x). \quad (23)$$

The most common choice of h is the isotropic Gaussian low-pass filter

$$h_\sigma(x) := \frac{1}{(2\pi\sigma^2)^{d/2}} \exp\left(-\frac{\|x\|^2}{2\sigma^2}\right) = \prod_{i \in [d]} h_\sigma(x_i), \quad \sigma > 0 \quad (24)$$

that factorizes (called *separable filter*) and therefore can be implemented efficiently. The corresponding filters $\partial^\alpha h_\sigma(x)$, $|\alpha| \geq 1$ are called *Derivative-of-Gaussian (DoG) filters*.

To examine its effect, it suffices to consider any coordinate due to factorization, that is, the one-dimensional case. Figure 6 illustrates that values $\sigma \geq 1$ lead to filters that are sufficiently band limited so as to conform to the sampling theorem. The price to pay for effective noise suppression however is a more restricted range $\text{supp}[\mathcal{F}(g(x, t))] = [0, \omega_{x,\max}]$, $\omega_{x,\max} \ll \pi$ that observed image sequence functions have to satisfy, so as to enable accurate computation of partial derivatives and in turn accurate motion estimates based on the differential approach. Figure 5 further details and illustrates this crucial fact.

Assignment or Differential Approach?

For image sequence functions $g(x, t)$ satisfying the assumptions necessary to evaluate the key equation (6), the differential motion approach is more convenient. Accordingly, much work has been devoted to this line of research up to now. In particular, sophisticated multiscale representations of $g(x, t)$ enable to estimate larger velocities of image motion using smoothed feature mapping g (cf. section ‘‘Multiscale’’). As a consequence, differential approaches rank top at corresponding benchmark evaluations conforming to the underlying assumptions [11], and efficient implementations are feasible [12, 13].

On the other hand, the inherent limitations of the differential approach discussed above become increasingly more important in current applications, like optical flow computation for traffic scenes taken from a moving car at high speed. Figure 1, right panel, shows another challenging scenario where the spectral properties $\hat{g}(\omega_x, \omega_t)$ of the image sequence function and the velocity fields to be estimated render

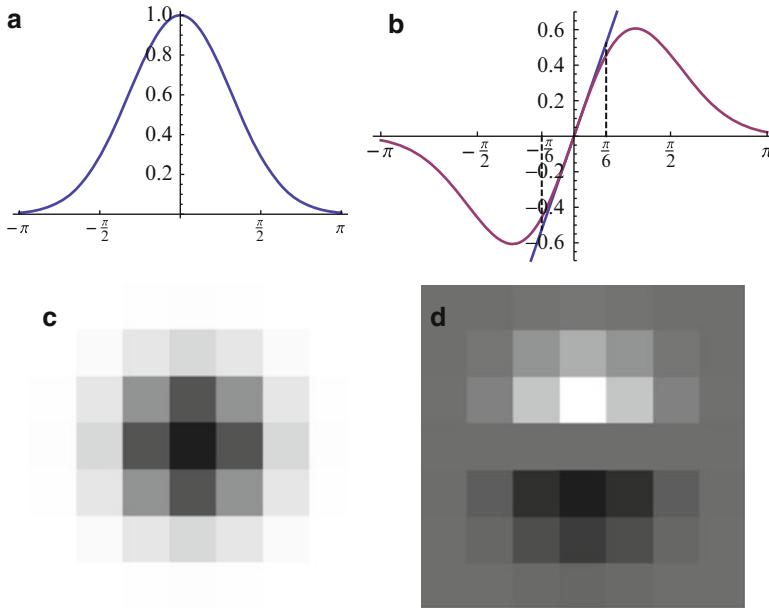

Fig. 6 (a) Fourier transform $\hat{h}_\sigma(\omega)$ of the Gaussian low pass (24), $\sigma = 1$. For values $\sigma \geq 1$, it satisfies the sampling condition $\text{supp}|\hat{h}_\sigma(\omega)| \subset [0, \pi]$ sufficiently accurate. (b) The Fourier transform of the *Derivative-of-Gaussian* (*DoG*) filter $\frac{d}{dx}h_\sigma(x)$ illustrates that for $|\omega| \leq \pi/6$ (partial) derivatives are accurately computed, while noise is suppressed at higher angular frequencies. (c), (d) The impulse responses $h_\sigma(x, t)$ and $\partial_t h_\sigma(x, t)$ up to size $|x|, |t| \leq 2$. Application of the latter filter together with $\partial_x h_\sigma(x, t)$ to the function $g(x, t)$ discussed in connection with Fig. 5 and evaluation of Eq. (14) yield the estimate $u = 2.02469$ at all locations (x, t) where $\partial_x g(x, t) \neq 0$

application of the differential approach difficult, if not impossible. In such cases, the assignment approach is the method of choice.

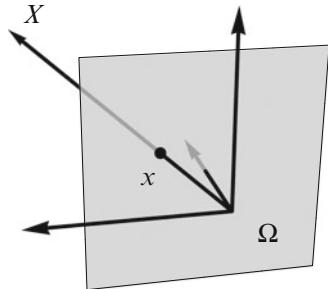

Combining both approaches in a complementary way seems most promising: Robust assignments enable to cope with fast image motions and a differential approach turns these estimates into spatially dense vector fields. This point is taken up in section “Unifying Aspects: Assignment by Optimal Transport.”

Basic Difficulties of Motion Estimation

This section concludes with a list of some basic aspects to be addressed by any approach to image motion computation:

- (i) Definition of a feature mapping g assumed to be conserved during motion (section “Invariance, Correspondence Problem”).
- (ii) Coping with lack of invariance of g , change of appearance due to varying viewpoint and illumination (sections “Handling Violation of the Constancy Assumption” and “Patch Features”).
- (iii) Spatial sparsity of distinctive features (section “Regularization”).

Fig. 7 The basic pinhole model of the mathematically ideal camera. Scene points X are mapped to image points x by perspective projection

- (iv) Coping with ambiguity of locally optimal feature matches (section “Assignment by Displacement Labeling”).
- (v) Occlusion and disocclusion of features.
- (vi) Consistent integration of available prior knowledge, regularization of motion field estimation (sections “Geometrical Prior Knowledge” and “Physical Prior Knowledge”).
- (vii) Runtime requirements (section “Algorithms”).

Two-View Geometry, Assignment and Motion Fields

This section collects few basic relationships related to the Euclidean motion of a perspective camera relative to a 3-D scene that induces both the assignment field and the motion field on the image plane, as defined in section “Definitions” by (4) and (7). Figures 7 and 12 illustrate these relationships. References [14, 15] provide comprehensive expositions.

It is pointed out once more that assignment and motion fields are purely *geometrical* concepts. The explicit expressions (43) and (53b) illustrate how discontinuities of these fields correspond to *discontinuities of depth* or to *motion boundaries* that separate regions in the image plane of scene objects (or the background) with different motions relative to the observing camera. Estimates of either field will be called *optical flow*, to be discussed in subsequent sections.

Two-View Geometry

Scene and corresponding image points are denoted by $X \in \mathbb{R}^3$ and $x \in \mathbb{R}^2$, respectively. Both are incident with the line λx , $\lambda \in \mathbb{R}$, through the origin. Such lines are points of the projective plane denoted by $y \in \mathbb{P}^2$. The components of y are called *homogeneous coordinates* of the image point x , whereas x and X are the *inhomogeneous coordinates* of image and scene points, respectively. Note that y stands for *any* representative point on the ray connecting x and X . In other words, when using homogeneous coordinates, scale factors do not matter. This equivalence is denoted by

$$y \simeq y' \Leftrightarrow y = \lambda y', \quad \lambda \neq 0. \quad (25)$$

Figure 7 depicts the mathematical model of a pinhole camera with the image plane located at $X_3 = 1$. Perspective projection corresponding to this model connects homogeneous and inhomogeneous coordinates by

$$x = \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \frac{1}{y_3} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix}. \quad (26)$$

A particular representative y with unknown depth $y_3 = X_3$ equals the scene point X . This reflects the fact that scale cannot be inferred from a single image. The 3-D space $\mathbb{R}^3 \setminus \{0\}$ corresponds to the affine chart $\{y \in \mathbb{P}^2 : y_3 \neq 0\}$ of the manifold \mathbb{P}^2 .

Similar to representing an image point x by homogeneous coordinates y , it is common to represent scene points $X \in \mathbb{R}^3$ by *homogeneous coordinates* $Y = (Y_1, Y_2, Y_3, Y_4)^\top \in \mathbb{P}^3$, in order to linearize transformations of 3-D space. The connection analogous to (26) is

$$X = \frac{1}{Y_4} \begin{pmatrix} Y_1 \\ Y_2 \\ Y_3 \end{pmatrix}. \quad (27)$$

Rigid (Euclidean) transformations are denoted by $\{h, R\} \in \text{SE}(3)$ with translation vector h and proper rotation matrix $R \in \text{SO}(3)$ characterized by $R^\top R = I$, $\det R = +1$. Application of the transformation to a scene point X and some representative Y reads

$$RX + h \quad \text{and} \quad QY, \quad Q := \begin{pmatrix} R & h \\ 0^\top & 1 \end{pmatrix}, \quad (28)$$

whereas the inverse transformation $\{-R^\top h, R^\top\}$ yields

$$R^\top(X - h) \quad \text{and} \quad Q^{-1}Y, \quad Q^{-1} = \begin{pmatrix} R^\top & -R^\top h \\ 0^\top & 1 \end{pmatrix}. \quad (29)$$

The nonlinear operation (26), entirely rewritten with homogeneous coordinates, takes the linear form

$$y = PY, \quad P = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix} = (I_{3 \times 3}, 0), \quad (30)$$

with the *projection matrix* P and *external or motion parameters* $\{h, R\}$. In practice, additional *internal parameters* characterizing real cameras to the first order of

approximation are taken into account in terms of a *camera matrix* K and the corresponding modification of (30),

$$y = PY, \quad P = K(I_{3 \times 3}, 0). \quad (31)$$

As a consequence, the transition to *normalized (calibrated)* coordinates

$$\tilde{y} := K^{-1}y \quad (32)$$

corresponds to an *affine* transformation of the image plane.

Given an image point x , taken with a camera in the canonical position (30), the corresponding ray meets the scene point X ; see Figure 12b. This ray projects in a second image, taken with a second camera positioned by $\{h, R\}$ relative to the first camera and with projection matrix

$$P' = K'R^\top(I, -h), \quad (33)$$

to the line l' , on which the projection x' of X *corresponding* to x must lie. Turning to homogeneous coordinates, an elementary computation shows that the *fundamental matrix*

$$F := K'^{-\top}R^\top[h]_x K^{-1} \quad (34)$$

maps y to the *epipolar line* l' ,

$$l' = Fy. \quad (35)$$

This relation is symmetrical in that F^\top maps y' to the corresponding epipolar line l in the first image,

$$l = F^\top y'. \quad (36)$$

The *epipoles* e, e' are the image points corresponding to the projection centers. Because they lie on l and l' for *any* x' and x , respectively, it follows that

$$Fe = 0, \quad F^\top e' = 0. \quad (37)$$

The incidence relation $x' \in l'$ algebraically reads $\langle l', y' \rangle = 0$. Hence by (35),

$$\langle y', Fy \rangle = 0 \quad (38)$$

This key relation constrains the correspondence problem $x \leftrightarrow x'$ for arbitrary two views of the same unknown scene point X . Rewriting (38) in terms of *normalized* coordinates by means of (32) yields

$$\langle y', Fy \rangle = \langle K'^{-1}y', K'^\top FK(K^{-1}y) \rangle = \langle K'^{-1}y', E(K^{-1}y) \rangle \quad (39)$$

with the *essential matrix* E that, due to (34) and the relation $[Kh]_\times \simeq K^{-\top}[h]_\times K^{-1}$, is given by

$$E = K'^\top FK = R^\top[h]_\times. \quad (40)$$

Thus, essential matrices are parametrized by transformations $\{h, R\} \in \text{SE}(3)$ and therefore form a smooth manifold embedded in $\mathbb{R}^{3 \times 3}$.

Assignment Fields

Throughout this section, the internal camera parameters K are assumed to be known, and hence normalized coordinates (32) are used. As a consequence,

$$K = I \quad (41)$$

is set in what follows.

Suppose some motion h, R of a camera relative to a 3-D scene causes the image point x of a fixed scene point X to move to x' in the image plane. The corresponding *assignment vector* $u(x)$ represents the *displacement* of x in the image plane,

$$x' = x + u(x), \quad (42)$$

which due to (29) and (26) is given by

$$u(x) = \frac{1}{\langle r^3, X - h \rangle} \begin{pmatrix} \langle r^1, X - h \rangle \\ \langle r^2, X - h \rangle \end{pmatrix} - \frac{1}{X_3} \begin{pmatrix} X_1 \\ X_2 \end{pmatrix}. \quad (43)$$

Consider the special case of pure translation, i.e., $R = I$, $r^i = e^i$, $i = 1, 2, 3$. Then

$$u(x) = \frac{1}{X_3 - h_3} \begin{pmatrix} X_1 - h_1 \\ X_2 - h_2 \end{pmatrix} - \frac{1}{X_3} \begin{pmatrix} X_1 \\ X_2 \end{pmatrix} \quad (44a)$$

$$= \frac{1}{\tilde{h}_3 - 1} \left(\begin{pmatrix} \tilde{h}_1 \\ \tilde{h}_2 \end{pmatrix} - \tilde{h}_3 \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \right), \quad \tilde{h} := \frac{1}{X_3}h. \quad (44b)$$

The image point x_e where the vector field u vanishes, $u(x_e) = 0$, is called *focus of expansion (FOE)*

$$x_e = \frac{1}{\tilde{h}_3} \begin{pmatrix} \tilde{h}_1 \\ \tilde{h}_2 \end{pmatrix}. \quad (45)$$

x_e corresponds to the epipole $y = e$ since $Fe \simeq R^\top[h]_\times h = 0$.

Next the transformation is computed of the image plane induced by the motion of the camera in terms of projection matrices $P = (I, 0)$ and $P' = R^\top(I, -h)$ relative to a plane in 3-D space

$$\langle n, X \rangle - d = n_1 X_1 + n_2 X_2 + n_3 X_3 - d = 0, \quad (46)$$

with unit normal n , $\|n\| = 1$ and with signed distance d of the plane from the origin 0. Setting $p = (\begin{smallmatrix} n \\ -d \end{smallmatrix})$, Eq. (46) reads

$$\langle p, Y \rangle = 0. \quad (47)$$

In order to compute the point X on the plane satisfying (46) that projects to the image point y , the ray $Y(\lambda) = (\begin{smallmatrix} \lambda y \\ 1 \end{smallmatrix})$, $\lambda \in \mathbb{R}$, is intersected with the plane.

$$\langle p, Y(\lambda) \rangle = \lambda \langle n, y \rangle - d = 0 \Rightarrow \lambda = \frac{d}{\langle n, y \rangle}, \quad Y = \begin{pmatrix} \frac{d}{\langle n, y \rangle} y \\ 1 \end{pmatrix} \simeq \begin{pmatrix} y \\ \frac{1}{d} \langle n, y \rangle \end{pmatrix}. \quad (48)$$

Projecting this point onto the second image plane yields

$$\begin{aligned} y' &= P' Y(\lambda) = R^\top \left(y - \frac{1}{d} \langle n, y \rangle h \right) = R^\top (I - \frac{1}{d} h n^\top) y \\ &=: Hy \end{aligned} \quad (49)$$

Thus, moving a camera relative to a 3-D plane induces a *homography* (projective transformation) H of \mathbb{P}^2 which by virtue of (26) yields an assignment field $u(x)$ with *rational* components.

Motion Fields

Motion fields (7) are the instantaneous (differential) version of assignment fields. Consider a smooth path $\{h(t), R(t)\} \subset \text{SE}(3)$ through the identity $\{0, I\}$ and the corresponding path of a scene point $X \in \mathbb{R}^3$

$$X(t) = h(t) + R(t)X, \quad X = X(0). \quad (50)$$

Let $R(t)$ be given by a rotational axis $q \in \mathbb{R}^3$ and a rotation angle $\varphi(t)$. Using Rodrigues' formula and the skew-symmetric matrix $[q]_\times \in \mathfrak{so}(3)$ with $\dot{\varphi} = \dot{\varphi}(0) := \|q\|$, matrix $R(t)$ takes the form

$$R(t) = \exp(t[q]_\times) = I + \frac{\sin(\dot{\varphi}t)}{\dot{\varphi}t} t[q]_\times + \frac{1 - \cos(\dot{\varphi}t)}{(\dot{\varphi}t)^2} t^2 [q]_\times^2. \quad (51)$$

Equation (50) then yields

$$\dot{X}(0) = v + [q]_\times X, \quad v := \dot{h}(0), \quad (52)$$

where v is the translational velocity at $t = 0$. Differentiating (26) with $y = X$ (recall assumption (41)) and inserting (52) give

$$\frac{d}{dt}x = \frac{1}{X_3^2} \begin{pmatrix} X_3\dot{X}_1 - X_1\dot{X}_3 \\ X_3\dot{X}_2 - X_2\dot{X}_3 \end{pmatrix} = \frac{1}{X_3} \begin{pmatrix} \dot{X}_1 - x_1\dot{X}_3 \\ \dot{X}_2 - x_2\dot{X}_3 \end{pmatrix} \quad (53a)$$

$$= \frac{1}{X_3} \left[\begin{pmatrix} v_1 \\ v_2 \end{pmatrix} - v_3 \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \right] + \begin{pmatrix} q_2 - q_3x_2 - q_1x_1x_2 + q_2x_1^2 \\ -q_1 + q_3x_1 + q_2x_1x_2 - q_1x_2^2 \end{pmatrix}. \quad (53b)$$

Comparing (53b) to (43) and (44b) shows a similar structure of the translational part with FOE

$$x_v := \frac{1}{v_3} \begin{pmatrix} v_1 \\ v_2 \end{pmatrix}, \quad (54)$$

whereas the rotational part merely contributes an incomplete second-order degree polynomial to each component of the motion field that does not depend on the scene structure in terms of the depth X_3 .

Consider the special case of a motion field induced by the relative motion of a camera to a 3-D plane given by (46) and write

$$\frac{1}{X_3} = \frac{1}{d} \left(n_3 + \begin{pmatrix} n_1 \\ n_2 \end{pmatrix}^\top \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \right). \quad (55)$$

Insertion into (53b) shows that the overall expression for the motion fields takes a simple polynomial form.

Early Pioneering Work

It deems proper to the authors to refer at least briefly to early pioneering work related to optical flow estimation, as part of a survey paper. The following references constitute just a small sample of the rich literature.

The information of motion fields, induced by the movement of an observer relative to a 3-D scene, was picked out as a central theme more than three decades ago [16, 17]. Kanatani [18] studied the representation of $\text{SO}(3)$ and invariants in connection with the space of motion fields induced by the movement relative to a 3-D plane. Approaches to estimating motion fields followed soon, by determining optical flow from local image structure [19–24]. Poggio and Verri [25] pointed out both the inexpedient, restrictive assumptions making the invariance assumption (6) hold in the simple case $g(x) = f(x)$ (e.g., Lambertian surfaces in the 3-D scene) and the stability of structural (topological) properties of motion fields (like, e.g., the FOE (45)). The local detection of image translation as orientation in spatiotemporal frequency space, based on the

energy and the phase of collections of orientation-selective complex-valued band-pass filters (low-pass filters shifted in Fourier space, like, e.g., Gabor filters), was addressed by [26–28], partially motivated by related research on natural vision systems.

The variational approach to optical flow was pioneered by Horn and Schunck [29], followed by various extensions [30–32] including more mathematically oriented accounts [33–35]. The work [36] classified various convex variational approaches that have unique minimizers.

The computation of discontinuous optical flow fields, in terms of piecewise parametric representations, was considered by [8, 37], whereas the work [38] studied the information contained in correspondences induced by motion fields over a longer time period. Shape-based optimal control of flows determined on discontinuous domains as control variable was introduced in [39], including the application of shape derivative calculus that became popular later on in connection with level sets. Markov random fields and the Bayesian viewpoint on the nonlocal inference of discontinuous optical flow fields were introduced in [40]. The challenging aspects of estimating both motion fields and their segmentation in a spatiotemporal framework, together with inferring the 3-D structure, have remained a topic of research until today.

This brief account shows that most of the important ideas appeared early in the literature. On the other hand, it took many years until first algorithms made their way into industrial applications. A lot of work remains to be done by addressing various basic and applied research aspects. In comparison to the fields of computer vision, computer science, and engineering, not much work has been done by the mathematical community on motion-based image sequence analysis.

Benchmarks

Starting with the first systematic evaluation in 1994 by Baron et al. [41], benchmarks for optical flow methods have stimulated and steered the development of new algorithms in this field. The *Middlebury database* [42] further accelerated this trend by introducing an online ranking system and defining challenging data sets, which specifically address different aspects of flow estimation such as large displacements or occlusion.

The recently introduced *KITTI Vision Benchmark Suite* [43] concentrates on *outdoor* automotive sequences that are affected by disturbances such as illumination changes and reflections, which optical flow approaches are expected to be robust against.

While real imagery requires sophisticated measurement equipment to capture reliable reference information, *synthetic* sequences such as the novel *MPI Sintel Flow Dataset* [44] come with free ground truth. However, enormous efforts are necessary to *realistically* model the scene complexity and effects found in reality.

3 The Variational Approach to Optical Flow Estimation

In contrast to assignment methods, variational approaches to estimating the optical flow employ a *continuous* and *dense* representation of the variables $u : \Omega \mapsto \mathbb{R}^2$. The model describing the agreement of u with the image data defines the *data term* $E_D(u)$. It is complemented by a *regularization term* $E_R(u)$ encoding prior knowledge about the *spatial smoothness* of the flow. Together these terms define the *energy function* $E(u)$, and estimating the optical flow amounts to finding a global minimum u , possibly constrained by a set U of admissible flow fields, and using an appropriate numerical method:

$$\inf_{u \in U} E(u), \quad E(u) := E_D(u) + E_R(u) \quad (56)$$

$E(u)$ is non-convex in general, and hence only suboptimal solutions can be determined in practice.

Based on the variational approach published in 1981 by Horn and Schunck [29], a vast number of refinements and extensions were proposed in literature. Recent comprehensive empirical evaluations [42, 43] reveal that algorithms of this family yield best performance. Section “The Approach of Horn and Schunck” introduces the approach of Horn and Schunck as reference for the following discussion, after deriving the required linearized invariance assumption in section “Differential Constraint Equations, Aperture Problem.”

Data and regularization terms designed to cope with various difficulties in real applications are presented in sections “Data Terms” and “Regularization,” respectively. Section “Algorithms” gives a short overview over numerical algorithms for solving problem (56). Section “Further Extensions” addresses some important extensions of the discussed framework.

Differential Constraint Equations, Aperture Problem

All variational optical flow approaches impose an invariance assumption on some feature vector $g(x, t) \in \mathbb{R}^p$, derived from an image sequence $f(x, t)$ as discussed in section “Invariance, Correspondence Problem.” Under perfect conditions, any point moving along the trajectory $x(t)$ over time t with speed $u(x, t) := \frac{d}{dt}x(t)$ does not change its appearance, i.e.,

$$\frac{d}{dt}g(x(t), t) = 0. \quad (57)$$

Without loss of generality, motion at $t = 0$ is considered only in what follows. Applying the chain rule and dropping the argument $t = 0$ for clarity leads to the *linearized* invariance constraint:

$$\mathbf{J}_g(x)u(x) + \partial_t g(x) = 0. \quad (58)$$

Validity of this approximation is limited to displacements of about 1 pixel for real data as elaborated in section ‘‘Common Aspects and Differences,’’ which seriously limits its applicability. However, section ‘‘Multiscale’’ describes an approach to alleviating this restriction, and thus for now it is safe to assume that the assumption is fulfilled.

A least squares solution to (58) is given by $(S(x))^{-1}(\mathbf{J}_g^\top(x)(\partial_t g(x)))$ where

$$S(x) := \mathbf{J}_g^\top(x)\mathbf{J}_g(x). \quad (59)$$

However, in order to understand the actual information content of equation system (58), the locally varying properties of the Jacobian matrix $\mathbf{J}_g(x)$ have to be examined:

- $\text{rank}(\mathbf{J}_g) = 0$: *void constraints* on $u(x)$ (for $g(x, 0) = \text{const.}$);
- $\text{rank}(\mathbf{J}_g) = 1$: *ill-conditioned constraints*, a single component of $u(x)$ is determined only;
- $p = \text{rank}(\mathbf{J}_g) = 2$: *unique solution* $u(x) = -\mathbf{J}_g^{-1}(x)(\partial_t g(x))$;
- $p > \text{rank}(\mathbf{J}_g) = 2$: *over-determined* and possibly conflicting constraints on $u(x)$, cf. Fig. 8.

In the case of gray-valued features, $g(x) = f(x) \in \mathbb{R}$, (58) is referred to as the *linearized brightness constancy constraint* and imposes *only one* scalar constraint on $u(x) \in \mathbb{R}^2$, in the direction of the image gradient $\mathbf{J}_g(x) = (\nabla g(x))^\top \neq 0$, i.e.,

$$\left\langle \frac{\nabla g(x)}{\|\nabla g(x)\|}, u(x) \right\rangle = -\frac{\partial_t g(x)}{\|\nabla g(x)\|}. \quad (60)$$

This limitation which only allows to determine the *normal flow* component is referred to as the *aperture problem* in the literature.

Furthermore, for real data, invariance assumptions do not hold exactly, and compliance is measured by the data term as discussed in section ‘‘Data Terms.’’ Section ‘‘Regularization’’ addresses regularization terms which further incorporate regularity priors on the flow so as to correct for data inaccuracies and local ambiguities not resolved by (58).

The Approach of Horn and Schunck

The approach by Horn and Schunck [29] is described in the following due to its importance in the literature, its simple formulation, and the availability of well-understood numerical methods for efficiently computing a solution.

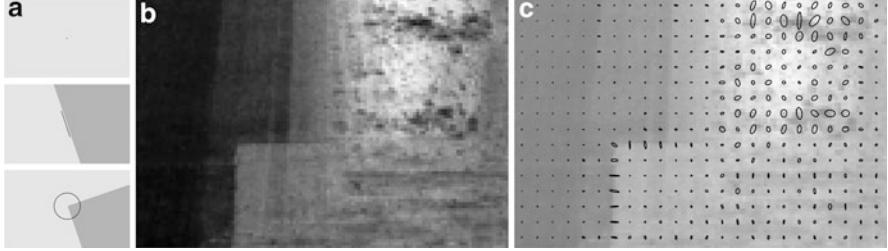

Fig. 8 Ellipse representation of $S = J_g^T J_g$ as in (57) for a patch feature vector with $p \gg 2$ (see section “Patch Features”). (a) Three synthetic examples with J_g having (top to bottom) rank 0, 1, and 2, respectively. (b) Real image data with homogeneous (left) and textured (right) region, image edges, and corner (middle). (c) Locally varying information content (see section “Differential Constraint Equations, Aperture Problem”) of the path features extracted from (b)

Model

Here the original approach [29], expressed using the variational formulation (56), is slightly generalized from gray-valued features $g(x) = f(x) \in \mathbb{R}$ to arbitrary feature vectors $g(x) \in \mathbb{R}^p$. Deviations from the constancy assumption in (58) are measured using a quadratic function $\rho_D = \rho_2^2$, leading to

$$E_D(u) = \frac{1}{2} \int_{\Omega} \rho_D (\|J_g(x)u(x) + \partial_t g(x)\|_F) dx. \quad (61)$$

As for regularization, the quadratic length of the flow gradients is penalized using $\rho_R = \rho_2^2$, to enforce smoothness of the vector field and to overcome ambiguities of the data term (e.g., aperture problem; see section “Differential Constraint Equations, Aperture Problem”):

$$E_R(u) = \frac{1}{2\sigma^2} \int_{\Omega} \rho_R (\|J_u(x)\|_F) dx. \quad (62)$$

The only parameter $\sigma > 0$ weights the influence of regularization against the data term.

Discretization

Finding a minimum of $E(u) = E_D(u) + E_R(u)$ using numerical methods requires discretization of variables and data in time and space. To this end, let $\{x^i\}_{i \in [n]}$ define a regular two-dimensional grid in Ω , and let $g^1(x^i)$ and $g^2(x^i)$ be the discretized versions of $g(x, 0)$ and $g(x, 1)$ of the input image sequence, respectively. Motion variables $u(x^i)$ are defined on the same grid and stacked into a vector u :

$$u(x^i) = \begin{pmatrix} u_1(x^i) \\ u_2(x^i) \end{pmatrix}, \quad u = \begin{pmatrix} (u_1(x^i))_{i \in [n]} \\ (u_2(x^i))_{i \in [n]} \end{pmatrix} \in \mathbb{R}^{2n}. \quad (63)$$

The appropriate filter for the discretization of the spatial image gradients $\partial_i g$ strongly depends on the signal and noise properties as discussed in section ‘‘Differential Motion Estimation: Case Study (1D).’’ A recent comparison [11] reports that a 5-point derivative filter ($\frac{1}{12}\{-1, 8, 0, -8, 1\}$) applied to $\frac{1}{2}(g^1 + g^2)$ performs best. Temporal gradients are approximated as $\partial_t g(x^i) \approx g^2(x^i) - g^1(x^i)$.

As a result, the discretized objective function can be rewritten as

$$E(u) = \frac{1}{2} \|Du + c\|^2 + \frac{1}{2\sigma^2} \|Lu\|^2, \quad (64)$$

using the linear operators

$$D := \begin{pmatrix} D_{1,1} & D_{1,2} \\ \vdots & \vdots \\ D_{p,1} & D_{p,2} \end{pmatrix}, \quad c := \begin{pmatrix} c_1 \\ \vdots \\ c_p \end{pmatrix}, \quad L := \begin{pmatrix} L_{1,1} \\ L_{1,2} \\ L_{2,1} \\ L_{2,2} \end{pmatrix}, \quad (65)$$

with *data* derivatives $c_j := (\partial_t g_j(x^i))_{i \in [n]}$ and $D_{j,k} := \text{diag}((\partial_k g_j(x^i))_{i \in [n]})$. The matrix operator $L_{l,k}$ applied to *variable* u approximates the spatial derivative ∂_k of the flow component u_l using the 2-tap linear filter $\{-1, +1\}$ and Neumann boundary conditions.

Solving

Objective function (64) is strictly convex in u under mild conditions [33], and thus a *global* minimum of this problem can be determined by finding a solution to $\nabla_u E(u) = 0$. This condition explicitly reads

$$(D^\top D + \sigma^{-2} L^\top L)u = -D^\top c \quad (66)$$

which is a linear equation system of size $2n$ in $u \in \mathbb{R}^{2n}$ with a positive definite and sparse matrix. A number of well-understood iterative methods exist to efficiently solve this class of problems even for large n [45].

Examples

Figure 9 illustrates the method by Horn and Schunck for a small synthetic example. The choice of parameter σ is a trade-off between smoothing out motion boundaries (see Fig. 9b) in the true flow field (Fig. 9a) and sensitivity to noise (Fig. 9d).

Probabilistic Interpretation

Considering $E(u)$ as the log-likelihood function of a probability density function gives rise to the maximum a posteriori interpretation of the optimization problem (56), i.e.,

$$\sup_{u \in U} p(u | g, \sigma), \quad p(u | g, \sigma) \propto \exp(-E(u)). \quad (67)$$

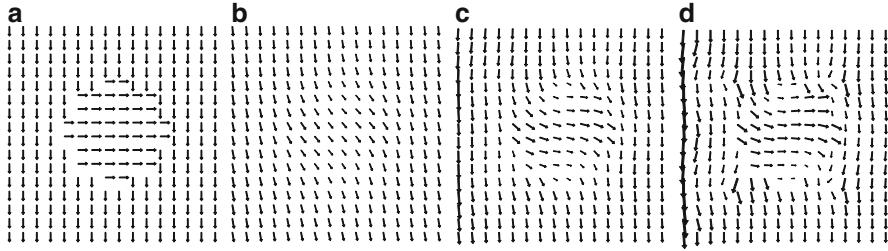

Fig. 9 (a) Synthetic flow field used to deform an image. (b)–(d) Flow field estimated by the approach by Horn and Schunck with decreasing strength of the smoothness prior

As $E(u)$ is quadratic and positive definite due to the assumptions made in section “Solving,” this posterior is a Gaussian multivariate distribution

$$p(u|g, \sigma) = \mathcal{N}(u; \mu, \Sigma) \quad (68)$$

with precision (inverse covariance) matrix $\Sigma^{-1} = D^\top D + \sigma^{-2} L^\top L$ and mean vector $\mu = -\Sigma^{-1} D^\top c$ that solves (66).

Examining the conditional distribution of $u^i \in \mathbb{R}^2$ allows to quantify the sensitivity of u . To this end a permutation matrix $Q = \begin{pmatrix} Q_i \\ Q_{\bar{i}} \end{pmatrix} \in \mathbb{R}^{2n \times 2n}$, $Q^\top Q = I$, is defined such that $u^i = Q_i u$. Then, fixing $Q_{\bar{i}} u = Q_{\bar{i}} \mu$ leads to

$$p(u^i | Q_{\bar{i}} u) = \mathcal{N}\left(\hat{\mu}^i, \hat{\Sigma}^i\right) \quad (69)$$

with $\hat{\mu}^i = Q_i \mu$ and

$$\hat{\Sigma}^i = Q_i \Sigma Q_i^\top - (Q_{\bar{i}} \Sigma Q_i^\top) (Q_{\bar{i}} \Sigma Q_{\bar{i}}^\top)^{-1} (Q_i \Sigma Q_{\bar{i}}^\top). \quad (70)$$

Using the matrix inversion theorem to invert Σ block wise according to Q and restricting the result to u_i reveals

$$Q_i \Sigma^{-1} Q_i = \left(Q_i \Sigma Q_i^\top - (Q_{\bar{i}} \Sigma Q_i^\top) (Q_{\bar{i}} \Sigma Q_{\bar{i}}^\top)^{-1} (Q_i \Sigma Q_{\bar{i}}^\top) \right)^{-1}. \quad (71)$$

Comparison of (70) to (71) and further analysis yield (for non-boundary pixels)

$$\hat{\Sigma}^i = (Q_i \Sigma^{-1} Q_i)^{-1} = (S^i + 4\sigma^{-2} I)^{-1} \quad (72)$$

with $S^i = S(x^i)$ as defined by (59). Consequently, smaller values of σ reduce the sensitivity of u^i , but some choice $\sigma > 0$ is inevitable for singular S^i .

Data Terms

Handling Violation of the Constancy Assumption

The data term as proposed by Horn and Schunck was refined and extended in literature in several ways with the aim to cope with the challenging properties of image data of real applications; see section ‘‘Basic Difficulties of Motion Estimation.’’

Changes of the camera viewpoint as well as moving or transforming objects may cause previously visible image features to disappear due to occlusion, or vice versa to emerge (disocclusion), leading to discontinuous changes of the *observed* image features $g(x(t), t)$ over time and thus to a violation of the invariance constraint (57).

Surface reflection properties like specular reflections that vary as the viewpoint changes, and varying emission or illumination (including shadows), also cause appearance to change, in particular in natural and outdoor scenes.

With some exceptions, most approaches do not explicitly model these cases and instead replace the quadratic distance function ρ_2^2 by the convex ℓ^2 -distance or its differentiable approximation $\rho_{2,\epsilon}$, to reduce the impact of outliers in regions with strong deviation from the invariance assumption. A number of *non-convex* alternatives have been proposed in the literature, including the truncated square distance $\rho_{2,\lambda}$, which further extend this concept and are often referred to as ‘‘robust’’ approaches.

Another common method is to replace the constancy assumption on the image brightness by one of the more complex feature mappings $g(x, t)$ introduced in section ‘‘Invariance, Correspondence Problem,’’ or combinations of them. The aim is to gain more descriptive features that overcome the ambiguities described in section ‘‘Differential Constraint Equations, Aperture Problem,’’ e.g., by including color or image structure information from a local neighborhood. Furthermore, robustness of the data term can be increased by choosing features invariant to specific image transformations. For example, $g(x) = \nabla f(x)$ is immune to additive illumination changes.

Patch Features

Contrary to the strongly localized brightness feature $g(x) = f(x)$, local image patches sampled from a neighborhood $\mathcal{N}(x)$ of x ,

$$g(x^i, t) = (f(x^j, t))_{x^j \in \mathcal{N}(x^i)} \in \mathbb{R}^p, \quad p = |\mathcal{N}(x^i)| \quad (73)$$

provide much more reliable information on u in textured image regions. In fact, *local* approaches set $E_R(u) = 0$ and rely only the information contained in the data term.

The most prominent instance introduced by Lucas and Kanade [19] chooses a Gaussian-weighted quadratic distance function,

$$\rho_{w^i}^2(z) := \left\| \text{diag}(w^i)^{\frac{1}{2}} z \right\|^2, \quad w^i := (w(x^i - x^j))_{x^j \in \mathcal{N}(x^i)} \quad (74)$$

and $w(x) := \exp(-\|x\|^2/(2\sigma^2))$. Solving the variational problem (56) decomposes into n linear systems of dimension 2 each. Furthermore, the sensitivity in terms of (72) reduces to $\hat{\Sigma}^i = (S^i)^{-1}$ and

$$S^i = \sum_{x^j \in \mathcal{N}(x^i)} w(x^i - x^j) \left(J_g^\top(x^j) J_g(x^j) \right) \quad (75)$$

equals the so-called *structure tensor*. At locations with numerically ill-conditioned J_g , cf. Fig. 8 and the discussion in section “Differential Constraint Equations, Aperture Problem,” no flow can be determined reliably which leads to possibly sparse results. The works [46, 47] overcome this drawback by complementing this data term by a regularization term.

Multiscale

As discussed in section “Differential Motion Estimation: Case Study (1D),” the range of displacements $u(x)$ that can be accurately estimated is limited to about 1 pixel which does not conform to the larger magnitude of motion fields typically encountered in practical applications. Multiscale methods allow to remove this restriction to some extent. They implement a *coarse-to-fine* strategy for approximately determining large displacements on spatially band-limited image data and complementing flow details on finer scales.

The underlying idea is introduced by means of a multiscale representation $\{g^{[l]}\}_{l \in [n_l]}$ of image data, where $l = 0$ and $l = n_l - 1$ refer to the finest and coarsest scale, respectively. More precisely, $g^{[l]}$ is a spatially band-limited version of g with $\omega_{x,\max} < s_l \pi$ with $1 = s_0 > s_1 \dots s_{n_l-1} > 0$. The computation is described by the following recursive scheme with $u^{[n_l]}(x) = 0$:

- $g^{[l]}(x, t) := h_l * g(x + t \cdot u^{[l+1]}, t)$
- $\delta u^{[l]} := \arg \min_u E(u)$ on data $g^{[l]}(x, t)$
- $u^{[l]}(x) := u^{[l+1]}(x) + \delta u^{[l]}(x)$

with a suitable approximation of the ideal low-pass filter h_l with frequency response

$$\hat{h}_l(\omega_x, \omega_t) \approx \begin{cases} 1 & \|\omega_x\|_\infty < s_l \pi \\ 0 & \text{otherwise} \end{cases}. \quad (76)$$

Figure 10 demonstrates the method for two simple examples.

Actual implementations further make use of the band-limited spectrum of the filtered data and subsample the data according to the Nyquist-Shannon sampling theorem, leading to a data representation referred to as *resolution pyramid*. The recursive structure allows in turn to approximate h_l by chaining filters with small support for computational efficiency.

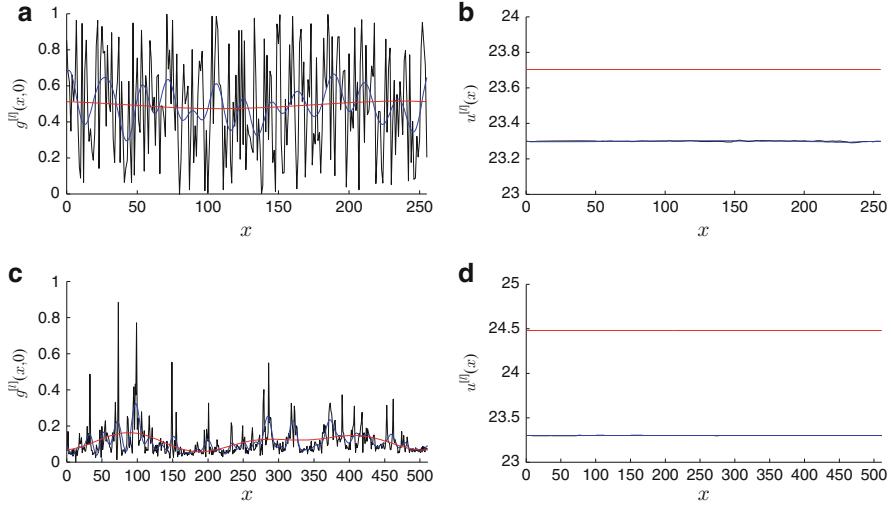

Fig. 10 Multiscale flow estimation: (a) an image (white noise) $g^{[l]}(x, 0)$ represented at multiscale levels $l = 0$ (black), $l = 3$ (blue), and $l = 6$ (red) with $s_l = 2^{-l}$, i.e., band limited to $s_l \pi$. (b) Estimate $u^{[l]}$ (same color encoding as in (a)) of correct constant flow $u(x) = 23.3$ on multiscale level l . (c)–(d) Same as (a)–(b) for a single line of a real image (©LaVision GmbH) as found in particle image velocimetry, an optical fluid flow estimation method

Regularization

Ill-posed data terms, sensor noise, and other distortions lead to *sparse* and *locally inaccurate* flow estimates. Variational approaches allow to incorporate priors on the motion regularity by means of additional terms $E_R(u)$. For suitable models $E_D(u)$ and $E_R(u)$, accuracy profits from this concept as the global solution to minimization problem (56) represents the best flow field according to both observations and priors. Furthermore, in contrast to local methods, *missing* flow information is approximately inferred according to the smoothness prior. This is in particular essential in connection with ill-posed data terms (cf. section “Differential Constraint Equations, Aperture Problem”).

Regularity Priors

A number of a priori constraints $u \in U$ for flow estimation have been proposed in the literature, based on prior knowledge specific to the application domain. Examples include

- Inherent geometrical constraints induced by multi-camera setups (section “Geometrical Prior Knowledge”),
- Physical properties of flows in experimental fluid mechanics (section “Physical Prior Knowledge”).

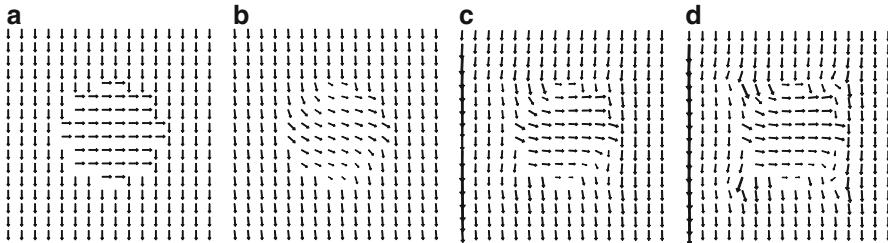

Fig. 11 (a) Synthetic flow field used to deform an image. (b)–(d) Flow field estimated by the approach by Horn and Schunck, however with $\ell_1 - TV$ -regularization, with decreasing strength of the smoothness prior

Formally, strict compliance with a constraint $u \in U$ can be incorporated into the variational formulation (56) by means of the corresponding indicator function

$$E_R(u) = \delta_U(u). \quad (77)$$

In many applications, however, the set U cannot be specified precisely. Then a common approach is to replace δ_U by a smoother function measuring the distance of u to U in some sense,

$$E_R(u) = \rho(u - \Pi_U u). \quad (78)$$

For example, the regularization term of the Horn and Schunck approach presented in section “The Approach of Horn and Schunck” may be written as

$$E_R(u) = \|Lu\|^2 = \|u - \Pi_{\ker(L)}(u)\|_L^2 \quad (79)$$

with semi-norm $\|x\|_L := \|Lx\|$ and set $U = \ker(L)$. Generalizations of the approach of Horn and Schunck are based on the same L and modify the distance function (section “Distance Functions”) or refine them to become locally adaptive and anisotropic (section “Adaptive, Anisotropic, and Nonlocal Regularization”).

Further extensions replace the gradient operator in (62) and its discretization L by other operators having a larger space $U = \ker(L)$. For example, operators involving second-order derivatives ∇div and ∇curl have been used for flow estimation in experimental fluid dynamics [48–50] (cf. section “Physical Prior Knowledge”).

Distance Functions

Occlusion of objects does not only lead to sudden changes of the projected appearance (cf. section “Data Terms”) but also to *motion discontinuities* whose preservation during flow estimation is crucial in many applications and for the interpretation of videos. The penalization of large motion gradients J_u can be

reduced by replacing the quadratic distance function ρ_2^2 in (62) by convex or non-convex alternatives; see (3) for some examples.

Figure 11 demonstrates the effect of replacing the quadratic distance measure of the approach by Horn and Schunck (section “The Approach of Horn and Schunck”) by $\rho_R = \rho_2$. It becomes apparent that motion discontinuities can be better resolved than with $\rho_R = \rho_2^2$ (see Fig. 9).

Adaptive, Anisotropic, and Nonlocal Regularization

A further option is to include a priori information on the *location* and *alignment* of motion discontinuities by using a spatially varying, *adaptive*, and possibly *anisotropic* norm in (62)

$$E_R(u) = \sigma^{-2} \int_{\Omega} \rho_R(\|J_u(x)\|_{W(x)}) dx, \quad (80)$$

with $\|A\|_W := \|AW\|_F$ and (omitting the dependency on x)

$$W = (w_1 e^1 \ w_2 e^2). \quad (81)$$

The normalized orthogonal directions $e^1, e^2 \in \mathbb{R}^2$ point *across* and *along* the assumed motion boundary, respectively. The positive eigenvalues w_1 and w_2 control relative penalization of flow changes in the according direction.

A common assumption made in literature, e.g., [36, 51], is that image edges and flow discontinuities coincide and facilitate changes of $u(x)$ *across* the assumed boundary e_1 . For general features $g(x)$, the notion of image edge is here defined by choosing e^1 and e^2 as the normalized direction e of the largest and smallest change of $\|J_g e\|$, respectively, given by the eigenvectors of $S = J_g^T J_g$. The associated eigenvalues $\lambda_1 \geq \lambda_2 \geq 0$ of S control the strength of smoothness by setting $w_i = 1 - \rho(\lambda_i)$, $i = 1, 2$ and suitable increasing $\rho(x) \in [0, 1]$ with $\rho(0) = 0$. This defines an *anisotropic* and *image-driven* regularization. Note that for the gray-valued case $g(x) = f(x) \in \mathbb{R}$, the formulation simplifies to $e^1 = \|\nabla g\|^{-1} \nabla g$, $\lambda_1 = \|\nabla g\|^2$, and $\lambda_2 = 0$. The class of *flow-driven* approaches replace the dependency on $g(x)$ of the terms above by the flow $u(x)$ to be estimated. This nonlinear dependency can be taken into account without compromising convexity of the overall variational approach [36].

While the approaches so far measure *locally* the regularity of flows u , approaches such as [52] adopt nonlocal functionals for regularization developed in other contexts [53–55] for optical flow estimation. Regularization is then more generally based on the similarity between *all* pairs $(u(x), u(x'))$ with $x, x' \in \Omega$, weighted by mutual position and feature distances.

Further Extensions

Three extensions of the basic variational approach are sketched: a natural extension of spatial regularizers to the spatiotemporal domain (section “Spatiotemporal Approach”), regularization based on the two-view geometry (cf. section “Two-View Geometry, Assignment and Motion Fields”) and relative rigid motions for computer vision applications (section “Geometrical Prior Knowledge”), and a case study of PDE-constrained variational optical flow estimation in connection with imaging problems in experimental fluid dynamics (section “Physical Prior Knowledge”).

Spatiotemporal Approach

The preceding discussion reduced the motion estimation problem to determining displacements between *two* image frames only and thus ignored consistencies of the flow *over time*. Although in many applications recording rates are fast compared to dynamical changes due to modern sensors, only few approaches exploit this fact by introducing *temporal smoothness priors*.

The work [35] proposed to process a batch of image frames *simultaneously* and to extend the flow field domain along the time axis $u : \Omega \times [0, T] \mapsto \mathbb{R}^2$. While data terms are independently imposed for each time t , the smoothness prior is extended by a temporal component to

$$E_R(u) := \int_{\Omega \times [0, T]} \rho_R(\|J_{u,t}(x, t)\|_W) dx dt. \quad (82)$$

Here, $J_{u,t}$ represents the spatiotemporal derivatives, and $\rho_R \|\cdot\|_W$ is a three-dimensional extension of the *anisotropic, flow-driven* distance function discussed in section “Adaptive, Anisotropic, and Nonlocal Regularization.” It allows to account for *small* position changes of moving objects between consecutive frames within the support of the regularization term (≤ 1 px) by supporting smoothness *along* an assumed trajectory.

Larger displacements, however, require matching of temporally associated regions, e.g., using a multiscale framework (section “Multiscale”), but then enable to regularize smoothness of *trajectories* over multiple frames as proposed in [56].

Online methods are an appealing alternative whenever processing a batch of image frames is not feasible due to resource limitations. This approach is addressed in section “Probabilistic Modeling and Online Estimation.”

Geometrical Prior Knowledge

In applications with a perspective camera as image sensor, the geometrical scene structure strongly determines the observed optical flow (section “Two-View Geometry, Assignment and Motion Fields”). This section briefly addresses the most common assumptions made and the constraints that follow.

Often, a *static scene* assumption is made, meaning that all visible scene points have zero velocity with respect to a world coordinate system. Then the observed motion is only induced by the camera moving in the scene. Using the notation

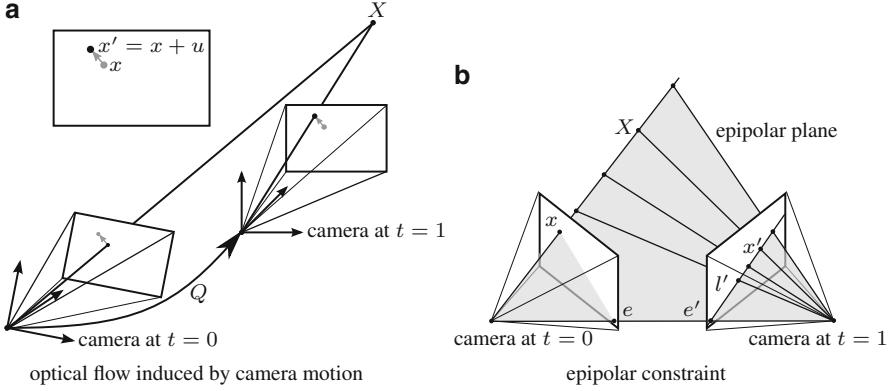

Fig. 12 (a) Relative motion $Q \in \text{SE}(3)$ of the camera w.r.t. a world coordinate system causes the projection x of a static scene point $X = z(x)y$ to move from x to $x' = x + u(x)$ in the image plane. (b) Any two projections x, x' of a scene point X are related by the essential matrix E as in (84), defining an *epipolar plane* and their projection, the *epipolar lines* defined by $\{x, e\}$ and $\{x', e'\}$ in the image plane at $t = 0$ and $t = 1$, respectively

introduced in section “Two-View Geometry, Assignment and Motion Fields,” the camera motion is denoted by $Q \in \text{SE}(3)$ (cf. Fig. 12a), parametrized by rotation $R \in \text{SO}(3)$ and translation $h \in \mathbb{R}^3$, so that any scene point $Y \in \mathcal{Q}$ is transported to $Y' \simeq Q^{-1}Y$.

The following discussion of common setups and their implications on the observed motion implicitly assumes that the scene point is visible in both frames. Using assumption (41) for the internal camera parameters allows to work with normalized coordinates (32). The point corresponding to x is denoted by x' , due to (42).

Static scene, general motion Let the depth map $z(x) : \Omega \mapsto \mathbb{R}$ parametrize the scene point $X := z(x) \begin{pmatrix} x \\ 1 \end{pmatrix}$ visible at x in the camera plane in the first frame. Then the projected correspondences are given in homogeneous coordinates by

$$y' \simeq PQ^{-1}Y = R^\top(z(x) \begin{pmatrix} x \\ 1 \end{pmatrix} - h), \quad (83)$$

see Fig. 12a for an illustration. Figure 13 shows the optical flow field $u(x)$ conforming to constraint (83) for a real application.

It is possible to eliminate the dependency on $z(x)$ that typically is unknown by means of the *essential matrix* $E := R^\top[h]_x$, leading to the *epipolar constraint*

$$(y')^\top E y = 0, \quad (84)$$

as illustrated by Fig. 12b. This gives rise to an orthogonal decomposition [58] of an observed correspondence \hat{x}' into

Fig. 13 (a) A single frame from an image sequence recorded by a camera moving forward through an approximately static scene. (b) Optical flow estimated using the parametrization $u(x) = u(x; Q, z(x))$ according to (83) and global optimization for $Q \in \text{SE}(3)$, $z \in \mathbb{R}^n$; see [57] for details. Displacement length and direction are encoded by saturation and hue, respectively; see color code on the right. (c) Estimated depth parameter $z(x)$ using the color code on the right. Scene structure is more evident in this representation, and therefore the spatial smoothness prior on the flow was formulated as regularization term on the *depth* $z(x)$ instead of displacements $u(x)$

$$\hat{x}' = \hat{x}'_e + \hat{x}'_{\perp} \quad (85)$$

with \hat{x}'_e fulfilling (84) and orthogonal deviations \hat{x}'_{\perp} .

Even without knowing a priori (R, h) , Eq. (84) provides a valuable prior: Valgaerts et al. [59] propose joint computation of the fundamental matrix F related to E by (40) and optical flow constrained via (84). They show that estimation of F is more stable and that flow accuracy is significantly increased.

Static scene, coplanar camera motion If the camera translates parallel to the image plane only, i.e., $R = I$ and $h = \begin{pmatrix} b \\ 0 \end{pmatrix}$ with $b \in \mathbb{R}^2$, the observed flow is constrained to a locally varying *one-dimensional* subspace parametrized by the inverse depth:

$$u(x) = z^{-1}(x)b. \quad (86)$$

Stereoscopic camera setups fulfill the static scene assumption as they can be interpreted as an instantaneous camera motion with baseline $\|b\|$. For details see, e.g., [5].

Planar and static scene, general camera motion In applications where the scene can be (locally) approximated by a plane such that $\langle n, X \rangle - d = 0$ for all space points X with plane parameters d, n as in (46), all correspondences fulfill

$$y' \simeq Hy, H = R^T \left(I - \frac{1}{d} hn^T \right), \quad (87)$$

where $H \in \mathbb{R}^{3 \times 3}$ defines a *homography* – cf. Eq. (49).

Physical Prior Knowledge

Imaging of dynamic phenomena in natural sciences encounters often scenarios where physical prior knowledge applies. Examples include particle image velocime-

try [60] or Schlieren velocimetry [61], where the motion of fluids is observed, that is, governed by physical laws. While local methods such as cross-correlation methods are commonly used to evaluate the obtained image sequences [60, 62], variational approaches [63–65] provide a more appropriate mathematical framework for exploiting such prior knowledge and the estimation of physically consistent optical flows.

For instance, the Helmholtz decomposition of vector fields enables to define regularizers in terms of higher-order partial flow derivatives in a natural way [48–50]. Constraints like incompressibility can be enforced as hard or soft constraints using advanced methods of convex programming, to cope with imaging imperfections. Conversely, flow field estimates obtained by other image processing methods can be denoised so as to restore physically relevant structure [66].

A particularly appealing approach exploits directly some equation from fluid dynamics that governs the flow as state of the physical system which is observed through an imaging sensor [67, 68]. The state is regarded as hidden and only observable through the data of an image sequence that depicts the velocity of some tracer suspended in the fluid. The variational approach of fitting the time varying state to given image sequence data results in a PDE-constrained optimization or distributed parameter control problem, respectively.

As example the approach [67] is sketched based on the Stokes system

$$-\mu \Delta u + \nabla p = f_\Omega \quad \text{in } \Omega, \quad (88a)$$

$$\operatorname{div} u = 0 \quad \text{in } \Omega, \quad (88b)$$

$$u = f_{\partial\Omega} \quad \text{on } \partial\Omega, \quad (88c)$$

that for given $f_\Omega, f_{\partial\Omega}$ with $\int_{\partial\Omega} \langle n, f_{\partial\Omega} \rangle ds = 0$ (n denotes the outer unit normal of the Lipschitz domain Ω) has a unique solution u, p under classical assumptions [69, Ch. I]. Here $f_\Omega, f_{\partial\Omega}$ are not regarded as given data but as control variables, to be determined so that the flow u not only satisfies (88) but fits also given image sequence data. To achieve the latter, both the state variables u, p and the control variables $f_\Omega, f_{\partial\Omega}$ are determined by minimizing in the two-dimensional case $d = 2$ the objective

$$E(u, p, f_\Omega, f_{\partial\Omega}) = E_D(u) + \alpha \int_\Omega \rho_2^2(f_\Omega) dx + \gamma \int_{\partial\Omega} \rho_2^2(\langle n^\perp, \nabla f_{\partial\Omega} \rangle) ds, \quad \alpha, \gamma > 0. \quad (89)$$

The first term $E_D(u)$ denotes a data term of the form (61), and the remaining two terms regularize the control variables so as to make the problem well posed.

For related mathematical issues (e.g., constraint qualification and existence of Lagrange multipliers), see [70, Ch. 6] and [71, Ch. 1] and furthermore [70, 72] for related work outside the field of mathematical imaging based on the general Navier-Stokes system.

Algorithms

The choice of an optimization method for numerically minimizing the functional (56) depends on the specific formulation of the terms E_D and E_R involved. Suitable methods can be broadly classified into

- Algorithms for minimizing *smooth convex* functionals,
- Algorithms for minimizing *non-smooth convex* functionals,
- Algorithms for locally minimizing *non-convex* functionals.

In view of the typical multiscale implementation of the data term (section “Multiscale”) that enables a quadratic approximation at each resolution level, this classification is applied to the regularizer E_R only, and each class is discussed in turn in the sections to follow. The reader should note that convex non-quadratic data terms, as discussed in section “Handling Violation of the Constancy Assumption,” can be handled in a similar way as the convex non-smooth regularizer below, and a number of closely related alternatives exist (e.g., [73]). Since convex programming has been extensively studied in the literature, the following presentation is confined to representative case studies that illustrate in each case the underlying idea and application of a general principle.

Smooth Convex Functionals

It is useful to distinguish quadratic and non-quadratic functionals. The approach of Horn and Schunck (section “The Approach of Horn and Schunck”) is a basic representative of the former class. Solving the corresponding linear positive definite sparse system can be efficiently done by established methods [45]. More sophisticated implementations are based on numerical multigrid methods [74]. These are optimal in the sense that runtime complexity $O(n)$ linearly depends on the problem size n . Dedicated implementations run nearly at video frame rate on current PCs.

For more general data-dependent quadratic regularizers and especially so for non-quadratic convex regularizers (cf. section “Adaptive, Anisotropic, and Nonlocal Regularization” and [36]), multigrid implementation that achieves such runtimes requires some care. See [12, 13, 75] for details and [76] for a general exposition.

Non-smooth Convex Functionals

This class of optimization problems has received considerable attention in connection with mathematical imaging, inverse problems, and machine learning and in other fields during the recent years, due to the importance of non-smooth convex sparsity enforcing regularization. See [77] for a recent overview.

The *total variation* regularizer

$$\begin{aligned} E_R(u) = TV(u) &:= \sup_{v \in \mathcal{D}} - \int_{\Omega} \langle u, \operatorname{Div} v \rangle dx, \\ \mathcal{D} &:= \{v \in C_0^\infty(\Omega; \mathbb{R}^d) : \|v(x)\|_F \leq 1, \forall x \in \Omega\}, \\ \operatorname{Div} v &= (\operatorname{div} v^1, \dots, \operatorname{div} v^d)^\top \end{aligned} \quad (90)$$

is a basic representative of the class of non-smooth convex functionals and appropriate to expose a general strategy of convex programming that is commonly applied: problem splitting into subproblems for which the proximal mapping can be efficiently evaluated.

The simplest *anisotropic* discretization of (90) that is particularly convenient from the viewpoint of convex programming reads

$$\sum_{ij \in E(G)} \sum_{k \in [d]} |u_k(x^i) - u_k(x^j)|, \quad (91)$$

where $\{x^i\}_{i \in [n]}$ are the locations indexed vertices $V = [n]$ of a grid graph $G = (V, E)$ in Ω , and $E = E(G)$ are the corresponding edges connecting adjacent vertices resp. locations along the coordinate axes. Defining the vector

$$z \in \mathbb{R}^{d \times |E(G)|}, \quad z_{k,ij} = u_k(x^i) - u_k(x^j) \quad (92)$$

leads to the reformulation of (91)

$$\|z\|_1, \quad Lu = z \quad (93)$$

where the linear system collects all equations of (92). As a consequence, the overall discretized problem reads

$$\min_{u,z} E_D(u) + \alpha \|z\|_1 \quad \text{subject to} \quad Lu - z = 0, \quad \alpha > 0 \quad (94)$$

to which the ADMM approach [78] can be applied that entails a sequence of partial minimizations of the augmented Lagrangian corresponding to (94),

$$L_\lambda(u, z, w) = E_D(u) + \alpha \|z\|_1 + \langle w, Lu - z \rangle + \frac{\lambda}{2} \|Lu - z\|^2. \quad (95)$$

Specifically, with some parameter value $\lambda > 0$ and multiplier vector w , the three-step iteration

$$u^{k+1} = \arg \min_u E_D(u) + \langle w^k, Lu \rangle + \frac{\lambda}{2} \|Lu - z^k\|^2, \quad (96a)$$

$$z^{k+1} = \arg \min_z \alpha \|z\|_1 - \langle w^k, z \rangle + \frac{\lambda}{2} \|Lu^{k+1} - z\|^2, \quad (96b)$$

$$w^{k+1} = w^k + \lambda(Lu^{k+1} - z^{k+1}), \quad (96c)$$

is iteratively applied for $k = 0, 1, 2, \dots$, with arbitrary initializations z^0, q^0 , until a suitable termination criterion is met [78, Section 3.3.1].

Assuming a quadratic form or approximation of $E_D(u)$ at some resolution level (section ‘‘Multiscale’’), subproblem (96a) amounts to solve a sparse positive definite linear system similar to the basic approach of Horn and Schunck, to which a multigrid solver can be applied as discussed above. Subproblem (96b) amounts to computing the proximal mapping for the ℓ^1 -norm and hence to perform a simple shrinkage operation. See [79, 80] for corresponding surveys.

Non-convex Functionals

Similar to the preceding non-smooth convex case, approaches are of interest that can be conducted by solving a sequence of *simple* subproblems efficiently. Clearly, convergence to a *local* minimum can be only expected. In contrast to the simpler convex cases above, the absence of parameters is preferable that would have to be set properly, to ensure convergence to some local minimum for any initialization. For example, Lipschitz constants of gradients are rarely known in practice, and setting corresponding parameters savely enough will unduly slow down convergence even for smooth problems.

A general strategy will be outlined next and its application to the non-convex extension of the regularizer (91), using the distance function (3f),

$$\sum_{ij \in E(G)} \rho_{2,\lambda}(u(x^i) - u(x^j)). \quad (97)$$

In order to illustrate graphically the non-convexity of this regularizer from the viewpoint of optimization, consider three summands of the ‘‘fully’’ anisotropic version of (97),

$$\sum_{ij \in E(G)} \sum_{k \in [d]} \rho_{2,\lambda}(u_k(x^i) - u_k(x^j)). \quad (98)$$

defined on edges that meet pairwise in a common vertex,

$$\rho_{2,\lambda}(u_k(x^{i_1}) - u_k(x^{i_2})) + \rho_{2,\lambda}(u_k(x^{i_2}) - u_k(x^{i_3})) + \rho_{2,\lambda}(u_k(x^{i_3}) - u_k(x^{i_4})). \quad (99)$$

Setting for simplicity and w.l.o.g. $u_k(x^{i_1}) = u_k(x^{i_4}) = 0$ to obtain a function of two variables $u_k(x^{i_2}), u_k(x^{i_3})$ results in the corresponding graph depicted by Fig. 14. It illustrates the presence of many non-strict local minima and that the design of a convergent minimization algorithm is not immediate.

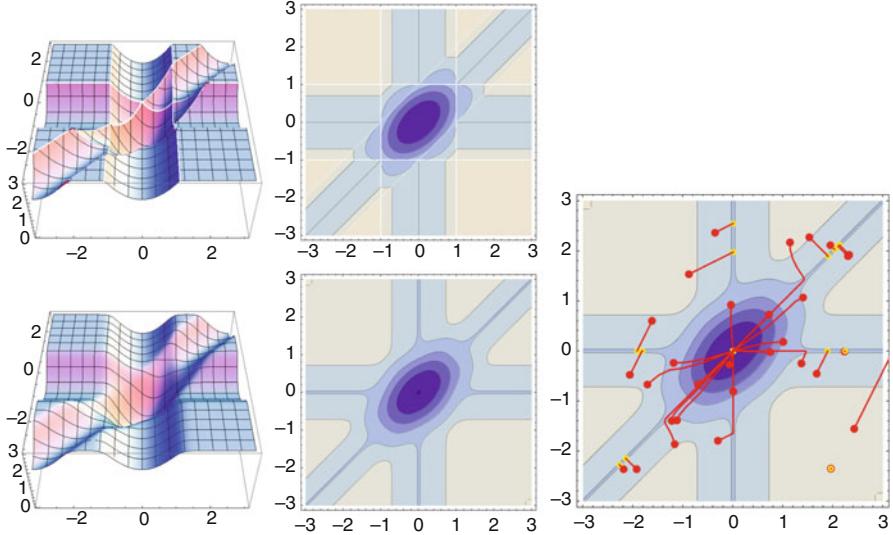

Fig. 14 Top row, left: two different illustrations of the non-convex, non-smooth objective (99). Bottom row, left: the objective (99) smoothed by replacing the distance function $\rho_{2,\lambda}$ by $\rho_{2,\lambda,\varepsilon}$ with $\varepsilon = 0.2$, as defined by (3g). Right panel: sequences of iterates generated by (103) for 30 random points $(z_2, z_3)^\top$ (initial and final iterates are marked with red and yellow, respectively). The regularizer enforces fitting of the components z_2, z_3 to the data $z_1 = z_4 = 0$ as well as $z_2 = z_3$. It is robust in the sense that components that are too distant to either of these criteria are not affected accordingly

Next consider a single summand $\rho_{2,\lambda}(z_i - z_j)$ of (98) with two scalar variables denoted by z_i and z_j for simplicity. This function can be decomposed into the difference of two proper, lower semicontinuous (lsc), convex functions g and h :

$$\begin{aligned} \rho_{2,\lambda}(z_i - z_j) &= \tau(z_i - z_j)^2 - \left(\tau(z_i - z_j)^2 - \rho_{2,\lambda}(z_i - z_j) \right) \\ &=: g(z_i, z_j) - h(z_i, z_j), \quad \tau > 1. \end{aligned} \tag{100}$$

Applying this decomposition to each term of (98) yields

$$g(u) - h(u) \tag{101}$$

with $g(u) = \tau \|Lu\|^2$ as in (64), and with $h(u)$ equal to the sum of all edge terms of the form $h(u_k(x^i), u_k(x^j))$, $ij \in E$, $k \in [d]$, given by (100).

DC-programming (DC stands for Difference-of-Convex functions [81]) amounts to locally minimize (101) by solving a sequence of convex problems, defined by the closed affine majorization of the concave part $-h$,

$$u^{k+1} = \arg \min_u g(u) - (h(u^k) + \langle v^k, u - u^k \rangle), \quad v^k \in \partial h(u^k), \tag{102}$$

where $\partial h(u^k)$ denotes the subdifferential of h at u^k . This two-step iteration in terms of (u^k, v^k) converges under mild conditions [82]. Smoothing the problem slightly by replacing the distance function $\rho_{2,\lambda}$ by $\rho_{2,\lambda,\varepsilon}$ defined by (3g), and replacing accordingly h by h_ε , yields $v^k = \nabla h_\varepsilon(u^k)$ and hence turns (102) into the sequence of problems

$$u^{k+1} = \arg \min_u g(u) - \langle \nabla h_\varepsilon(u^k), u - u^k \rangle. \quad (103)$$

Taking additionally into account the data term $E_D(u)$ and assuming it (or its approximation) has quadratic form at some resolution level (section “Multiscale”), solving (103) amounts to a sequence of Horn and Schunck type problems to which numerical multigrid can be applied, due to the simple form $g(u) = \tau \|Lu\|^2$. Not any single parameter, e.g., for selecting the stepsize, has to be set in order to ensure convergence, and available code for a variational method can be directly applied. The price to pay for this convenience is a moderate convergence rate.

Figure 14 illustrates the beneficial effect of smoothing and robustness of the non-convex regularizer: Only the components of points ($\frac{z_2}{z_3}$) that are close enough to the data $z_1 = u_k(x^{i_1}) = z_4 = u_k(x^{i_4}) = 0$, as specified by λ , are fitted to these data. For distant points with $z_2 \approx z_3$, regularization enforces $z_2 = z_3$ or does not affect them at all if $|z_2 - z_3|$ is large.

Applying the scheme (103) to (97) instead of (98) is straightforward. This does not affect $g(u)$ but merely ∇h_ε in (103), due to replacing the scalar variables in (100) by the corresponding vectors.

4 The Assignment Approach to Optical Flow Estimation

In this section approaches to determining the assignment field $u(x, t)$ (4) are considered that establish the correspondence (2) of a given feature mapping $g(x, t)$ in two given images.

The following sections conform to a classification of these approaches. Both the scope and the application areas associated with each class of approaches overlap with the variational approach of Sect. 3 but otherwise differ. The presentation focuses on the former aspects and the essential differences, whereas an in-depth discussion of the latter aspects is beyond the scope of this survey.

Section “Local Approaches” discusses local approaches to the assignment problem, whereas the remaining three sections are devoted to global approaches. In section “Assignment by Displacement Labeling” the correspondence problem is reformulated as a labeling problem so that methods for solving the *Maximum A Posteriori (MAP)* problem with the corresponding *Markov random field (MRF)* model can be applied. Assignment by *variational image registration* is briefly considered in section “Variational Image Registration.”

Local Approaches

Key feature of the class of assignment approaches is the restriction of the set of feasible assignment fields $u(x)$ to a *finite* set. This set is defined by restricting at each location $\{x^i\}_{i \in [n]} \in \Omega$ the range of $u(x^i) \in \mathcal{U}(x^i)$ to a finite set $\mathcal{U}(x^i)$.

Local approaches determine the optimal $u(x^i)$ independently, i.e., they solve for each $i \in [n]$

$$u(x^i) \in \arg \min_{u \in \mathcal{U}(x^i)} \rho(g(x^i, t), g(x^i + u, t + \delta t)). \quad (104)$$

The usually small sets $|\mathcal{U}(x^i)|$ allow *exhaustive search* to find an optimal solution. Thus, the general distance function $\rho(\cdot, \cdot)$ is not required to be convex or differentiable and allows for more involved formulations.

Since local methods do not make use of (nonlocal) spatial smoothness priors w.r.t. u , they require – and, in fact, solely rely on – discriminative features, typically derived from local images patches also used by local *variational* methods; see (73):

$$g(x^i, t) = (f(x^j, t))_{x^j \in \mathcal{N}(x^i)} \in \mathbb{R}^p, \quad p = |\mathcal{N}(x^i)| \quad (105)$$

with some neighborhood $\mathcal{N}(x^i)$, e.g., a square region.

In the following some common choices for ρ are addressed. For brevity, the discussion omits references to x^i and some fixed $u = u(x^i)$ and puts $g^1 := g(x^i, t^1)$, $g^2 := g(x^i + u, t^2)$ with $t^2 = t^1 + \delta t$.

Template-based matching methods compare a template g^1 pixel wise to a potential match g^2 and derive some similarity measure from it. Direct comparison of gray values,

$$\rho(g^1, g^2) = \rho(g^1 - g^2) \quad (106)$$

is usually avoided in favor of distance functions which are invariant to brightness or geometric changes. Two popular choices are:

- The *normalized cross-correlation* [83] derives patch features which are invariant to global additive and multiplicative changes of g by defining

$$\bar{g}^k = \frac{g^k - \mu(g^k)}{\sigma(g^k)}, \quad k = 1, 2 \quad (107)$$

with mean $\mu(g^k)$ and standard deviation $\sigma(g^k)$ of samples $\{g_j^k\}_{j \in [p]}$. Then the distance function is defined as

$$\rho_{\text{NCC}}(g^1, g^2) = 1 - \frac{1}{p} \langle \bar{g}^1, \bar{g}^2 \rangle = \frac{1}{2p} \rho_2^2(\bar{g}^1 - \bar{g}^2) \quad (108)$$

- where the last equation follows from $\langle \bar{g}^k, \bar{g}^k \rangle = p\sigma^2(\bar{g}^k) = p$.
- The *Census transform* creates binary descriptors

$$\bar{g}^k = \left(\psi_{\mathbb{R}_+}(g_j^k - m^k) \right)_{j \in [p]} \in \{0, 1\}^p, \quad k = 1, 2 \quad (109)$$

with $m^k := g(x^i, t^k)$, which approximate directional derivatives [84] and measures the Hamming distance

$$\rho_{\text{CT}}(g^1, g^2) = \rho_1(\bar{g}^1 - \bar{g}^2) = \|\bar{g}^1 - \bar{g}^2\|_1. \quad (110)$$

This transformation is in particular invariant to any strictly monotonically increasing transformation $\gamma: \mathbb{R} \mapsto \mathbb{R}$ uniformly applied to all components of g^1 and g^2 .

Histogram-based methods relax the pixel-by-pixel comparison in (106) to achieve additional invariance to geometric transformations.

Exemplarily, a method frequently used in medical images registration [85] and stereo disparity estimation [86] is detailed. It uses the concept of *mutual information* [87] to measure distances between gray-value probability distributions $\hat{p}_k(f; g^k)$, $k = 1, 2$, determined as kernel density estimates [88] from the samples $\{g_j^k\}_{j \in [p]}$. Their entropies are given by

$$H(\hat{p}_k; g^k) = - \int \hat{p}_k(f; g^k) \log \hat{p}_k(f; g^k) df, \quad k = 1, 2. \quad (111)$$

The joint distribution $\hat{p}_{1,2}(f^1, f^2; g^1, g^2)$ is defined accordingly with joint entropy

$$H(\hat{p}_{1,2}; g^1, g^2) = - \int \hat{p}_{1,2}(f^1, f^2; g^1, g^2) \log \hat{p}_{1,2}(f^1, f^2; g^1, g^2) df^1 df^2. \quad (112)$$

Then the mutual information defines the distance function

$$\rho_{\text{MI}}(g^1, g^2) = H(\hat{p}_1; g^1) + H(\hat{p}_2; g^2) - H(\hat{p}_{1,2}; g^1, g^2) \quad (113)$$

which shows some robustness against rotation, scaling, and illumination changes.

Complex approaches such as *scale-invariant feature transform (SIFT)* [3] and *speeded-up robust features (SURF)* [4] combine several techniques including histogram of orientations and multiple resolution to optimize robustness, reliability, and speed.

Assignment by Displacement Labeling

Consider again sets $\mathcal{U}(x^i)$ of assignment vectors as discussed in section ‘‘Local Approaches.’’ In contrast to local approaches presented in the previous section, this section is devoted to methods that *simultaneously* select vectors $u(x^i) \in \mathcal{U}(x^i)$ for all locations $x^i, i \in [n]$, based on optimization criteria that evaluate desired properties of assignment fields u . The feasible set of u is denoted by $\mathcal{U} := \cup_{i \in V} \mathcal{U}(x^i)$. It will be convenient to index locations $\{x^i\}_{i \in V} \in \Omega$ by vertices $i \in V = [n]$ of a graph $G = (V, E)$.

As a consequence of the twofold discretization of both the underlying domain $\Omega \subset \mathbb{R}^d$ and the range of $u(x)$, it makes sense to associate with each location x^i an integer-valued variable

$$\ell_i := \ell(x^i) \in [m_i], \quad m_i := |\mathcal{U}(x^i)|, \quad (114)$$

whose value determines the assignment vector $u(x^i) \in \mathcal{U}(x^i)$. This separates the problem formulation in terms of the *labeling field* $\ell := \{\ell_i\}_{i \in V}$ from the set of assignment vectors \mathcal{U} that may vary, as is further discussed below.

Analogous to objectives (56) of variational approaches, a functional as criterion for labelings ℓ defines an approach,

$$\begin{aligned} J(\ell; \mathcal{U}) &= J_D(\ell) + J_R(\ell) \\ &= \sum_{i \in V} \varphi_i(\ell_i; \mathcal{U}) + \sum_{ij \in E} \varphi_{ij}(\ell_i, \ell_j; \mathcal{U}), \end{aligned} \quad (115)$$

together with an algorithm for determining an assignment field u in terms of a minimizing labeling field ℓ . For instance, in view of a data term like (61), a reasonable definition of the function $\varphi_i(\cdot; \mathcal{U})$ of (115) is

$$\varphi_i(\ell_i; \mathcal{U}) = \rho_D (\|J_g(x^i)u_{\ell_i} + \partial_t g(x^i)\|_F), \quad u_{\ell_i} \in \mathcal{U}(x^i), \quad \ell_i \in [m_i] \quad (116)$$

where ℓ_i enumerates all possible assignment vectors u_{ℓ_i} at x^i . However, getting back to the differences to the differential approach addressed in section ‘‘Common Aspects and Differences,’’ a major motivation of formulation (115) is to disregard partial derivatives of the feature map involved in differential variational approaches (section ‘‘Differential Constraint Equations, Aperture Problem’’) and hence to avoid the corresponding limitations discussed in sections ‘‘Differential Motion Estimation: Case Study (1D)’’ and ‘‘Multiscale.’’ Rather, data terms J_D are directly defined by setting up and evaluating *locally* possible assignments $u_{\ell_i} \in \mathcal{U}(x^i)$ that establish a correspondence between local features (2), extracted from the given image pair, and by defining costs $\varphi_i(\ell_i; \mathcal{U})$ accordingly. Notice that no smoothness of φ_i is required – any distance discussed in section ‘‘Local Approaches’’ may be employed as in (116). For a discussion of the distance (113) in this connection, see [89].

The same remarks apply to the definition of J_R in (115). A common choice in the literature however is the discrete version of the non-convex regularizer (97)

$$\varphi_{ij}(\ell_i, \ell_j; \mathcal{U}) = \rho_{2,\lambda}(u_{\ell_i} - u_{\ell_j}; \mathcal{U}). \quad (117)$$

The reader should notice that the *non-convex* regularizer (97) has been replaced by the *combinatorial* version (117). Likewise, the *non-convex* data term (61) has been replaced by the *discrete-valued* term (116). More generally, the problem related to the variational approach to cope with the non-convexity of the data term (section “Multiscale”) by means of a multiscale implementation (section “Multiscale”), and with the non-convexity of the overall functional by computing a “good” local minimum (section “Non-convex Functionals”), has been replaced by the combinatorial problem to determine an optimal assignment by minimizing (115). This problem is known in the literature as *maximum a posteriori (MAP) problem* w.r.t. the discrete probabilistic graphical model

$$p_G(\ell; \mathcal{U}) = \frac{1}{Z} \exp(-J(\ell; \mathcal{U})), \quad Z = \sum_{\ell} \exp(-J(\ell; \mathcal{U})), \quad (118)$$

that is the problem to compute the *mode* $\arg \max p_G(\ell; \mathcal{U})$ of the *Markov random field* p_G defined on the undirected graph G . See [90, 91] for background and further details.

Many past and current research activities are devoted to this problem, across various fields of computer science and applied mathematics. Approaches range from integer programming techniques to various convex relaxations and combinations thereof. To get a glimpse of the viewpoint of polyhedral combinatorics on the problem to minimize (115), consider a single summand $\varphi_i(\ell_i; \mathcal{U})$ and define the vector

$$\theta^i \in \mathbb{R}^{m_i}, \quad \theta_{\ell_i}^i := \varphi_i(\ell_i; \mathcal{U}), \quad \ell_i \in [m_i], \quad (119)$$

whose components specify the finite range of the function φ_i . Then the problem of determining $\bar{\ell}_i$ corresponding to the minimal value of $\varphi_i(\ell_i; \mathcal{U})$ can be rewritten as

$$\min_{\mu^i \in \Delta_{m_i}} \langle \theta^i, \mu^i \rangle, \quad (120)$$

which is a *linear program (LP)*. Clearly, for general data defining θ^i by (119), the vector $\bar{\mu}^i$ minimizing (120) is a vertex of the simplex Δ_{m_i} corresponding to the indicator vector $\bar{\mu}^i = (0, \dots, 0, 1, 0, \dots, 0)^\top$ of the value $\bar{\ell}_i$. This reformulation can be applied in a straightforward way to the overall problem of minimizing (115), resulting in the LP

$$\min_{\mu \in \mathcal{M}_G} \langle \theta, \mu \rangle, \quad (121)$$

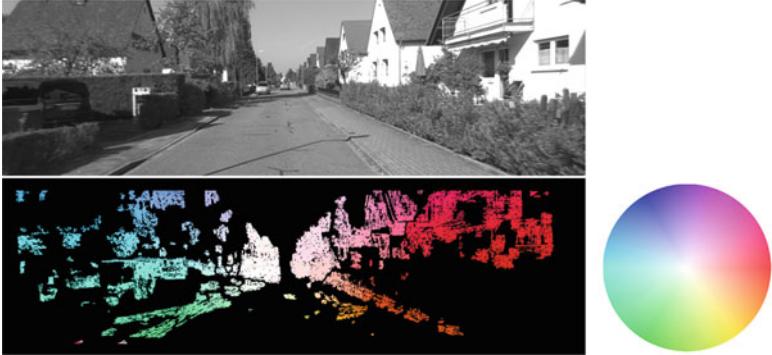

Fig. 15 *Top* Frame of a sequence, taken with a fast moving camera from the KITTI benchmark (section “Benchmarks”). *Bottom* Optical flow estimate based on MAP inference. The disk on the right displays the color code of flow vectors. Each image patch localized at x^i where a sufficiently discriminative feature could be extracted is associated with a set $\mathcal{U}(x^i)$ of possible assignment vectors $u_{\ell_i} \in \mathcal{U}(x^i)$. The displayed assignment field $\bar{u} := \{u_{\ell_i}\}_{i \in V}$ is determined by a labeling field $\bar{\ell}$ minimizing the functional (115). The latter combinatorial task has been solved to global optimality by an approach combining convex relaxation and integer programming [93]. Global optimality enables model validation: any deficiencies of the assignment field estimate are solely due to the model components, feature extraction, and constraints, as encoded by the MRF (118) through $J(\ell; \mathcal{U})$

defined over the so-called *marginal polytope* \mathcal{M}_G . This polytope is the convex hull of feasible vectors μ , as is the simplex Δ_{m_i} in (120) for the feasible vectors μ^i . The combinatorial complexity of determining the integer-valued minimizer of (115) is reflected by the complexity of the marginal polytope \mathcal{M}_G . This complexity is due to the interaction of variables ℓ_i, ℓ_j as defined by the edges $ij \in E$ of the underlying graph, besides the integer constraints $\ell_i \in [m_i], \forall i \in [n]$.

Formulation (121) is the starting point for *convex relaxations* by optimizing over simpler polytopes, defined by a *subset* of inequalities that specify facets of \mathcal{M}_G . The recent paper [92] reports a comprehensive evaluation of a broad range of approaches to problem (121). Figure 15 illustrates an application to optical flow estimation.

While research on inference methods for graphical models is supporting the design of new approaches to optical flow estimation, the need to restrict the range of u to a finite set \mathcal{U} is a significant restriction. As a consequence, approaches either exploit prior knowledge about u , so as to enable a covering of the relevant range of u with high resolution through the set \mathcal{U} with bounded size $|\mathcal{U}|$, or solve problem (117) once more after refining \mathcal{U} , based on a first estimate of u .

For instance, the work [94] exploits the probabilistic model (118) in order to estimate locally the uncertainty of a first estimate u , which in turn is used to refine the set \mathcal{U} so as to accommodate the discretization to the local variability of $u(x)$. The approach [95] first determines a coarse estimate of u in a preprocessing stage by global phase-based correlation, followed by defining possible refinements of $u(x)$ in terms of \mathcal{U} . The authors of [96]

rely on a prior estimate of the fundamental matrix F (34) using standard methods, which enables to properly define \mathcal{U} based on the epipolar constraint (38).

In a way, while the former two approaches mimic range refinement of variational methods through representing u at multiple scales (section “Multiscale”), the latter approach exploits geometrical prior knowledge in a similar way to variational methods as discussed in section “Geometrical Prior Knowledge.” Future research during the next decade will have to reveal more clearly the pros and cons of these related methods.

Variational Image Registration

The objective of *image registration* is to assign two images in terms of a diffeomorphism $u: \Omega \rightarrow \Omega$ of the underlying domain. A major motivation for this inherent *smoothness* of u has been applications to computational anatomy [97], based on fundamental work of Grenander, Dupuis, Trouve, Miller, Younes, and others – cf. [97–100] and references therein.

Another basic motivation for the methodology of image registration is the use of point features, so-called landmarks, for establishing sparse assignments, which need to be interpolated in a subsequent step to obtain a transform of the entire underlying domain. This is usually accomplished by kernel functions that span a corresponding Hilbert space of smooth functions with bounded point-evaluation functional [101, 102]. Interpolation with thin-plate splines is a well-known example, and extensions to approximating deformations are straightforward. See [103, 104] for corresponding overviews in connection with medical imaging.

The *large deformation diffeomorphic metric matching (LDDMM)* approach [99, 100, 105] that emerged from the works cited above has evolved over the years into a theoretical and computational framework for diffeomorphic image registration. In particular, the application to the assignment of point sets, in connection with kernel functions, leads to a canonical system of ODEs whose numerical solution generates a diffeomorphic assignment along a geodesic path on the diffeomorphism group. See [106] for recent references and an extension for better handling deformations at multiple scales.

The importance of this framework is due to the well-developed mathematical basis and due to its broad applicability in the fields of computational anatomy and medical imaging. The mathematical relations to continuum and fluid mechanics and the corresponding relevancy to imaging problems with physical prior knowledge (cf. section “Physical Prior Knowledge”) are intriguing as well. In the field of computer vision, deformable shape matching constitutes a natural class of applications, unlike the more common optical flow fields in natural videos that typically exhibit discontinuities, caused by depth changes and independently moving objects.

5 Open Problems and Perspectives

Unifying Aspects: Assignment by Optimal Transport

The mathematical theory of *optimal transport* [107, 108] provides a general formulation of the assignment problem that bears many relations to the approaches discussed so far.

Consider again the setup discussed in section ‘‘Assignment by Displacement Labeling’’: At each location x^i indexed by vertices $i \in V = [n]$, a vector $u(x^i) \in \mathcal{U}(x^i)$ from a set of candidates $\mathcal{U}(x^i)$ has to be selected. Put $\mathcal{U} = \cup_{i \in [n]} \mathcal{U}(x^i)$. Denote by V' the index set of all locations $\{x^i + u(x^i)\}_{u(x^i) \in \mathcal{U}(x^i)}$, $\forall i \in V$, that u may assign to the locations indexed by V . Then this setup is represented by the bipartite graph $G = (V, V'; E)$ with edge set $E = \{ij \in V \times V': \exists u \in \mathcal{U}, x^i + u = x^j\}$. The first term of the objective (115) specifies edge weights $\varphi_i(\ell_i; \mathcal{U})$ for each edge corresponding to the assignment $x^i + u_{\ell_i} = x^j$, and minimizing only the first term $\sum_{i \in V} \varphi_i(\ell_i; \mathcal{U})$ would *independently* select a unique vector $u(x^i)$ from each set $\mathcal{U}(x^i)$, $i \in V$, as solution to (120).

A classical way to remove this independency is to require the selection of *non-incident* assignments, that is, besides uniquely assigning a vector $u \in \mathcal{U}(x^i)$ to x^i , $\forall i \in V$, it is required that there is *at most one* correspondence $x^i + u = x^j$ for all $j \in V'$. This amounts to determining an optimal weighted *matching* in the bipartite graph $G = (V, V'; E)$. Formally, collecting the edge weights $\varphi_i(\ell_i; \mathcal{U})$ by a vector $\theta \in \mathbb{R}^m$, $m = \sum_{i \in V} m_i$, with subvectors given by (119), the LP

$$\min_{\mu \in \mathbb{R}^{|E(G)|}} \langle \theta, \mu \rangle \quad \text{subject to} \quad \mu \geq 0, \quad B_G \mu \leq \mathbf{1}_{|V \cup V'|}, \quad B_G \in \{0, 1\}^{|V \cup V'| \times |E|}, \quad (122)$$

has to be solved where B_G is the incidence matrix of graph G . It is well known that the polyhedron $\mathbb{R}_+^{|E|} \cap \{\mu: B_G \mu \leq \mathbf{1}_{|V \cup V'|}\}$ is integral [109], which implies a binary solution $\bar{\mu} \in \{0, 1\}^{|E|}$ to (122) satisfying the required uniqueness condition. Note that this condition may be regarded as a weak regularity condition enforcing a minimal degree of ‘‘smoothness’’ of the assignment field u .

The connection to optimal transport can be seen by reformulating problem (122). Put $n' = |V'|$ and let the matrix $c \in \mathbb{R}^{n \times n'}$ encode the *costs* of assigning (transporting) location x^i to $x^j = x^i + u$, $u \in \mathcal{U}(x^i)$. Then consider the problem

$$\min_{\mu \in \mathbb{R}^{n \times n'}} \langle c, \mu \rangle \quad \text{subject to} \quad \mu \geq 0, \quad \mu \mathbf{1}_{n'} = \mathbf{1}_n, \quad \mu^\top \mathbf{1}_n \leq \mathbf{1}_{n'}, \quad n \leq n', \quad (123)$$

where the unknowns are deliberately denoted again by μ . The second constraint says that each node $i \in V$ (location x^i) is uniquely assigned to some node $j \in V'$ (location x^j). The third constraint says that at most one vertex $i \in V$ is assigned to each $j \in V'$. The last condition $n' \geq n$ naturally holds in practical applications. It is straightforward to show [110, Prop. 4.3] that the solution $\bar{\mu} \in \{0, 1\}^{n \times n'}$ to (123) is again integral.

In the case $n = n'$, problem (123) equals the *linear assignment problem*, which is a discrete version of *Monge-Kantorovich* formulation of the *optimal transport* problem. The constraints of (123) then define the Birkhoff polytope, and the minimizer $\bar{\mu}$ at some vertex of this feasible set is a permutation matrix that uniquely maps V and V' onto each other. Matrices μ that are not vertices (extreme points) of the polytope are doubly stochastic; hence rows $\mu_{i,\bullet} \in \Delta_n$, $i \in [n]$ and columns $\mu_{\bullet,j}$, $j \in [n]$ represent *nondeterministic* assignments of vertices $i \in V$ and $j \in V'$, respectively.

The general formulation [107] considers Polish probability spaces $(\mathcal{X}, \mu_{\mathcal{X}})$, $(\mathcal{Y}, \mu_{\mathcal{Y}})$ with Borel probability measures $\mu_{\mathcal{X}} \in \mathcal{P}(\mathcal{X})$, $\mu_{\mathcal{Y}} \in \mathcal{P}(\mathcal{Y})$, and the set of *coupling measures*, again deliberately denoted by μ , that have $\mu_{\mathcal{X}}, \mu_{\mathcal{Y}}$ as marginals,

$$\begin{aligned} \mathcal{M}(\mu_{\mathcal{X}}, \mu_{\mathcal{Y}}) = \{ &\mu \in \mathcal{P}(\mathcal{X} \times \mathcal{Y}) : \mu(A \times \mathcal{Y}) = \mu_{\mathcal{X}}(A), \mu(\mathcal{X} \times B) = \mu_{\mathcal{Y}}(B), \\ &\forall A \subseteq \mathcal{B}(\mathcal{X}), \forall B \subseteq \mathcal{B}(\mathcal{Y}) \}. \end{aligned} \quad (124)$$

Given a Borel cost function $c: \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R} \cup \{+\infty\}$, the problem analogous to (123) in the case $n = n'$ reads

$$\inf_{\mu \in \mathcal{M}(\mu_{\mathcal{X}}, \mu_{\mathcal{Y}})} \int_{\mathcal{X} \times \mathcal{Y}} c(x, y) d\mu(x, y). \quad (125)$$

A central question concerns conditions on c that imply existence of *deterministic* minimizers $\bar{\mu}$ of (125), that is, existence of a measurable function $T: \mathcal{X} \rightarrow \mathcal{Y}$ such that for random variables (X, Y) with law μ , the relation $Y = T(X)$ holds. The *assignment* T is called *transportation map* that “pushes forward” the “mass” represented by $\mu_{\mathcal{X}}$ onto $\mu_{\mathcal{Y}}$, commonly denoted $T_{\#}$:

$$T_{\#}\mu_{\mathcal{X}} = \mu_{\mathcal{Y}} \quad \text{with} \quad \mu_{\mathcal{Y}}(B) = \mu_{\mathcal{X}}(T^{-1}(B)), \quad \forall B \in \mathcal{B}(\mathcal{Y}). \quad (126)$$

Likewise, $\bar{\mu}$ is concentrated on the graph of T , akin to the concentration of minimizers of (123) on a set of binary matrices.

Due to its generality formulation, (125) provides a single framework for addressing a range of problems, related to optical flow estimation by assignment. This particularly includes:

- The representation of both discrete and continuous settings, as sketched above, and the applicability to the assignment of arbitrary objects, as defined by the spaces \mathcal{X}, \mathcal{Y} .
- The focus on the combinatorial nature of the assignment problem, on convex duality and tightness or lack of tightness of the convex relaxation (125), together with a probabilistic interpretation in the latter case.
- Conservation of mass reflects the invariance assumption underlying (2) and (6), respectively.
- The differential, dynamic viewpoint: Let $\mathcal{X} = \mathbb{R}^d$ and define the cost function

$$c(x, y) = \|x - y\|^2 \quad (127)$$

and the *Wasserstein space* $(\mathcal{P}_2(\mathcal{X}), W_2)$ of Borel probability measures

$$\mathcal{P}_2(\mathcal{X}) := \{\mu_{\mathcal{X}} \in \mathcal{P}(\mathcal{X}): \int_{\mathcal{X}} \|x - y\|^2 d\mu_{\mathcal{X}}(x) < \infty, \forall y \in \mathcal{X}\}, \quad (128)$$

equipped with the *Wasserstein distance*

$$W_2(\mu_{\mathcal{X}}, \mu'_{\mathcal{X}}) := \left(\int_{\mathcal{X} \times \mathcal{X}} \|x - y\|^2 d\bar{\mu}(x, y) \right), \quad \forall \bar{\mu} \text{ solving } (125), \quad (129)$$

with $\mu_{\mathcal{Y}}$ replaced by $\mu'_{\mathcal{X}}$ in (125). Then the path $(\mu_{\mathcal{X},t})$ defined by

$$\mu_{\mathcal{X},t} = ((1-t)I + tT)_{\#}\mu_{\mathcal{X}} \quad (130)$$

and some optimal map T via (126) satisfies the continuity equation

$$\frac{d}{dt} \mu_t + \operatorname{div}(v_t \mu_t) = 0 \quad (131)$$

with velocity field $v_t: \mathbb{R}^d \rightarrow \mathbb{R}^d$ given by $v_t = (T - I) \circ ((1-t)I + tT)^{-1}$, $\forall t$ in the sense of distributions. Equation (131) provides a natural connection to continuum and fluid mechanics (cf., e.g., [111]) and also to flows generating diffeomorphic assignments under additional assumptions [100, Ch. 11]. Comparing (131) and (58) shows that, if g is regarded as a density for the scalar case $p = 1$, condition (57) is a strong assumption implying $\operatorname{div}u = 0$.

The generality of this framework explains too, however, why the regularity of solutions to the Monge-Kantorovich problem is a subtle issue, even when given as deterministic assignment T . This is also apparent through Euler's equation (131), which lacks any viscous term that would induce some regularity.

From this viewpoint, much of the research related to variational optical flow estimation, and to the related problems discussed in Sect. 4, can be understood as:

- (i) Interplay between modeling additional terms that induce a desired degree of spatial regularity
- (ii) Investigation of how this affects relaxation of the assignment problem from the optimization point of view and the accuracy of its solution.

As a consequence, *no sharp boundaries can (and should) be defined that separate these subfields of research*. For instance,

- The paper [112] suggested an early heuristic attempt to combine bipartite graph matching and thin-plate spline-based registration.
- The work [113] combines smoothing with radial basis functions and MRF-based labeling (section “Assignment by Displacement Labeling”) for medical image registration.
- More generally, concerning image labeling, modeling spatial context by the edge-indexed terms φ_{ij} of the objective (115) entails the need to relax combinatorially complex polyhedral feasible sets like the marginal polytope in (121), whose vertices may *not* correspond to deterministic assignments, unlike assignments as solutions in the simpler case (122).
- The authors of [114] introduce a smoothing operator to solve numerically the Monge-Kantorovich problem.
- In [115] a related objective from continuum mechanics is proposed that, for a limiting value of some parameter, models a *viscous* fluid, hence ensures spatial regularity in a physically plausible way, as opposed to the pure continuity equation (131) that is lacking any such term. Assignments are computed by numerically tracing corresponding geodesic paths.
- Much more general objectives for assignments are addressed in [116] that take explicitly into account the metric structure of the underlying space \mathcal{X} . The problem to “linearize” this combinatorially complex objective in terms of the Monge-Kantorovich problem is studied in [110], along with the problem to define a cost function c so as to preserve the discriminative power of the original objective as much as possible.
- The recent work [117] exploits the Wasserstein distance (129) so as to solve simultaneously template-based assignment and image segmentation, by globally minimizing a corresponding joint variational objective.

This sample of the literature suggests to conclude that in the field of variational image registration (e.g., [100, 115]), sophisticated variational approaches exist that are satisfying in both respects (i),(ii) discussed above: these approaches clearly exhibit their properties mathematically, and they induce regularity without compromising accuracy of assignments, due to a good agreement with the physical properties of the objects being matched.

Outside these fields, a similar quality only holds for variational approaches to optical flow estimation that are constrained by – again: physically motivated – state equations (section “Physical Prior Knowledge”). A similar level of rigor has not been reached yet in a major application area of optical flow estimation: motion-based analysis of videos of unrestricted scenes with uncontrolled viewpoint changes and with independently moving rigid and articulated objects. This deficiency of related models is aggravated by the need for natural extensions of frame-to-frame assignments to the permanent analysis of *dynamic* scenarios over time (cf. section “Probabilistic Modeling and Online Estimation”).

Motion Segmentation, Compressive Sensing

Research on *compressive sensing* [118, 119] and corresponding applications has been pervading all fields of empirical data analysis, including image reconstruction and more recently video analysis. A central theme is provable guarantees of signal recovery in polynomial runtime using sub-Nyquist sampling rates and convex relaxations of combinatorial objective functions for signal reconstruction. For instance, the most common scenario concerns the recovery of $u \in \mathbb{R}^n$ from $m \ll n$ linear measurements $Au = b \in \mathbb{R}^m$, by minimizing

$$\min_u \|u\|_1 \quad \text{subject to} \quad Au = b, \quad (132)$$

under the assumption that u is k -sparse, i.e.,

$$\|u\|_0 := |\text{supp}(u)| = |\{i \in [n]; u_i \neq 0\}| \leq k. \quad (133)$$

The objective in (132) constitutes a convex relaxation of the combinatorial objective $\|u\|_0$, and suitable conditions on A , e.g., A is close to an isometry on the subset of $2k$ -sparse vectors, guarantee unique recovery of u with high probability.

This section presents next an extension of this basic reconstruction principle to video analysis by sketching the recent work reported by [120]. Let

$$f_t \in \mathbb{R}^n, \quad t \in [T], \quad (134)$$

denote the raw image sequence data in terms of vectorized image frames f_t , $t = 1, 2, \dots, T$. Assuming a stationary camera as in surveillance applications, the objective is to separate the static background from objects moving in the foreground. The ansatz is based on the following modeling assumptions:

- At each point of time $t \in T$, image data are only sampled on a subset $\Omega_t \subset \Omega$ of the discretized domain Ω , resulting in subvectors

$$f_{\Omega_t}, \quad t \in [T]. \quad (135)$$

The sample set Ω_t may vary with t .

- The variation of components of f_{Ω_t} corresponding to the static background is caused by global smooth illumination changes. Hence, this part of f_{Ω_t} can be represented by a low-dimensional subspace

$$U_{\Omega_t} v_t, \quad U_{\Omega_t} \in \mathbb{R}^{|\Omega_t| \times n_U}, \quad t \in [T], \quad (136)$$

generated by n_U orthonormal columns of a matrix U_t that are subsampled on Ω_t and some coefficient vector v_t . Research in computer vision [121, 122] supports this subspace assumption.

- Objects moving in the foreground cover only small regions within Ω . Hence they can be represented by vectors

$$s_{\Omega_t} \quad \text{with} \quad |\text{supp}(s)| \ll n. \quad (137)$$

Putting all together the model reads

$$f_{\Omega_t} = U_{\Omega_t} v_t + s_{\Omega_t}, \quad t \in [T], \quad (138)$$

and convex relaxation of minimizing $|\text{supp}(s)|$ due to (137) leads to the recovery approach

$$\min_{U, v_t, s_{\Omega_t}} \|s_{\Omega_t}\|_1 \quad \text{subject to} \quad U_{\Omega_t} v_t + s_{\Omega_t} = f_{\Omega_t}. \quad (139)$$

Comparison to (132) shows similar usage of the sparsity-inducing ℓ^1 norm and subsampled measurements (135) as input data. On the other hand, the low-dimensional representation (136) of the static part of the video is estimated as well, and the entire video is recovered in terms of U_t (hence U rather than U_{Ω_t} is optimized in (139)). In fact, this joint optimization problem is *non-convex* and handled in [120] by alternating optimization:

- For *fixed* U_t , problem (139) is solved by applying ADMM (cf. section “Non-smooth Convex Functionals”) to the augmented Lagrangian $L_\lambda(U, v_t, s_{\Omega_t}, w_{\Omega_t})$ with multiplier vector w_{Ω_t} and parameter λ as in (95).
- Having determined $v_t, s_{\Omega_t}, w_{\Omega_t}$, the subspace U_t is tracked by performing gradient descent with respect to $L(\cdot, v_t, s_{\Omega_t}, w_{\Omega_t})$ on the Grassmannian $\mathcal{G}(n_U, \mathbb{R}^n)$ (cf., e.g., [123]), resulting in U_{t+1} .

The closely related static viewpoint on the same problem reveals its relevancy to several important research directions. Let

$$F = [f_1, \dots, f_T] = L + S \quad (140)$$

denote the whole video data that, due to the reasoning above, are supposed to be decomposable into a *low-rank* matrix L and a *sparse* matrix S . The corresponding convex relaxation approach [124] reads

$$\min_{L, S} \|L\|_* + \alpha \|S\|_1 \quad \text{subject to} \quad L + S = F, \quad (141)$$

where $\|L\|_* = \sum_i \sigma_i(L)$ denotes the nuclear norm in terms of the singular values of L and $\|S\|_1 = \sum_{i,j} |S_{ij}|$. Here, the nuclear norm $\|\cdot\|_*$ constitutes a convex relaxation of the combinatorial task to minimize the rank of L , analogous to replacing the combinatorial objective $\|u\|_0$ in (133) by $\|u\|_1$ in (132). Clearly, the online ansatz (138) along with the corresponding incremental estimation approach

is more natural for processing *long* videos. The price to pay is the need to cope with a non-convex (albeit smooth) problem, whereas the batch approach (141) is convex.

Future research will tackle the challenging, more general case of non-static backgrounds and moving cameras, respectively. For scenarios with small displacements $u(x)$, work that represents the state of the art is reported in [125]. Results in computer vision that support subspace models and low-rank assumptions have been established [126], and the problem of clustering data lying in unknown low-dimensional subspaces has received considerable attention [127–129].

From a broader perspective, video analysis and motion-based segmentation provide attractive connections to research devoted to union-of-subspaces models of empirical data and relevant compressive sensing principles [130–132] and to advanced *probabilistic* models and methods for nonparametric inference [133, 134].

Probabilistic Modeling and Online Estimation

There is a need for advanced probabilistic models, and three related aspects of increasing difficulty are briefly addressed:

- A persistent issue of most variational models of mathematical imaging, including those for optical flow estimation, concerns the *selection of appropriate hyperparameter values*, like the parameter σ of (62) weighting the combination of data term and regularizer (56). In principle, Bayesian hierarchical modeling [135] provides the proper framework for calibrating variational models in this respect. The paper [136] illustrates an application in connection with optical flow estimation, based on the marginal data likelihood [137] interpreted as hyperparameter (model) evidence.

Estimating hyperparameter values from the given data in this way entails the evaluation of high-dimensional integrals for marginalization, commonly done using Laplace’s method and a corresponding approximation by Gaussian (quadratic) integrals [138, 139]. A validation for complex high-dimensional posterior distributions encountered in variational imaging is involved, however, and is also stimulating more recent research in the field of statistics [140].

Using discrete variational models (section “Assignment by Displacement Labeling”) aggravates this problem, due to considerable computational costs and since no widely accepted methods have been established analogous to the abovementioned approximations.

- Computational costs in connection with runtime requirements become a serious problem when *dynamic scenarios* are considered. While extensions of the domain to $\Omega \times [0, T]$ like in (82) are straightforward mathematically and have proven to significantly increase accuracy of optical flow estimation, employing a static model in terms of elliptic Euler-Lagrange systems to a dynamic system appears somewhat odd, not to mention the need to shift the time interval $[0, T]$ along the time axis in order to analyze long image sequences.

Such extensions appear more natural in connection with dynamic physical models constraining optical flow estimation, as opposed to stationary formulations like (88). See [141] for a corresponding approach to data assimilation [142]. A nice feature of this method is the ability to estimate initial conditions that are generally unknown, too. On the other hand, the computational costs necessitate to propagate a low-dimensional POD-projection of the state variables (POD: proper orthogonal decomposition) since the control of dynamical systems [70] entails looping forward and backward through the entire time interval.

- The last remark points to the need for *online estimation methods* that are *causal and optimal*, in connection with the analysis of dynamical system through image analysis. Again the proper framework is known since decades: Given stochastic state and observation processes

$$S = \{S_t\}_{t \geq 0}, \quad G = \{G_t\}_{t \geq 0}, \quad (142)$$

stochastic filtering[143] amounts to determine the conditional distribution of S_t given the observation history and to evaluate it in terms of expectations of the form $\mathbb{E}[\varphi(S_t)|g_s, 0 \leq s \leq t]$, for some statistic $\varphi(\cdot)$ of interest (e.g., simply $\varphi(S_t) = S_t$) and conditioned on realizations g_s of G_s , $s \in [0, t]$. Most research during the last decade considered the design of particle filters [143, 144] to the estimation of *low*-dimensional states based on image measurements. This does not scale-up however to high-dimensional states like optical flows $S_t = u_t$.

An attempt to mimic online estimation in connection with instationary optical flows related to experimental fluid dynamics is presented in [68], with states and their evolution given by vorticity transport. For low signal-to-noise ratios and sufficiently high frame rates, the approach performs remarkably well. Another dynamical computer vision scenario is discussed in the recent work [57]. Here the states $S_t = (z_t, \{h_t, R_t\}) \in \mathbb{R}^n \times \text{SE}(3)$ are dense depth-maps z_t (cf.(83)) together with varying motion parameters $\{h_t, R_t\}$ describing the observer's motion relative to the scene, to be estimated from image sequence features g_t as measurements via optical flow estimates u_t – see Fig. 13. The approach involves prediction and fusion steps based on Gaussian approximation and joint optimization, yet cannot be considered as direct application of the stochastic filtering framework, in a strict sense. This assessment applies also to labeling approaches (section “Assignment by Displacement Labeling”) and their application to dynamic scenarios.

6 Conclusion

Optical flow estimates form an essential basis for low-level and high-level image sequence analysis and thus are relevant to a wide range of applications. Corresponding key problems, concepts, and their relationships were presented, along with numerous references to the literature for further study. Despite three decades of research, however, an overall coherent framework that enables to mathematically

model, predict, and estimate the performance of corresponding computational systems in general scenarios is still lacking. This short survey will hopefully stimulate corresponding methodological research.

7 Basic Notation

List of major symbols used in the text

| Symbol | Brief description | Reference |
|---|---|---|
| r.h.s. | abbr.: right-hand side (of some equation) | |
| w.r.t. | abbr.: with respect to | |
| w.l.o.g. | without loss of generality | |
| LP | linear program | |
| $\mathbb{1}_n \in \mathbb{R}^n$ | $(1, 1, \dots, 1)^\top$ | |
| $[n], n \in \mathbb{N}$ | integer range $\{1, 2, \dots, n\}$ | |
| $[n]_0, n \in \mathbb{N}$ | integer range $\{0, 1, \dots, n - 1\}$ | |
| $\Omega \subset \mathbb{R}^d$ | image domain; typically $d \in \{2, 3\}$ | |
| $x = (x_1, \dots, x_d)^\top \in \Omega$ | image point | |
| $u(x, t) \in \mathbb{R}^d$ | assignment, motion or optical flow field | (4), (7), (8) |
| $X = (X_1, X_2, X_3)^\top \in \mathbb{R}^3$ | scene point | Sections “Assignment Fields” and “Motion Fields” |
| $y \in \mathbb{P}^2, Y \in \mathbb{P}^3$ | homogeneous representation of image and scene points x and X , resp. | Section “Two-View Geometry” |
| $\text{SO}(3), \mathfrak{so}(3)$ | special orthog. group and its Lie algebra | |
| $\text{SE}(3)$ | group of Euclidean (rigid) transf. of \mathbb{R}^3 | |
| $\{h, R\} \in \text{SE}(3)$ | Euclidean transformation of \mathbb{R}^3 | (28) |
| $[q]_\times \in \mathfrak{so}(3), q \in \mathbb{R}^3$ | skew-symm. matrix defined by | |

(continued)

Abstract

Image registration is to automatically establish geometrical correspondences between two images. It is an essential task in almost all areas involving imaging. This chapter reviews mathematical techniques for nonlinear image registration and presents a general, unified, and flexible approach. Taking into account that image registration is an ill-posed problem, the presented approach is based on a variational formulation and particular emphasis is given to regularization functionals motivated by mathematical elasticity. Starting out from one of the most commonly used linear elastic models, its limitations and extensions to nonlinear regularization functionals based on the theory of hyperelastic materials are considered. A detailed existence proof for hyperelastic image registration problems illustrates key concepts of polyconvex variational calculus. Numerical challenges in solving hyperelastic registration problems are discussed and a stable discretization that guarantees meaningful solutions is derived. Finally, two case studies highlight the potential of hyperelastic image registration for medical imaging applications.

1 Introduction

Image registration is an essential task in a variety of areas involving imaging techniques such as astronomy, geophysics, and medical imaging; see, e.g., [11, 27, 31, 45, 52, 55, 73] and references therein. The goal of image registration is to automatically find geometrical correspondences between two or more images acquired; see also Fig. 1 for a simplified example. Measurements may result from different times, from different devices, or perspectives. More specifically, one aims to find a *reasonable* transformation, such that a transformed version of the first image is *similar* to the second one. Mathematically, image registration is an ill-posed problem and is thus typically phrased as a variational problem involving data fit and regularization. The data fit or distance functional measures the similarity of the images. The regularization functional quantifies the reasonability of the transformation and can also be used to guarantee a mathematically sound formulation and to favor solutions that are realistic for the application in mind.

This chapter presents a comprehensive overview of mathematical techniques used for nonlinear image registration. A particular focus is on regularization techniques that ensure a mathematically sound formulation of the problem and allow stable and fast numerical solution.

Starting out from one of the most commonly used linear elastic models [10, 55], its limitations and extensions to nonlinear regularization functionals based on the theory of hyperelastic materials are discussed. A detailed overview of the available theoretical results is given and state-of-the-art numerical schemes as well as results for real-life medical imaging applications are presented.

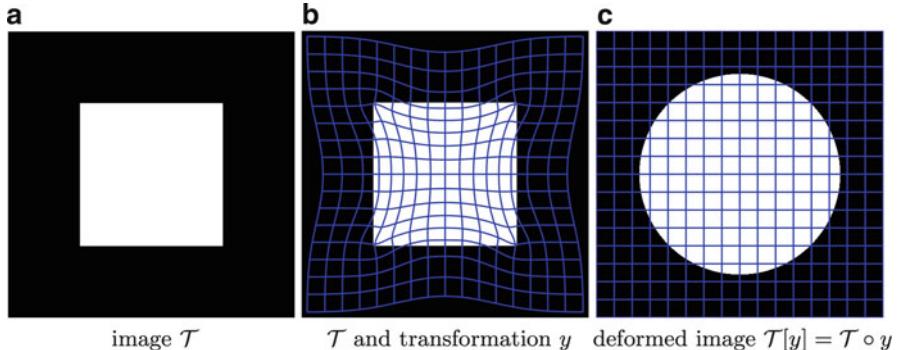

Fig. 1 Transforming a square into a disc: template image \mathcal{T} is a white square on black background (left), reference image \mathcal{R} is a white disk on black background (not displayed), the transformation y is visualized by showing a regular grid X as overlay on the deformed image $\mathcal{T}[y]$ (right) and as $y(X)$ on the template image (center); note that $\mathcal{T}[y](x) = \mathcal{T}(y(x))$

2 The Mathematical Setting

The purpose of this section is to provide a brief, conceptual introduction to a variational formulation of image registration, see section “Variational Formulation of Image Registration”. For brevity, the presentation is restricted to a small subset of the various configurations of the variational problem and is limited to 3D problems which today is most relevant in medical imaging applications. Section “Images and Transformation” defines a continuous model for images and formalizes the concept of transformations y and transformed images $\mathcal{T}[y]$. Section “Length, Area, and Volume Under Transformation” discusses the transformation of length, area, and volume. These geometrical quantities play an important role for the computation of locally invertible transformations, which are important for many clinical applications.

After having discussed the general concepts on a rather broad level, specific building blocks of the variational framework are examined in more detail. Section “Distance Functionals” introduces two common choices of distance functionals \mathcal{D} , which measures the alignment of the images. After motivating the demand for regularization by illustrating the ill-posedness of the variational problem in section “Ill-Posedness and Regularization”, an overview of elastic regularization functionals and a discussion of their limitations is given in section “Elastic Regularization Functionals”.

Motivated by the limitations of elastic regularization functionals extensions to hyperelastic functionals, designed to ensure invertible and reversible transformations, are presented in section “Hyperelastic Regularization Functionals”. Subsequently, section “Constraints” presents two examples that demonstrate how constraints \mathcal{C} can be used to restrict set of admissible transformations \mathcal{A} , to favor

practically relevant solutions, and most importantly, to exclude practically infeasible solutions.

Finally, a comprehensive overview of related literature and suggestions for further readings are provided in section “Related Literature and Further Reading”.

Variational Formulation of Image Registration

Given the so-called template image \mathcal{T} and the so-called reference image \mathcal{R} , the image registration problem can be phrased as a variational problem. Following [55], an energy functional \mathcal{J} is defined as a sum of the data fit \mathcal{D} depending on the input images and the transformation and a regularization \mathcal{S} ,

$$\mathcal{J}[y] := \mathcal{D}[\mathcal{T}, \mathcal{R}; y] + \mathcal{S}[y]. \quad (1)$$

The objective is then to find a minimizer y of \mathcal{J} in a feasible set \mathcal{A} to be described,

$$\min \mathcal{J}[y] \quad \text{for } y \in \mathcal{A}. \quad (2)$$

Advantages of this formulation are its great modelling potential and its modular setting that allows to obtain realistic models tailored to essentially any particular application.

Images and Transformation

This section introduces a continuous image model, transformations, and discusses geometrical transformations of images. Although the image dimension is conceptually arbitrary, the description is restricted to 3D images for ease of presentation.

Definition 1 (Image). Let $\Omega \subset \mathbb{R}^3$ be a domain, i.e., bounded, connected, and open. An *image* is a one-time continuously differentiable function $\mathcal{T} : \mathbb{R}^3 \rightarrow \mathbb{R}$ compactly supported in Ω . The set of all images is denoted by $\text{Img}(\Omega)$.

Note that already a simple transformation of an image such as a rotation requires a continuous image model. Therefore, a continuous model presents no limitation, even if only discrete data is given in almost all applications. Interpolation techniques are used to lift the discrete data to the continuous space; see, e.g., [55] for an overview. As registration is tackled as an optimization problem, continuously differentiable models can provide numerical advantages.

Definition 2 (Transformation). Let $\Omega \subset \mathbb{R}^3$ be a domain. A *transformation* is a function $y : \Omega \rightarrow \mathbb{R}^3$. For a differentiable transformations, the *Jacobian matrix* is denoted by

$$\nabla y := \begin{pmatrix} \partial_1 y & | & \partial_2 y & | & \partial_3 y \end{pmatrix} := \begin{pmatrix} \partial_1 y_1 & \partial_2 y_1 & \partial_3 y_1 \\ \partial_1 y_2 & \partial_2 y_2 & \partial_3 y_2 \\ \partial_1 y_3 & \partial_2 y_3 & \partial_3 y_3 \end{pmatrix}.$$

The function $u : \Omega \rightarrow \mathbb{R}^3$ satisfying $y(x) = x + u(x)$ is called *displacement*, $\nabla y = I + \nabla u$, where I denotes a diagonal matrix of appropriate size with all ones on its diagonal.

Example 1. An important class of transformations are *rigid transformations*. Let $b \in \mathbb{R}^3$ describes a translation and $Q \in \mathbb{R}^{3 \times 3}$ a rotation matrix,

$$\begin{aligned} \mathcal{A}_{\text{rigid}}(\Sigma) := \{y : y(x) = Qx + b \text{ a.e. on } \Sigma, \\ b \in \mathbb{R}^3, Q \in \mathbb{R}^{3 \times 3}, Q^\top Q = I, \det Q = 1\}. \end{aligned}$$

A transformation y is rigid on Σ , if $y \in \mathcal{A}_{\text{rigid}}(\Sigma)$.

Given an image \mathcal{T} and an invertible transformation y , there are basically the Eulerian or Lagrangian way to define the transformed version $\mathcal{T}[y]$; see [38, 55] for more details. In the Eulerian approach the transformed image is defined by

$$\mathcal{T}[y] : \mathbb{R}^3 \rightarrow \mathbb{R}, \quad \mathcal{T}[y](x) := \mathcal{T}(y(x)). \quad (3)$$

In other words, assigning position x in $\mathcal{T}[y]$ the intensity of \mathcal{T} at position $y(x)$; see illustration in Fig. 1. The Lagrangian approach transports the information $(x, \mathcal{T}(x))$ to $(y(x), \mathcal{T}(x))$, where the first entry denotes location and the second intensity. In image registration, typically, the Eulerian framework is used. However, the Lagrangian framework can provide advantages in a constrained setting; see [38] for a local rigidity constrained and the discussion in section “Constraints”.

Length, Area, and Volume Under Transformation

This section relates changes of length, area, and volume in the deformed coordinate system to the gradient of the transformation y . To simplify the presentation, it is assumed that y is invertible and at least twice continuously differentiable.

Using Taylor’s formula [18], a local approximation of the transformation at an arbitrary point x in direction $v \in \mathbb{R}^3$ is given by

$$y(x + v) = y(x) + \nabla y(x) v + \mathcal{O}(|v|^2). \quad (4)$$

Choosing $v = he_i$, it can be seen that the columns of the gradient matrix $\nabla y(x)$ approximate the edges of the transformed reference element; see also Fig. 2. Thus, changes of length, area, and volume of a line segment L connecting x and $x + he_i$,

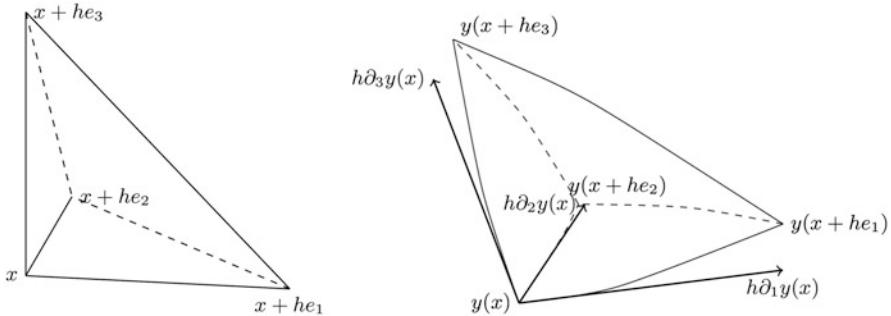

Fig. 2 Visualization of a deformation of a tetrahedron and the Taylor approximation of the transformation y . At an arbitrary point x a tetrahedron is spanned by the scaled Euclidean unit vectors (*left*). The edges of the deformed tetrahedron are approximated by the columns of the gradient $\nabla y(x)$ (*right*). Due to this approximation property, geometric quantities such as volume, area, and length can be related to the gradient matrix, its cofactor, and its determinant

a triangle T spanned by x , $x + he_j$, and $x + he_k$, and a tetrahedron P spanned by x and the three scaled Euclidean vectors are approximately

$$\text{length}(y(L)) = |y(x + he_i) - y(x)| = |\partial_i y| + \mathcal{O}(h^2),$$

$$\text{area}(y(T)) = \frac{h^2}{2} |\partial_j y \times \partial_k y| + \mathcal{O}(h^2),$$

$$\text{vol}(y(P)) = h^3 \det(\partial_1 y \mid \partial_2 y \mid \partial_3 y) + \mathcal{O}(h^2) = h^3 \det \nabla y + \mathcal{O}(h^2),$$

where \times denotes the outer product in \mathbb{R}^3 .

The cofactor matrix $\text{cof} \nabla y$ summarizes, column wise, the area changes of the three triangles spanned by x with two scaled Euclidean vectors each,

$$\text{cof} \nabla y = (\partial_2 y \times \partial_3 y \mid \partial_3 y \times \partial_1 y \mid \partial_1 y \times \partial_2 y) \in \mathbb{R}^{3 \times 3}.$$

At this point, the importance of limiting the range of $\det \nabla y$ for many clinical applications should be stressed. Due to the inverse function theorem [25, Sect. 5], a transformation $y \in C^1(\Omega, \mathbb{R}^3)$ is locally one-to-one if $\det \nabla y \neq 0$. From the above considerations, it can be seen that $\det \nabla y = 0$ indicates annihilation of volume and $\det \nabla y < 0$ indicates a change of orientation. Thus, controlling the range of $\det \nabla y$, or analogously the range of compression and expansion of volume, ensures local invertibility and thus is of utmost importance in practical applications.

Distance Functionals

The variational formulation of the image registration problem (2) characterizes an optimal transformation as a minimizer of the sum of a distance and a regularization

functional subject to optional constraints. These three building blocks will be introduced and discussed in the following sections.

Distance functionals mimic the observer's perception to quantify the similarity of images. In the following, two examples of distance measures will be presented and the reader is referred to [55] for further options. Emphasis is on a mass-preserving distance measure, which is an attractive option for the registration of density images such as Positron Emission Tomography (PET) images; see also section "Motion Correction of Cardiac PET".

A robust and widely used distance measure is the L^2 -norm of the intensity differences commonly referred to as the *sum-of-squared-difference* (SSD),

$$\mathcal{D}^{\text{SSD}}[y] = \mathcal{D}^{\text{SSD}}[\mathcal{T}, \mathcal{R}; y] = \frac{1}{2} \int_{\Omega} (\mathcal{T}(y(x)) - \mathcal{R}(x))^2 dx. \quad (5)$$

For this distance measure to be effective, intensity values at corresponding points in the reference and template image are assumed to be equal. This assumption is often satisfied when comparing images of the same modality, commonly referred to as *mono-modal* registration. Hence, \mathcal{D}^{SSD} is a prototype of *mono-modal* distance functionals.

In some applications intensities at corresponding points differ conceptually. Typical examples of multimodal image registration include the fusion of different modalities like anatomy (such as CT or MRI) and functionality (such as SPECT or PET); see, e.g., [55] for further options and discussions.

Mass densities are another example for conceptional different image intensities. The necessity of mass-preserving transformations was first discussed in [29]. Recently, mass-preserving distance functionals were used to register images from Positron Emission Tomography (PET); see section "Motion Correction of Cardiac PET" and [14, 30, 60]. Another application is the correction of image distortions arising from field inhomogeneities in Echo-Planar Magnetic Resonance Imaging; see section "Susceptibility Artefact Correction of Echo-Planar MRI" and [15, 62].

Due to mass-preservation, change of volume causes change of intensities. Note that the simple model for transformed images (3) does not alter image intensities. Let $V \subset \Omega$ denotes a small reference volume. Ideally, the mass of \mathcal{R} contained in V has to be equal to the mass of \mathcal{T} contained in $y(V)$. Formally,

$$\int_V \mathcal{R}(x) dx = \int_{y(V)} \mathcal{T}(x) dx = \int_V \mathcal{T}(y(x)) \cdot \det \nabla y(x) dx, \quad (6)$$

where the second equality holds by the transformation theorem [18, p. 31f], assuming that the transformation is injective, continuously differentiable, orientation preserving, and that its inverse is continuous. A natural *mass-preserving* extension of the SSD distance functional thus reads

$$\mathcal{D}^{\text{MP}}[y] := \frac{1}{2} \int_{\Omega} (\mathcal{T}(y(x)) \cdot \det \nabla y(x) - \mathcal{R}(x))^2 dx. \quad (7)$$

III-Posedness and Regularization

A naive approach to image registration is to simply minimize the distance functional \mathcal{D} with respect to y . However, this is an *ill-posed* problem [23, 27, 46, 55]. According to Hadamard [41], a problem is *well-posed*, if there exists a solution, the solution is unique, and the solution depends continuously on the data. If one of these criteria is not fulfilled, the problem is called *ill-posed*.

In general, existence of a minimizer of the distance functional cannot be expected. Even the rather simple SSD distance functional (5) depends in a non-convex way on the transformation; for a discussion of more general distance functionals, see [55, p. 112]. If the space of plausible transformations is infinite dimensional, existence of solutions is thus critical.

A commonly used approach to bypass these difficulties and to ensure existence is to add a regularization functional that depends convexly on derivatives of the transformation [10, 67, 68]. This strategy is effective for distance functionals are independent of or depend convexly on the gradient of the transformation. This is the case in most applications of image registration, for instance, for the SSD in (5). However, further arguments are required for the mass-preserving distance functional in (7) due to the non-convex of the determinant; see Sect. 1.

It is also important to note that distance functionals may be affected considerably by noise; see also [55]. This problem is often (partially) alleviated by using regularization functionals based on derivatives of the transformation. This introduces a coupling between adjacent points, which can stabilize the problem against such local phenomena.

Note, even though regularization ensures existence of solutions, the objective functional depends in a non-convex way on the transformation and thus a solution is generally not unique as the following example illustrates.

Example 2. Consider an image of a plain white disc on a plain black background as a reference image and a template image showing the same disc after a translation. After shifting the template image to fit the reference image, both images are identical regardless of rotations around the center of the disc. Hence, there are infinitely many rigid transformations yielding images with optimal similarity. Regularization can be used to differentiate the various global optimizers.

Elastic Regularization Functionals

The major task of the regularization functional \mathcal{S} is to ensure existence of solutions to the variational problem (2) and to ensure that these solutions are plausible for the application in mind. Therefore, regularization functionals that relate to a physical model are commonly used. In this section it is assumed that the transformation y is at least one time continuously differentiable and sufficiently measurable. A formal

definition of an elastic regularization functional and its associated function spaces is postponed to section “Hyperelastic Regularization Functionals”.

The idea of elastic regularization can be traced back to the work of Fischler and Elschlager [28] and particularly the landmarking thesis of Broit [10]. The assumption is that the objects being imaged deform elastically. By applying an external force, one object is deformed in order to minimize the distance to the second object. This *external* force is counteracted by an *internal* force given by an elastic model. The registration process is stopped in an equilibrium state, that is, when external and internal forces balance.

In linear elastic registration schemes, the internal force is based on the displacement u and the *Cauchy strain tensor*

$$V = V(u) = (\nabla u + \nabla u^\top)/2,$$

which depends linearly on u . The *linear elastic* regularization functional is then defined as

$$\mathcal{S}^{\text{elas}}[u] = \int_{\Omega} \nu(\text{trace } V)^2 + \mu \text{trace}(V^2) \, dx,$$

where ν and μ are the so-called Lamé constants [18, 53].

Benefits and drawbacks of the model $\mathcal{S}^{\text{elas}}$ relate to the linearity of V in ∇u . Its simplicity has been exploited for the design of computationally efficient numerical schemes such as in [37]. A drawback is the limitation to small strains, that is, transformations with $\|\nabla u\| \ll 1$; see [10, 18, 55]. For large geometrical differences, the internal forces are modelled inadequately and thus solutions may become meaningless.

While the motivation in [10] is to stabilize registration against low image quality, elastic regularization also ensures existence of solutions in combination with many commonly used distance functionals. Another desired feature of this regularizer is that smooth transformations are favored, which is desirable in many applications.

In order to overcome the limitation to small strains, Yanovsky et al. [72] proposed an extension to nonlinear elasticity. They used the *Green-St.-Venant strain tensor*

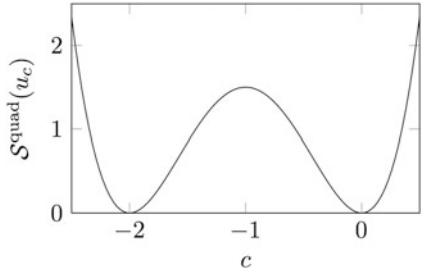

$$E = E(u) = (\nabla u + \nabla u^\top + \nabla u^\top \nabla u)/2, \quad (8)$$

which is a quadratic in ∇u . Revisiting the computations of changes in length in section “Length, Area, and Volume Under Transformation”, it can be shown that E penalized changes of lengths. The *quadratic elastic* regularization functional of [72] reads

$$\mathcal{S}^{\text{quad}}[u] = \int_{\Omega} \nu(\text{trace } E)^2 + \mu \text{trace}(E^2) \, dx. \quad (9)$$

While relaxing the small strain assumption, the functional is not convex as the following example shows. Thus, additional arguments are required to prove existence of a solution to the variational problem based on $\mathcal{S}^{\text{quad}}$.

Fig. 3 Non-convexity of $\mathcal{S}^{\text{quad}}$ in (9) also used in Yanovsky et al. [72]. The value of $\mathcal{S}^{\text{quad}}$ is plotted for transformations $y_c := x + \text{diag}(c, c, 0)x$, $c \in [-2.5, 0.5]$ assuming parameters $\nu = \mu = 1$

Example 3 (Non-convexity of $\mathcal{S}^{\text{quad}}$). For $c \in \mathbb{R}$ a transformation y_c is defined as $y_c(x) := x + \text{diag}(c, c, 0)x$ such that $u_c(x) = \text{diag}(c, c, 0)x$. Thus, $E(u_c) = \text{diag}(c + c^2/2, c + c^2/2, 0)$. Assuming $\nu = \mu = 1$ in (9), it holds that $\mathcal{S}^{\text{quad}}[u_c] = 6(c + c^2/2)^2$.

Picking $c = 0$ and $c = -2$, it holds $\mathcal{S}^{\text{quad}}(u_{-2}) = \mathcal{S}^{\text{quad}}(u_0) = 0$; see also Fig. 3 for the landscape of $\mathcal{S}^{\text{quad}}(u_c)$. The non-convexity of $\mathcal{S}^{\text{quad}}$ with respect to y_c can then be seen by considering convex combinations of y_{-2} and y_0 . Since $\mathcal{S}^{\text{quad}}(u_{-1}) = 3/2 > 0$, $\mathcal{S}^{\text{quad}}$ is not convex in y . Also note that y_{-1} is non-invertible and still has finite energy.

Another serious drawback of both the energies $\mathcal{S}^{\text{elas}}$ and $\mathcal{S}^{\text{quad}}$ is that both yield finite energy for transformations that are not one-to-one; see Example 4. In addition, even for invertible transformations, the above regularization functionals do not explicitly control tissue compression and expansion; see Example 5. Thus, unlimited compression is performed, if sufficient reduction of the distance functional can be gained.

Example 4. Consider the non-invertible trivial map $y(x) \equiv 0$, with $u(x) = -x$ and $\nabla u = -I$. Clearly, $V = 4E = -2I$ and $\mathcal{S}^{\text{elas}}[u] = 4\mathcal{S}^{\text{quad}}[u] = (9\nu + 3\mu)\text{vol}(\Omega)$. These regularizers give thus finite values that depend only on the Lamé constants and the volume of the domain Ω .

Example 5. For the sequence of transformations $y^{(n)}(x) := 2^{-n}x$, it follows $u(x) = (2^{-n} - 1)x$ and $\det \nabla y = 2^{-3n}$. For large n , this transformation heavily compresses volume. However, the components of ∇u are bounded below by -1 , showing that arbitrary compressions are not detected properly.

Hyperelastic Regularization Functionals

Motivated by these observations, a desirable property of regularization functionals is rapid growth to infinity for $\det \nabla y \rightarrow 0^+$. In the Example 5, the Jacobian determinant is $\det \nabla y = 2^{-3n}$ indicating that the volume of a reference domain goes rapidly to zero with growing n . Controlling compression and expansion to

physically meaningful ranges has been a central theme in image registration; see, e.g., [34–36, 40, 58, 59].

Models for the so-called Ogden materials [4, 18] use an energy function that satisfies this important requirement,

$$\mathcal{S}^{\text{Ogden}}[y] = \int_{\Omega} \frac{1}{2} \alpha_\ell |\nabla u|^2 + \alpha_a \|\text{cof} \nabla y\|_F^2 + \alpha_v \psi_O(\det \nabla y) dx, \quad (10)$$

with regularization parameters $\alpha_\ell, \alpha_a, \alpha_v > 0$, the *Frobenius norm* $\|A\|_F^2 = \sum_{i,j=1}^3 a_{ij}^2$, and the convex penalty $\psi_O(v) = v^2 - \log v$. Note that this penalty ensures $\lim_{v \rightarrow 0^+} \psi_O(v) = \lim_{v \rightarrow \infty} \psi_O(v) = \infty$ and thus gives infinite energy for non-invertible transformations. For small strains, linear elasticity is an approximation to this regularization functional; see [18]. For image registration, this energy was introduced first by Droske and Rumpf [23].

While ensuring invertible transformations, the hyperelastic regularization functional (10) has drawbacks in the context of image registration: On the one hand, setting $\alpha_a > 0$ puts a bias towards transformations that reduce surface areas. On the other hand, setting $\alpha_a = 0$ prohibits the standard existence theory as presented in the next section. In addition, ψ_O is not symmetric with respect to inversion, that is, $\psi_O(v) \neq \psi_O(1/v)$. Since $\det \nabla y^{-1} = (\det \nabla y)^{-1}$ the value of the volume regularization term changes, when interchanging the role of template and reference image; see [17] for a discussion of the *inverse consistency* property.

To overcome these two drawbacks, the following *hyperelastic regularizer* as a slight modification of the Ogden regularizer (10) was introduced in [14],

$$\mathcal{S}^{\text{hyper}}[y] = \int_{\Omega} \frac{1}{2} \alpha_\ell(x) |\nabla u|^2 + \alpha_a(x) \phi_c(\text{cof} \nabla y) + \alpha_v(x) \psi(\det \nabla y) dx.$$

Making the regularization parameter spatially dependent is a small conceptual contribution with potentially big impact for many applications. The main idea is to replace ψ_O by a convex penalty ψ , fulfilling the growth condition, and satisfying $\psi(v) = \psi(1/v)$. More precisely, the convex functions

$$\phi_c(C) = \sum_{i=1}^3 \max \left\{ \sum_{j=1}^3 C_{ji}^2 - 1, 0 \right\}^2 \text{ and } \psi(v) = \frac{(v-1)^4}{v^2}$$

were suggested in [14]. The penalty ϕ_c is a convexification of the distance to orthogonal matrices and the penalty $\psi(v)$ is essentially a polynomial of degree two, thus guaranteeing $\det \nabla y \in L^2$, which is important in mass-preserving registration. If $\det \nabla y \in L^1$ suffices, ψ can be replaced by its square root. Note that ϕ_c is designed to avoid the preference for area shrinkage in (10). A convexification is needed for the existence theory, which makes ϕ_c blind against shrinkage, allowing only penalization of area expansion.

Constraints

It is often beneficial to include additional prior knowledge or expectations on the wanted transformation into the model. Two case studies will show exemplarily how to restrict the set of admissible transformations. The first one is related to volume constraints [35, 36, 59] and the second one to local rigidity constraints [38, 65].

Volume-preserving constraints are particularly important in a setting such as monitoring tumor growth, where a change of volume due to the mathematical model can be critical. In addition, registration problems requiring highly nonlinear deformations, e.g., arising in abdominal or heart imaging, can be stabilized by restricting volume change to a certain class.

Constraining compression and expansion of volume has been a central topic in image registration over many years. Following [36], a formal description reads

$$\kappa_m(x) \leq \mathcal{C}^{\text{VC}}[y](x) := \det \nabla y(x) \leq \kappa_M(x) \text{ for } x \in \Omega,$$

where κ_m and κ_M are given bounds. Volume preservation was enforced by using penalties, equality constraints such as $\kappa_m = \kappa_M \equiv 1$, or box constraints; see, e.g., [34–36, 40, 58, 59].

Another example for image-based constraints is *local rigidity*. Local rigidity constraints can improve the model in applications in which images show bones or other objects that behave approximately rigidly, such as head-neck images, motion of prostate in the pelvis cage, or the modelling of joints. Rigidity on a subdomain $\Sigma \subset \Omega$ can be enforced by setting

$$\mathcal{C}^{\text{LR}}[y, \Sigma] := \text{dist}(y, \mathcal{A}_{\text{rigid}}(\Sigma)) = 0;$$

see also Example 1. This formulation can be extended to multiple regions; see [38, 65].

Based on the discussion in [38], the Lagrangian framework has the advantage that the set Σ does not depend on y and thus does not need to be tracked; see [54] for a tracked Eulerian variant. Tracking the constrained regions may add discontinuities to the registration problem. In the case of local rigidity constraints, constraint elimination is an efficient option and results linear constraints. However, the Lagrangian framework involves $\det \nabla y$ in the computations of \mathcal{D} and \mathcal{S} ; see [38] for details.

Related Literature and Further Reading

Due to its many applications and influences from different scientific disciplines, it is impossible to give a complete overview of the field of image registration. Therefore this overview is restricted to some of the works, which were formative for the field or are relevant in the scope of this chapter. For general introductions to

image registration, the reader is referred to the textbooks [33, 53, 55]. In addition, the development of the field has been documented in a series of review articles that appeared in the last two decades; see [11, 27, 31, 45, 52, 73].

A milestone for registration of images from different imaging techniques, or *modalities*, was the independent discovery of the *mutual information* distance functional by Viola and Wells [71] and Collignon et al. [19]. In this information theoretic approach, the reference and template images are discretized and interpreted as a sequence of grey values. The goal is to minimize the entropy of the joint distribution of both sequences. Due to its generality, mutual information distance measures can be used for a variety of image modalities. However, it is tailored to discrete sequences and thus the mutual information of two continuous images is not always well defined; see [42]. Furthermore, a local interpretation of the distance is impossible. To overcome these limitations, a *morphological* distance functional [23] and an approach based on *normalized gradient fields* [56] were derived for multimodal registration. Both approaches essentially use image gradients to align corresponding edges or level sets.

In addition to the already mentioned elastic and hyperelastic regularization functionals, another example is the *fluid registration* by Christensen [16]. The difference between fluids and elastic materials lies in the model for the inner force. In contrast to elastic materials, fluids have no memory about their reference state. Thus, the fluid registration scheme allows for large, nonlinear transformations while preserving continuity and smoothness. However, similar limitations arise from the fact that volume changes are not monitored directly.

It is well known that nonlinear registration schemes may fail if the geometrical difference between the images is too large. To overcome this, a preregistration with a rigid transformation model is usually employed. The above regularizers are, however, not invariant to rigid transformations. To overcome this limitation, the *curvature* regularization functional, based on second derivatives, was proposed [26, 43].

Similar to the linearized elastic regularization functional, fluidal or curvature regularized schemes fail to detect non-invertible transformations. As an alternative to hyperelastic schemes, the invertibility of the solution is to restrict the search for a plausible transformation to the set of diffeomorphisms as has been originally suggested by Trouv  in 1995 [69] and resulted in important works [3, 5, 70]. A transformation y is diffeomorphic, if y and y^{-1} exist and are continuously differentiable. The existence of an inverse transformation implies that diffeomorphisms are one-to-one. While invertibility is *necessary* in most problems, it is not always *sufficient* as the Example 5 indicates: for large n the size of the transformed domain has no physical meaning; see [55] for further discussions.

Image registration is closely related to the problem of determining *optical flow*, which is a velocity field associated with the motion of brightness pattern in an image sequence. First numerical schemes have been proposed by Horn and Schunck [48] and Lucas and Kanade [51] in 1981. In their original formulations, both approaches assume that a moving particle does not change its intensity. This gives one scalar constraint for each point. Hence, as image registration, determining the flow field is an under-determined problem. The under-determinedness is addressed differently

by both approaches. The method by Horn and Schunck generates dense and globally smooth flow fields by adding a regularization energy. Lucas and Kanade, in contrast, suggest to smooth the image sequence and compute the flow locally without additional regularization. A detailed comparison and a combination of the benefits of both approaches is presented in [12].

There are many variants of optical flow techniques. For example, Brune replaced the brightness constancy by a mass-conservation constraint; see [13]. This gives the optical flow pendant to mass-preserving image registration schemes; see [30, 60, 61] and sections “Distance Functionals” and “Motion Correction of Cardiac PET”. Further, rigidity constraints have been enforced in optical flow settings in [50].

One difference between image registration and optical flow lies in the available data. In optical flow problems, motion is typically computed based on an image sequence. Thus, the problem is space and time dependent. If the time resolution of the image sequence is sufficiently fine, geometrical differences between successive frames can be assumed to be small and displacements can be linearized. In contrast to that, in image registration the goal is typically to compute *one* transformation that relates two images with typically substantial geometrical differences.

The problem of mass-preserving image registration is closely related to the famous Monge–Kantorovich problem of *Optimal Mass Transport* (OMT) [1, 6, 24, 49]. It consists of determining a transport plan to transform one density distribution into another. To this end, a functional measuring transport cost is minimized over all transformations that satisfy $\mathcal{D}^{\text{MP}}[y] = 0$ in (7). A key ingredient is the definition of the cost functional which defines *optimality*. Clearly there is an analogy the cost functional in OMT and the regularization functional in mass-preserving image registration.

3 Existence Theory of Hyperelastic Registration

The variational image registration problem (2) is *ill-posed* problem in the sense of Hadamard; see section “Ill-Posedness and Regularization” and [27, 55]. As Example 2 of a rotating disc suggests, uniqueness can in general not be expected. However, hyperelastic image registration has a sound existence theory which will be revisited in this section.

The main result of this section is the existence theorem for unconstrained hyperelastic image registration that includes all commonly used distance measures. It is further shown that solutions satisfy $\det \nabla y > 0$, which is necessary in many applications. The theory is complicated due to the non-convexity of the determinant mapping as has been pointed out by Ciarlet [18, p.138f]. Using his notation $F = \nabla u$: “*The lack of convexity of the stored energy function with respect to the variable F is the root of a major difficulty in the mathematical analysis of the associated minimization problem.*”

This section organizes as follows: A sketch of the existence proof is given in section “Sketch of an Existence Proof”. Formal definitions of involved function spaces, the set of admissible transformations, and the hyperelastic regularization

functional $\mathcal{S}^{\text{hyper}}$ are given in section “Set of Admissible Transformations”. Finally, an existence result is shown in section “Existence Result for Unconstrained Image Registration”.

Sketch of an Existence Proof

This section gives an overview of the existence theory of hyperelastic image registration problems. The goal is to outline the major steps, give intuition about their difficulties, and introduce the notation. The presentation is kept as informal as possible. The mentioned definitions, proofs, and theorems from variational calculus can be found, for instance, in [25, Ch. 8] or [18, 20].

The objective functional in (1) can also be written as an integral over a function $f : \Omega \times \mathbb{R}^3 \times \mathbb{R}^{3 \times 3} \rightarrow \mathbb{R}$:

$$\mathcal{J}[y] = \int_{\Omega} f(x, y(x), \nabla y(x)) \, dx, \quad (11)$$

where the dependence on the template and reference images is hidden for brevity.

In the following it is assumed that f is continuously differentiable and measurable in x . This is granted for the part related to the hyperelastic regularization functional. For the part related to the distance functional, this can be achieved by using a continuous image model \mathcal{T} and \mathcal{R} and careful design of \mathcal{D} .

Typically, \mathcal{J} is bounded below by a constant $m := \inf_y \mathcal{J}[y]$. The goal is to find a minimizer in a certain set of admissible transformations \mathcal{A} , which is a subset of a suitable Banach space X . Since X must be complete under *Lebesgue norms*, our generic choice is a *Sobolev space* $W^{1,p}(\Omega, \mathbb{R}^3)$, with $p \geq 1$, rather than $C^1(\Omega, \mathbb{R}^3)$.

Existence of minimizers is shown in three steps. Firstly, a *minimizing sequence* $\{y^k\}_{k \in \mathbb{N}} \subset \mathcal{A}$ is constructed, that is, a sequence with $\lim_{k \rightarrow \infty} \mathcal{J}(y^k) = m$ containing a convergent subsequence. Secondly, it is shown that its limit y^* is a minimizer of \mathcal{J} , in other words, $\mathcal{J}[y^*] = m$. Finally, it is verified that y^* actually belongs to the admissible set \mathcal{A} .

Key ingredients of the existence proof are *coercivity* and *lower semicontinuity*.

In a finite dimensional setting, the coercivity inequality

$$\mathcal{J}[y] \geq C \|y\|_X + K \text{ for all } y \in \mathcal{A} \text{ and constants } C > 0 \text{ and } K \in \mathbb{R}, \quad (12)$$

guarantees that $\{y^k\}_k$ lies in a bounded and closed set. From the lower semicontinuity it follows

$$y^k \rightarrow y^* \Rightarrow m = \lim_{k \rightarrow \infty} \mathcal{J}[y^k] \geq \mathcal{J}[y^*] \geq m,$$

and thus y^* is a minimizer. However, $W^{1,p}(\Omega, \mathbb{R}^3)$ is infinite dimensional. Hence, bounded and closed sets are in general not compact and the existence of a

norm-convergent subsequence cannot be assumed. Thus, less strict definitions of convergence have to be used.

Note that $W^{1,p}(\Omega, \mathbb{R}^3)$ is *reflexive* for $p > 1$. For these cases, it can be shown that there exists a subsequence that converges in the *weak topology*, i.e., with respect to all continuous, linear functionals on $W^{1,p}(\Omega, \mathbb{R}^3)$. Consequently, if \mathcal{J} fulfills a coercivity condition (12), a bounded minimizing sequence can be constructed which yields weakly converging subsequence.

The second part, namely showing that the weakly convergent sequence actually converges to a minimizer, is in general more involved. Lower continuity of \mathcal{J} with respect to weak convergence typically requires convexity arguments. In many examples of variational calculus, the integrand f of \mathcal{J} is convex in ∇y . Thus, the integrand f can be bounded below by a linearization in the last argument around ∇y . Using the weak convergence of $\nabla y_k \rightharpoonup \nabla y^*$ and noting that $y_k \rightarrow y^*$ strongly in L^2 by a *compact embedding*, the linear term vanishes and lower semicontinuity follows; see Theorem 2.

When using hyperelastic regularization or mass-preserving distance functionals, \mathcal{J} also depends on the Jacobian determinant $\det \nabla y$. Thus, the dependence of f on ∇y is non-convex and further arguments are required to obtain lower semicontinuity. To overcome this complication, one can follow the strategy suggested by Ball [4]. The idea is to introduce a splitting in $(y, \text{cof} \nabla y, \det \nabla y)$ and show convergence of the sequence

$$\{(y^k, \text{cof} \nabla y^k, \det \nabla y^k)\}_k \subset W^{1,p}(\Omega, \mathbb{R}^3) \times L^q(\Omega, \mathbb{R}^{3 \times 3}) \times L^r(\Omega, \mathbb{R}) =: X$$

where the exponents $q > 0$ and $r > 0$ are appropriately chosen. A coercivity inequality in the $\|\cdot\|_X$ -norm yields a weakly converging subsequence as outlined above. Extending f by additional arguments, it follows

$$\begin{aligned} g : \Omega \times \mathbb{R}^3 \times \mathbb{R}^{3 \times 3} \times \mathbb{R}^{3 \times 3} \times [0, \infty) &\rightarrow \mathbb{R} \\ \text{with } g(x, y, \nabla y, \text{cof} \nabla y, \det \nabla y) &:= f(x, y, \nabla y) \end{aligned}$$

is measurable in x and continuously differentiable. Most importantly, g is convex in the last three arguments. Consequently, weak lower semicontinuity of \mathcal{J} in X can be shown, i.e., $(y^k, \text{cof} \nabla y^k, \det \nabla y^k) \rightharpoonup (y^*, H^*, v^*)$ implies

$$\lim_{k \rightarrow \infty} \int_{\Omega} g(x, y^k, \nabla y^k, \text{cof} \nabla y^k, \det \nabla y^k) dx \geq \int_{\Omega} g(x, y^*, \nabla y^*, H^*, v^*) dx = m.$$

To undo the splitting, the identifications $H^* = \text{cof} \nabla y^*$ and $v^* = \det \nabla y^*$ must be shown. This is uncritical if y is sufficiently measurable, i.e., p is greater than the space dimension d . Note that p is also the degree of the polynomial $\det \nabla y$. For hyperelastic regularization, it is possible to show existence under even weaker assumptions, i.e., for $d = 3$ and $p = 2$. Key is the identity

$$\det \nabla y \cdot I = \nabla y^\top \text{cof} \nabla y.$$

It will be shown that $H^* = \text{cof} \nabla y^*$ and $v^* = \det \nabla y^*$ for exponents $q = 4$ and $r = 2$; see Theorem 4.

A final note is related to the positivity of the determinant. To assure that the Jacobian determinant of a solution is strictly positive almost everywhere, sufficient growth of \mathcal{J} is required, i.e., $\mathcal{J}[y] \rightarrow \infty$ for $\det \nabla y \rightarrow 0^+$. Note, that $\det \nabla y^* > 0$ is not obvious. For example, $k^{-1} \rightarrow 0$ although $k^{-1} > 0$ for all k .

Set of Admissible Transformations

As pointed out, regularization functionals involving $\det \nabla y$ considerably complicate existence theory due to the non-convexity of the determinant mapping. Thus, a careful choice of function spaces and the set of admissible transformations is important for the existence theory to be investigated in the next section. The goal of this section is to define the function spaces and the set of admissible transformations underlying the hyperelastic regularization functional (10).

To begin with, the problems arising from the non-convexity of the determinant are addressed. One technique to bypass this issue is a splitting into the transformation, cofactor and determinant and study existence of minimizing sequences in a product space. Here the product space

$$X := W^{1,2}(\Omega, \mathbb{R}^3) \times L^4(\Omega, \mathbb{R}^{3 \times 3}) \times L^2(\Omega, \mathbb{R}) \quad (13)$$

with the norm

$$\|(y, \text{cof} \nabla y, \det \nabla y)\|_X := \|y\|_{W^{1,2}(\Omega, \mathbb{R}^3)} + \|\text{cof} \nabla y\|_{L^4(\Omega, \mathbb{R}^{3 \times 3})} + \|\det \nabla y\|_{L^2(\Omega, \mathbb{R})} \quad (14)$$

is considered. The space X is reflexive and the norms are motivated by the fact that the penalty functions ϕ_c and ψ presented in section “Hyperelastic Regularization Functionals” are essentially polynomials of degree four and two, respectively. The splitting is well defined for transformations in the set

$$\mathcal{A}_0 := \{y : (y, \text{cof} \nabla y, \det \nabla y) \in X, \det \nabla y > 0 \text{ a.e.}\}. \quad (15)$$

To satisfy a coercivity inequality, boundedness of the overall transformation is required. In the standard theory of elasticity, this is typically achieved by imposing boundary conditions; see [4, 18]. In the image registration literature, a number of conditions, for instance, *Dirichlet*, *Neumann*, or *sliding* boundary conditions were used; see [53].

Since finding boundary conditions that are meaningful for the application in mind often is difficult, the existence proof in section “Existence Result for Unconstrained Image Registration” is based on the following arguments. Recall that images are

compactly supported in a domain Ω , which can be bounded by a constant $M \in \mathbb{R}$. Since images vanish outside Ω , reasonable displacements are also bounded by a constant only depending on Ω ; see also discussions in [14, 58],

$$\|y\|_\infty \leq M + \text{diam}(\Omega).$$

For larger displacements, the distance functional is constant in y as the template image vanishes and thus no further reduction of the distance functional can be achieved. In this case, the regularization functional drives the optimization to a local minimum. Working with the supremum of y , however, complicates our analysis as the transformations in the non-reflexive space L^∞ . Therefore, an averaged version of a boundedness condition can be used:

$$\frac{1}{\text{vol}(\Omega)} \left| \int_{\Omega} y(x) dx \right| \leq M + \text{diam}(\Omega).$$

This leads to the following characterization of admissible transformations and definition of the hyperelastic regularization energy.

Definition 3 (Hyperelastic Regularization Functional). Let $\Omega \subset \mathbb{R}^3$ be a domain bounded by a constant $M > 0$, $\alpha_i \in \mathcal{C}^1(\Omega, \mathbb{R}^+)$ be regularization parameters with $\alpha_i(x) \geq a_i > 0$ for all x and $i = l, a, v$, and \mathcal{A}_0 as in (15). The set of *admissible transformations* is

$$\mathcal{A} = \{y \in \mathcal{A}_0 : \left| \int_{\Omega} y(x) dx \right| \leq \text{vol}(\Omega)(M + \text{diam}(\Omega))\}.$$

Then the *hyperelastic regularization* functional is defined as

$$\mathcal{S}^{\text{hyper}} : \mathcal{A} \rightarrow \mathbb{R}^+, \quad \mathcal{S}^{\text{hyper}}[y] = \mathcal{S}^{\text{length}}[y] + \mathcal{S}^{\text{area}}[y] + \mathcal{S}^{\text{vol}}[y], \quad (16)$$

with

$$\mathcal{S}^{\text{length}}[y] = \int_{\Omega} \alpha_l(x) |\nabla u(x)|^2 dx, \quad (17)$$

$$\mathcal{S}^{\text{area}}[y] = \int_{\Omega} \alpha_a(x) \phi_c(\text{cof} \nabla y(x)) dx, \quad (18)$$

$$\mathcal{S}^{\text{vol}}[y] = \int_{\Omega} \alpha_v(x) \psi(\det \nabla y(x)) dx, \quad (19)$$

and the convex functions $\phi_c : \mathbb{R}^{3 \times 3} \rightarrow \mathbb{R}^+$ and $\psi : \mathbb{R} \rightarrow \mathbb{R}^+$,

$$\phi_c(C) = \sum_{i=1}^3 \max \left\{ \sum_{j=1}^3 C_{ji}^2 - 1, 0 \right\}^2 \text{ and } \psi(v) = \frac{(v-1)^4}{v^2}.$$

Existence Result for Unconstrained Image Registration

This section shows that hyperelastic regularization is sufficient to guarantee the existence of optimal transformations for unconstrained image registration problems and that the Jacobian determinants of minimizers of \mathcal{J} in (2) are positive almost everywhere.

There are of numerous ways of showing existence. One option is to follow John Ball's proof for hyperelastic materials [4, 18, 20]. In [14], existence is obtained by verifying that the modified hyperelastic regularization functional still satisfies the assumptions of Ball's theorem which yields a very brief and concise result.

In this section, a new and different approach to the existence theory is given. Its main purpose is to give insight into the machinery behind Ball's proof and to prove existence in a simplified setting using only moderate theoretical tools. For the sake of clarity, some technical difficulties are avoided by making additional assumptions that are no limitation for most applications and also discussed below:

A1: The distance functional is of the form

$$\mathcal{D}[y] = \int_{\Omega} g_D(x, y(x), \text{cof} \nabla y(x), \det \nabla y(x)) \, dx,$$

where $g_D : \Omega \times \mathbb{R}^3 \times \mathbb{R}^{3 \times 3} \times \mathbb{R} \rightarrow \mathbb{R}^+$ is continuously differentiable, convex in its last argument, and measurable in x .

A2: The regularization parameters satisfy $\alpha_\ell = \alpha_a = \alpha_v = 1$.

A3: With $\text{Id}(x) = x$ for all x , it holds $\mathcal{J}(\text{Id}) < \infty$.

A4: The boundary $\partial\Omega$ of the domain Ω is in C^1 .

(A1) holds for a large class of distance functionals, including the ones in [55], the mass-preserving distance functional (7), and distance functionals in the Lagrangian frame. Differentiability of g_D requires a differentiable image model and is assumed for simplicity. It can be weakened to the concept of *Carathéodory* functions; see [14, 20]. (A2) is made for ease of presentation. In general, there exists a constant $a > 0$ such that for all three penalty functions $a_i(x) \geq a$. Hence, (A2) present no loss of generality. For practical applications, (A3) is satisfied as the distance functional is finite for the initial images. (A4) allows to use a generalized Poincaré inequality [25, Sect. 5.8] and an integration by parts formula [25, Sect. C.1].

The main goal of this section is to prove the following theorem.

Theorem 1 (Existence of Optimal Transformations). *Given are images $\mathcal{T}, \mathcal{R} \in \text{Img}(\Omega)$, a distance functional \mathcal{D} , $\mathcal{S}^{\text{hyper}}$ and \mathcal{A} as in Definition 3. Let the assumptions (A1)–(A4) be satisfied. There exists at least one minimizer $y^* \in \mathcal{A}$ of $\mathcal{J} = \mathcal{D} + \mathcal{S}^{\text{hyper}}$.*

The proof is divided into a number of Lemmata following the sketch presented in section “Sketch of an Existence Proof”. To begin with, coercivity of the objective functional in the space X as in (13) is shown. This means that \mathcal{J} grows sufficiently

fast with respect to the $\|\cdot\|_X$ norm; see (14). This will be essential to bound the norm of the minimizing sequence.

Lemma 1 (Coercivity of \mathcal{J}). *Under the assumptions of Theorem 1, the functional \mathcal{J} satisfies a coercivity inequality: $\exists C > 0, K \in \mathbb{R} \forall y \in \mathcal{A}$:*

$$\mathcal{J}[y] \geq K + C(\|y\|_{W^{1,2}}^2 + \|\text{cof}\nabla y\|_{L^4}^4 + \|\det\nabla y\|_{L^2}^2).$$

Proof. Let $y \in \mathcal{A}$ be an admissible transformation. Since $\mathcal{D} \geq 0$ by assumption, coercivity of \mathcal{J} follows from the coercivity of the regularization term

$$\mathcal{J}[y] \geq \mathcal{S}^{\text{hyper}}[y] = \int_{\Omega} \|\nabla y - I\|_{\text{Fro}}^2 + \phi_c(\text{cof}\nabla y) + \psi(\det\nabla y) dx.$$

The penalties ϕ_c and ψ are designed such that there exist constants $C_1 > 0$ and $K_1 \in \mathbb{R}$ such that

$$\mathcal{J}[y] \geq K_1 + C_1 \left(\int_{\Omega} \|\nabla y - I\|_{\text{Fro}}^2 + \|\text{cof}\nabla y\|_{\text{Fro}}^4 + (\det\nabla y)^2 \right) dx.$$

Using that $(a - b)^2 \geq \frac{1}{2}a^2 - b^2$ for all $a, b \in \mathbb{R}$, it follows that

$$\mathcal{J}[y] \geq K_1 + C_1 \left(\int_{\Omega} \frac{1}{2} \|\nabla y\|_{\text{Fro}}^2 - \|I\|_{\text{Fro}}^2 + \|\text{cof}\nabla y\|_{\text{Fro}}^4 + (\det\nabla y)^2 \right) dx.$$

With constants $C_2 > 0$ and $K_2 \in \mathbb{R}$, one obtains the inequality

$$\mathcal{J}[y] \geq K_2 + C_2 \left(\|\nabla y\|_{L^2}^2 + \|\text{cof}\nabla y\|_{L^4}^4 + \|\det\nabla y\|_{L^2}^2 \right). \quad (20)$$

It remains to be shown that the norm of ∇y in L^2 bounds the norm of the transformation y . To this end, assumption (A4) is used and a generalized Poincaré inequality [25, Sect. 5.8] is applied. In addition, the boundedness of the mean of transformations in \mathcal{A} is used:

$$\begin{aligned} \|\nabla y\|_{L^2}^2 &\geq C_3 \left\| y - \frac{1}{|\Omega|} \int_{\Omega} y(x) dx \right\|_{L^2}^2 = C_3 \|y\|_{L^2}^2 - |\Omega| \left(\frac{1}{|\Omega|} \left| \int_{\Omega} y(x) dx \right| \right)^2 \\ &\geq C_3 \|y\|_{L^2}^2 - |\Omega| \left(\frac{1}{|\Omega|} \int_{\Omega} |y(x)| dx \right)^2. \end{aligned}$$

Due to the assumption on \mathcal{A} , there exists a constant $K_3 \in \mathbb{R}$ independent on y such that

$$\|\nabla y\|_{L^2}^2 \geq K_3 + C_3 \|y\|_{L^2}^2. \quad (21)$$

Combining (20) and (21) and introducing cosmetics constants $C > 0$ and $K \in \mathbb{R}$ one obtains the desired growth condition

$$\mathcal{J}[y] \geq K + C(\|y\|_{W^{1,2}}^2 + \|\text{cof}\nabla y\|_{L^4}^4 + \|\det\nabla y\|_{L^2}^2).$$

Since y was chosen arbitrarily, the assertion follows.

The following theorem establishes lower semicontinuity of the objective functional \mathcal{J} . It is a modified version of Theorem 1 of Evans [25, Sec. 8.2]. In contrast to the version of Evans, the next theorem does not necessarily assume that ζ is replaced by ∇y . However, it is assumed that $f \geq 0$, $y^k \rightarrow y^*$ strongly, and $\zeta^k \rightharpoonup \zeta^*$ weakly.

Theorem 2 (A General Lower Semicontinuity Result). *Let $\Omega \subset \mathbb{R}^3$ be a domain. Let $f : \Omega \times \mathbb{R}^3 \times \mathbb{R}^N \rightarrow [0, \infty]$ be continuously differentiable and $f(\cdot, y, \zeta)$ be measurable for every fixed y and ζ . Let $f(x, y, \cdot)$ be convex. For two sequences $y^k \rightarrow y^*$ in $L^p(\Omega, \mathbb{R}^3)$ with $p \geq 1$ and $\zeta^k \rightharpoonup \zeta^*$ in $L^q(\Omega, \mathbb{R}^N)$ with $q \geq 1$, it holds*

$$\liminf_{k \rightarrow \infty} \int_{\Omega} f(x, y^k(x), \zeta^k(x)) dx \geq \int_{\Omega} f(x, y^*(x), \zeta^*(x)) dx.$$

Proof. The proof basically follows the one of Theorem 1 [25, Sec. 8.2]. Simplifications arise from the fact that the sequences $\{y^k\}_k$ and $\{\zeta^k\}_k$ converge by assumption and $f \geq 0$. Another difference is that the second argument of f is used for a general sequence ζ^k and its limit ζ^* instead of ∇y^k and ∇y^* , respectively. The proof is organized in three steps.

Step 1: Since $0 \leq f$, it follows

$$0 \leq m := \liminf_{k \rightarrow \infty} \int_{\Omega} f(x, y^k(x), \zeta^k(x)) dx,$$

thus there exists a (sub)-sequence $\{y^k, \zeta^k\}_k$ with

$$0 \leq m = \lim_{k \rightarrow \infty} \int_{\Omega} f(x, y^k(x), \zeta^k(x)) dx.$$

Step 2: The strong convergence $y^k \rightarrow y^*$ in L^2 implies convergence almost everywhere. Thus, Egoroff's Theorem [25, Sect. E.2] can be used, which implies that for each $\epsilon > 0$ there exists a set $\Omega_\epsilon^1 \subset \Omega$ with $\text{vol}(\Omega \setminus \Omega_\epsilon^1) \leq \epsilon$ such that

$$y^k \rightarrow y^* \text{ uniformly on } \Omega_\epsilon^1. \quad (22)$$

Next, Ω_ϵ^1 is reduced by regions where y^* or ζ^* are too large. Consider $\Omega_\epsilon := \Omega_\epsilon^1 \cap \{x \in \Omega : |y^*(x)| + |\zeta^*(x)| \leq \epsilon^{-1}\}$. It holds that

$$\text{vol}(\Omega \setminus \Omega_\epsilon) \rightarrow 0 \text{ for } \epsilon \rightarrow 0. \quad (23)$$

Step 3: From $f \geq 0$ and the convexity of f in the last argument (see also [25, Sect. B.1]), it follows for each fixed k that

$$\begin{aligned}
\int_{\Omega} f(x, y^k, \zeta^k) dx &\geq \int_{\Omega_\epsilon} f(x, y^k, \zeta^k) dx \\
&\geq \int_{\Omega_\epsilon} f(x, y^k, \zeta^*) dx + \int_{\Omega_\epsilon} d_\zeta f(x, y^k, \zeta^*) (\zeta^k - \zeta^*) dx.
\end{aligned} \tag{24}$$

Due to the uniform convergence of $\{y^k\}_k$, see (22) and (23), it follows

$$\lim_{k \rightarrow \infty} \int_{\Omega_\epsilon} f(x, y^k, \zeta^k) dx = \int_{\Omega_\epsilon} f(x, y^*, \zeta^k). \tag{25}$$

Since also $d_\zeta f(x, y_k, \zeta^*) \rightarrow d_\zeta f(x, y^*, \zeta^*)$ uniformly on Ω_ϵ and $\zeta^k \rightarrow \zeta^*$ it holds that

$$\lim_{k \rightarrow \infty} \int_{\Omega_\epsilon} d_\zeta f(x, y^k, \zeta^*) (\zeta^k - \zeta^*) dx = 0. \tag{26}$$

Combining (25), (26), and (24), it follows

$$m = \lim_{k \rightarrow \infty} \int_{\Omega} f(x, y^k, \zeta^k) dx \geq \int_{\Omega_\epsilon} f(x, y^*, \zeta^*) dx.$$

This inequality holds for all $\epsilon > 0$. Using $f \geq 0$, the measurability of f , the Monotone Convergence Theorem [25, Sect. E.3] and letting $\epsilon \rightarrow 0$, it follows that

$$m \geq \int_{\Omega} f(x, y^*, \zeta^*) dx,$$

which concludes the proof.

Having shown the above general lower semicontinuity result, it is now verified that the objective functional \mathcal{J} satisfies the assumptions that have been made.

Lemma 2 (Weak Lower Semicontinuity of \mathcal{J}). *Given are images $\mathcal{T}, \mathcal{R} \in \text{Img}(\Omega)$, a distance functional \mathcal{D} , $\mathcal{S}^{\text{hyper}}$, and \mathcal{A} as in Definition 3. Let the assumptions (A1)–(A4) be satisfied.*

- There exists a function $g : \Omega \times \mathbb{R}^3 \times \mathbb{R}^{3 \times 3} \times \mathbb{R}^{3 \times 3} \times (0, \infty] \rightarrow \mathbb{R}$ with

$$\mathcal{J}[y] = \int_{\Omega} g(x, y, \nabla y, \text{cof} \nabla y, \det \nabla y) dx$$

that is continuously differentiable, convex in its last three arguments, and measurable in its first argument.

- The objective functional \mathcal{J} is weakly lower semicontinuous, i.e.,

$$\liminf_{k \rightarrow \infty} \int_{\Omega} g(x, y^k, \nabla y^k, \text{cof} \nabla y^k, \det \nabla y^k) dx \geq \int_{\Omega} g(x, y, \nabla y, H, v) dx$$

whenever $y^k \rightarrow y$ in $W^{1,2}$, $\text{cof}\nabla y^k \rightarrow H$ in L^4 , $\det\nabla y^k \rightarrow v$ in L^2 .

Proof. Both results are proved separately.

First, \mathcal{J} is rewritten as

$$\begin{aligned} \mathcal{J}[y] &= \int_{\Omega} g_D(x, y, \nabla y, \text{cof}\nabla y, \det\nabla y) dx \\ &\quad + \int_{\Omega} \alpha_\ell(x) |\nabla y|^2 + \alpha_a(x) \phi(\text{cof}\nabla y) + \alpha_v(x) \psi(\det\nabla y) dx \end{aligned}$$

and combine the integrands to $g : \Omega \times \mathbb{R}^3 \times \mathbb{R}^{3 \times 3} \times \mathbb{R}^{3 \times 3} \times (0, \infty] \rightarrow \mathbb{R}$. By assumption on \mathcal{D} and design of $\mathcal{S}^{\text{hyper}}$, the mapping $g(x, y, \cdot, \cdot, \cdot)$ is convex for fixed x and y . Furthermore, since the images and the functions ϕ and ψ are continuously differentiable, the integrand g is continuously differentiable. Since the images are measurable, g is measurable in x for fixed $(y, D, H, v) \in \mathbb{R}^3 \times \mathbb{R}^{3 \times 3} \times \mathbb{R}^{3 \times 3} \times (0, \infty]$.

For the second part, one notes that the weak convergence of y^k to y in $W^{1,2}$ implies strong convergence of y^k in L^2 due to the compact embedding of $W^{1,2} \subset\subset L^2$; see [25, Sect. 5.7]. Hence using the first part yields weak lower semicontinuity of \mathcal{J} on X by applying Theorem 2.

Due to the coercivity of \mathcal{J} shown in Lemma 1, there exists a bounded minimizing sequence $\{y^k, \text{cof}\nabla y^k, \det\nabla y^k\}_k \subset X$, where X is the product space as in (13). Lemma 2 shows lower semicontinuity of \mathcal{J} , thus, the sequence converges to a minimizer (y, H, v) in X . In the next step, the relation between the components y, H and v is established. More specifically, a continuity results for the cofactor and determinant mappings for function in $W^{1,p}(\Omega, \mathbb{R}^3)$ is given.

Theorem 3 (Weak Continuity of Determinants). Assume $d < q < \infty$ and $y^k \rightarrow y$ in $W^{1,q}(\Omega, \mathbb{R}^d)$. Then $\det\nabla y^k \rightarrow \det\nabla y$ in $L^{q/d}(\Omega, \mathbb{R})$.

Proof. See Evans [25, p. 454] for a complete proof.

This result is expected as the minimizing sequences $\{y^k\}_k$ are bounded in the spaces $W^{1,q}(\Omega, \mathbb{R}^d)$ and $\{\det\nabla y^k\}_k$ as a polynomial of degree d can be bounded in $L^d(\Omega, \mathbb{R})$. Combining these two bounds yields the weak convergence of the sequence $\{\det\nabla y^k\}_k$ in $L^{q/d}(\Omega, \mathbb{R})$. This result is used in [58] to show existence of solutions to volume constrained image registration in $W^{1,p}$ and actually extended to $p \geq d$.

Using Theorem 3, one option to obtain the identification $v = \det\nabla y$ in L^2 is to tighten the measurability demands on y by, e.g., resorting to $W^{1,6}(\Omega, \mathbb{R}^3)$ similar to [60].

In hyperelastic image registration also the cofactor matrix is regularized by the area regularization functional. This can be used to improve the above result; see also [4, 18]. This allows to achieve an improved continuity result based on [18].

Theorem 4 (Weak Continuity of Cofactors and Determinants). *Let $\Omega \subset \mathbb{R}^3$ fulfill (A4). Then it holds*

$$\left. \begin{array}{l} y^k \rightharpoonup y \quad \text{in } W^{1,2}(\Omega, \mathbb{R}^3), \\ \text{cof} \nabla y^k \rightharpoonup H \quad \text{in } L^4(\Omega, \mathbb{R}^{3 \times 3}), \\ \det \nabla y^k \rightharpoonup v \quad \text{in } L^2(\Omega, \mathbb{R}) \end{array} \right\} \Rightarrow \left\{ \begin{array}{l} H = \text{cof} \nabla y, \\ v = \det \nabla y. \end{array} \right.$$

Proof. This proof combines the proofs of Theorems 7.5-1 and 7.6-1 in [18] and is structured into two steps.

For ease of presentation, define $\Gamma := \text{cof} \nabla y$.

Step 1: Weak continuity of the cofactor mapping. Without loss of generality, presentation is focussed on the top-left entry of the cofactor matrix, i.e., to show that $\Gamma_{11}(x) = H_{11}(x)$ for almost every $x \in \Omega$. The result extends straightforwardly to the remaining entries.

To begin with, it is assumed that $y \in \mathcal{C}^2(\Omega, \mathbb{R}^3)$. Then it holds

$$\Gamma_{11} = \partial_2 y_2 \partial_3 y_3 - \partial_2 y_3 \partial_3 y_2 = \partial_3(y_3 \partial_2 y_2) - \partial_2(y_3 \partial_3 y_2).$$

Since y is continuously differentiable and $\partial \Omega$ is smooth one can integrate by parts, see [25, Sect. C.2]. Thus for test functions $\zeta \in \mathcal{C}_0^\infty(\Omega, \mathbb{R})$ it holds

$$\int_\Omega \gamma_{11} \zeta \, dx = - \int_\Omega y_3 \partial_2 y_2 \partial_3 \zeta \, dx + \int_\Omega y_3 \partial_3 y_2 \partial_2 \zeta \, dx. \quad (27)$$

This equality is now extended to functions $y \in W^{1,2}(\Omega, \mathbb{R}^3)$ by the following approximation argument. Since $\mathcal{C}^\infty(\Omega, \mathbb{R}^3)$ is dense in $W^{1,2}(\Omega, \mathbb{R}^3)$ [25, Sect. 5.2], one can approximate y by a sequence of functions in \mathcal{C}^2 for which (27) holds. Note that for ζ being fixed both sides of (27) are continuous in the space \mathcal{C}^2 with the norm $\|\cdot\|_{W^{1,2}}$, since

$$\left| \int_\Omega \Gamma_{11} \zeta \, dx \right| \leq \|\Gamma_{11}\|_{L^1} \|\zeta\|_{L^1} \leq C_1(\zeta) \|y\|_{W^{1,2}}^2 \quad (28)$$

and for $i, j, l = 1, 2, 3$,

$$\left| \int_\Omega y_i \partial_j y_l \partial_l \zeta \, dx \right| \leq \|y_i\|_{L^1} \|\partial_j y_l\|_{L^1} \|\partial_l \zeta\|_{L^1} \leq C_2(\zeta) \|y\|_{W^{1,2}}^2. \quad (29)$$

Hence, (27) holds also for $y \in W^{1,2}(\Omega, \mathbb{R}^3)$ and thus its right hand side can be used to prove the desired equality $\Gamma = H$. To this end, consider a fixed test function ζ . By Hölder's inequality [25, Sect. B.2], it holds that the bilinear mapping

$$B(\cdot, \cdot) : L^2(\Omega, \mathbb{R}) \times W^{1,2}(\Omega, \mathbb{R}) \rightarrow \mathbb{R} \text{ with } (f, g) \mapsto \int_{\Omega} f \partial_i g \partial_m \zeta dx$$

is continuous. Due to the compact embedding $W^{1,2} \subset\subset L^2$ [25, Sect. 5.1], it holds

$$y^k \rightharpoonup y \text{ in } W^{1,2}(\Omega, \mathbb{R}^3) \Rightarrow y^k \rightarrow y \text{ in } L^2(\Omega, \mathbb{R}^3).$$

Because of the continuity of the bilinear form B , the strong convergence of $\{y^k\}_k$, and the weak convergence of $\{\partial_j y_l^k\}_k$, Theorem 7.1-5 in [18, p.348f] can be used to obtain that for all $i, j, l, m \in \{1, 2, 3\}$

$$y^k \rightharpoonup y \text{ in } W^{1,2}(\Omega, \mathbb{R}^3) \Rightarrow \int_{\Omega} y_i^k \partial_j y_l^k \partial_m \zeta dx \rightarrow \int_{\Omega} y_i \partial_j y_l \partial_m \zeta dx,$$

which due to (27) implies $\int_{\Omega} (\text{cof}\nabla y^k)_{11} \zeta dx \rightarrow \int_{\Omega} (\text{cof}\nabla y)_{11} \zeta dx$. Note that H_{11} is by assumption the weak limit of $\{(\text{cof}\nabla y^k)_{11}\}_k$ in $L^4(\Omega, \mathbb{R})$. Therefore, $(\text{cof}\nabla y)_{11}(x) = H_{11}(x)$ for almost every x and thus both functions are equal in $L^4(\Omega, \mathbb{R})$. Repeating these arguments for the remaining matrix entries yields $\text{cof}\nabla y = H$ in $L^4(\Omega, \mathbb{R}^{3 \times 3})$.

Step 2: Weak continuity of the determinant mapping. It is now shown that under the above assumptions $\det \nabla y(x) = v(x)$ for almost every $x \in \Omega$.

Recall that $(\det A) \cdot I = A(\text{cof}A)^T$ and hence $\det A = \sum_{j=1}^3 a_{1j} (\text{cof}A)_{1j}$. Starting with $y \in C^2(\Omega, \mathbb{R}^3)$,

$$\det \nabla y = \sum_{j=1}^n (\partial_j y_1) \cdot \Gamma_{1j} = \sum_{j=1}^n \partial_j [y_1 \Gamma_{1j}], \quad (30)$$

where the last equality holds, since the cofactor is divergence free [25, Sect. 8.1]: $\sum_{j=1}^3 \partial_j \Gamma_{ij} = 0$ for all $i = 1, 2, 3$. Since y is continuously differentiable and $\partial\Omega$ is smooth, one can integrate by parts [25, Sect. C.2] and see from (30) that for all test functions $\zeta \in C_0^\infty(\Omega, \mathbb{R})$

$$\int_{\Omega} \sum_{j=1}^3 (\partial_j y_1) \cdot \Gamma_{1j} \zeta dx = \int_{\Omega} \sum_{j=1}^3 \partial_j [y_1 \Gamma_{1j}] \zeta dx = - \int_{\Omega} \sum_{j=1}^n y_1 \Gamma_{1j} \partial_j \zeta dx. \quad (31)$$

For fixed ζ , the mapping $y \mapsto \int_{\Omega} \sum_{j=1}^n y_1 \Gamma_{1j} \partial_j \zeta dx$ is continuous with respect to the $W^{1,2}(\Omega, \mathbb{R}^3)$ norm. By applying the same approximation argument as above, one sees that functions $y \in W^{1,2}(\Omega, \mathbb{R}^3)$ are divergence free in the following sense:

$$\int_{\Omega} \sum_{j=1}^n (\text{cof}\nabla y)_{1j} \partial_j \zeta dx = 0 \text{ for all } \zeta \in C_0^\infty(\Omega, \mathbb{R}). \quad (32)$$

Now (31) is extended to functions $y \in \{y \in W^{1,2}(\Omega, \mathbb{R}^3) : \text{cof}\nabla y \in L^4(\Omega, \mathbb{R}^{3 \times 3})\}$ by showing that for all test functions $\zeta \in \mathcal{C}_0^\infty(\Omega, \mathbb{R})$,

$$\int_{\Omega} \sum_{j=1}^3 (\partial_j y_1) \Gamma_{1j} \zeta \, dx = - \int_{\Omega} \sum_{j=1}^3 y_1 \Gamma_{1j} \partial_j \zeta \, dx. \quad (33)$$

To this end, note that for fixed ζ , both sides of this equation are bounded bilinear forms in y_1 and Γ and thus continuous. Therefore, it can be assumed that $y_1 \in \mathcal{C}^\infty(\Omega, \mathbb{R}^3)$. But then it follows that $(y_1 \zeta) \in \mathcal{C}_0^\infty(\Omega, \mathbb{R})$ and thus

$$0 = \int_{\Omega} \sum_{j=1}^3 \Gamma_{1j} \partial_j (y_1 \zeta) \, dx = \int_{\Omega} \sum_{j=1}^3 y_1 \Gamma_{1j} \partial_j \zeta \, dx + \int_{\Omega} \sum_{j=1}^3 (\partial_j y_1) \Gamma_{1j} \zeta \, dx,$$

which yields the desired extension of (31).

Given that $y^k \rightharpoonup y$ in $W^{1,2}(\Omega, \mathbb{R}^3)$ and $\text{cof}\nabla y^k \rightharpoonup \text{cof}\nabla y$ in $L^4(\Omega, \mathbb{R}^{3 \times 3})$, one obtains the continuity result

$$\begin{aligned} \int_{\Omega} \det \nabla y^k \zeta \, dx &= - \int_{\Omega} \sum_{j=1}^3 y_1^k (\text{cof}\nabla y^k)_{1j} \partial_j \zeta \, dx \\ &\rightarrow - \int_{\Omega} \sum_{j=1}^3 y_1 (\text{cof}\nabla y)_{1j} \partial_j \zeta \, dx = \int_{\Omega} \det \nabla y \zeta \, dx \end{aligned}$$

as in the first part of the proof from the compact embedding of $W^{1,2}(\Omega, \mathbb{R}^3)$ into $L^2(\Omega, \mathbb{R}^3)$. Note that for fixed ζ both sides of (33) are bounded bilinear functions.

From $\det \nabla y^k \rightharpoonup v$ and $\det \nabla y^k \rightharpoonup \det \nabla y$ in $L^2(\Omega, \mathbb{R})$, it follows that $v = \det \nabla y$ almost everywhere, which concludes the proof.

This completes the ingredients for the proof of the main result in Theorem 1.

Proof (Proof of Theorem 1). By assumption, \mathcal{J} is bounded from below. Thus, there exists a minimizing sequence $\{y^k\}_k$ such that

$$\lim_{k \rightarrow \infty} \mathcal{J}[y^k] = \inf_{y \in \mathcal{A}} \mathcal{J}[y^k] =: m.$$

Note that \mathcal{J} is finite for $\text{Id}(x) = x$. Therefore, it can be assumed that $\{\mathcal{J}[y^k] : k \in \mathbb{N}\}$ is also bounded from above by a constant $M > 0$.

By Lemma 1, the sequence $\{(y^k, \text{cof}\nabla y^k, \det \nabla y^k)\}_k$ can be bounded in the Banach space X defined in (13) in terms of M . More precisely, there are constants $C > 0$ and $K \in \mathbb{R}$ such that for all k it holds

$$M \geq \mathcal{J}[y^k] \geq K + C(\|y^k\|_{W^{1,2}}^2 + \|\text{cof}\nabla y^k\|_{L^4}^4 + \|\det\nabla y^k\|_{L^2}^2).$$

Since X is a reflexive space, there exists a subsequence – again denoted by $\{(y^k, \text{cof}\nabla y^k, \det\nabla y^k)\}_k$ – that converges weakly to a $(y, H, v) \in X$.

Lemma 2 proofs \mathcal{J} to be weak lower continuous. Thus

$$\liminf_{k \rightarrow \infty} \int_{\Omega} g(x, y^k, \nabla y^k, \text{cof}\nabla y^k, \det\nabla y^k) dx \geq \int_{\Omega} g(x, y, \nabla y, H, v) dx.$$

Theorem 4 yields the identifications $H = \text{cof}\nabla y$ and $v = \det\nabla y$.

The last step is to show that y is admissible. It remains to show that $\det\nabla y > 0$ almost everywhere. To this end, consider a fixed $\epsilon \in [0, 1)$ and the set

$$S_\epsilon := \{x \in \Omega : \det\nabla y(x) < \epsilon\}.$$

It then holds that

$$\begin{aligned} \psi(\epsilon) \text{vol}(S_\epsilon) &\leq \int_{S_\epsilon} \psi(\epsilon) dx \leq \int_{S_\epsilon} \psi(\det\nabla y) dx \\ &\leq \int_{S_\epsilon} g(x, y, \nabla y, \text{cof}\nabla y, \det\nabla y) dx \\ &\leq \liminf_{k \rightarrow \infty} \int_{S_\epsilon} g(x, y^k, \nabla y^k, \text{cof}\nabla y^k, \det\nabla y^k) dx \leq M. \end{aligned}$$

Due to the growth condition $\psi(v) \rightarrow \infty$ for $v \rightarrow 0^+$, it follows that S_0 has zero volume. Thus, $\det\nabla y > 0$ almost everywhere in Ω and $y \in \mathcal{A}$, which completes the proof.

To summarize, the hyperelastic regularization functional $\mathcal{S}^{\text{hyper}}$ guarantees the existence of optimal transformations for the unconstrained variational image registration problem. The proof of Theorem 1 illustrates difficulties due to the non-convexity of the objective functional and shows remedies. The main idea is to split y into Jacobian, cofactor, and determinant components and to show convergence of a minimizing sequence in a product space by proving coercivity and lower semicontinuity; see Lemmas 1 and 2. Subsequently, weak continuity of the cofactor and determinant mapping is used to undo this splitting; see Theorem 4. The provided proof is a special case of the existence theory of *polyconvex* functionals; see [4, 18, 20, 25]. In addition to providing existence of optimal transformations, the theory shows that a solution y satisfies $\det\nabla y > 0$ almost everywhere.

Instead of striving for the most generalized result, this section intends to provide insight into machinery of [4]. Therefore, four simplifying assumptions were made that are, however, uncritical in most practical applications.

4 Numerical Methods for Hyperelastic Image Registration

Generally, image registration problems cannot be solved analytically. Thus, numerical methods are used to approximate an optimal transformation. This section presents numerical methods for hyperelastic image registration based on a discretize-then-optimize approach. The first step is to properly discretize the variational problem (2). Typically, a coarse-to-fine sequence of finite dimensional optimization problems is generated, where all problems are linked by the underlying variational problem (2). Each problem can then be solved using standard optimization methods. Note that the coarse-to-fine strategy adds further regularization and additionally speeds up the computations.

In the hyperelastic setting, discretization is not straightforward. A challenge is to ensure one-to-one numerical solutions to the optimization problems, which are mandatory in most practical applications and guaranteed in the continuous function space setting. It is well known that a discrete object does not necessarily mimic all the properties of its continuous counterpart. For example, a function that is non-negative on a discrete set may not be non-negative everywhere. Thus, an approximated solution may not satisfy $\det \nabla y > 0$ almost everywhere, although the above existence theory guarantees this for the solutions of the continuous problem.

This section organizes as follows. Section “Discretizing the Determinant of the Jacobian” illustrates difficulties arising in the discretization of Jacobian determinants using finite difference schemes. As one way to avoid these difficulties, Galerkin finite element methods are presented in section “Galerkin Finite Element Discretization”. The main idea is to compute a solution to the variational problem in the space of globally continuous and piecewise linear transformations. A key benefit is that for these transformations geometric quantities like area and volume can be computed exactly; see section “Galerkin Finite Element Discretization”. Consequently, solutions of the discrete problem are guaranteed to be one-to-one. Finally, section “Multi-level Optimization Strategy” presents multi-level numerical optimization approaches that solve the finite dimensional optimization problems; see also [55].

Discretizing the Determinant of the Jacobian

The variational image registration problem (2) can be discretized using finite difference schemes. The underlying idea is to approximate the solution to the variational problem on a *grid*, which is essentially a collection of points. Many commonly used algorithms for image registration are based on these principles; see, e.g., [55] for an overview.

However, deriving finite difference discretization of operators such as the determinant of the Jacobian is not straightforward as illustrated by a simplified 2D example. For a transformation $y \in C^2(\Omega, \mathbb{R}^2)$, the determinant of the Jacobian is

$$\det \nabla y(x) = \partial_1 y_1(x) \partial_2 y_2(x) - \partial_2 y_1(x) \partial_1 y_2(x). \quad (34)$$

Note that all entries of $\nabla y(x)$ are coupled, which causes difficulties for finite difference discretizations. This section analyzes this problem in detail and presents a finite volume technique that can be used to obtain a proper discretization.

Finite Differences in 1D

To start with the analysis, consider in a 1D setting discretization of the energy

$$\mathcal{S}[y] = \frac{1}{2} \int_{\Omega} (\partial y(x))^2 dx, \quad (35)$$

where $\Omega = [0, 1]$ is divided into m cells of width $h = 1/m$. The *cell-centered grid* $x^c \in \mathbb{R}^m$ and the *nodal grid* $x^n \in \mathbb{R}^{m+1}$ are defined by $x_i^c = (i - 0.5)h$ and $x_i^n = (i - 1)h$, respectively; see [55] for details. Assuming that $y \in \mathcal{C}^2(\Omega, \mathbb{R})$ and a *short central finite difference* yields

$$\partial y(x_i^c) = \frac{y(x_{i+1}^n) - y(x_i^n)}{h} + \mathcal{O}(h^2). \quad (36)$$

Note that the discretization is of second order for a price of a grid change. The function y is approximated on the nodal grid, whereas its derivative is approximated on the cell-centered grid. With the discrete partial differential operator $\partial_m^h : \mathbb{R}^{m+1} \rightarrow \mathbb{R}^m$,

$$\partial_m^h := \frac{1}{h} \begin{pmatrix} -1 & 1 \\ & \ddots & \ddots \\ & & -1 & 1 \end{pmatrix} \in \mathbb{R}^{m \times m+1}, \quad (37)$$

Equation (36) reads $\partial y(x^c) = \partial_m^h y(x^n) + \mathcal{O}(h^2)$. To avoid the grid change, one could also use the *long stencil* $\partial y(x_i^c) \approx (y(x_{i+1}^c) - y(x_{i-1}^c))/(2h)$. The price to be paid is the non-trivial null-space with high frequency components which are unseen by this discrete regularizer. While this might be tolerable on a fixed discretization level, it is a crucial drawback for multigrid schemes. Therefore, this discretization is not recommended. Finally, one could also think about a one-sided stencil, $\partial y(x_i^c) \approx (y(x_{i+1}^c) - y(x_i^c))/h$. Here, the price to be paid is that this approximation is only first order and this discretization is also not recommended. Thus, ∂_m^h is preferable for approximating derivatives of nodal quantities. Derivatives of cell-centered quantities can be approximated analogously on a subset of the nodal grid x^n using ∂_{m-1}^h .

Using a nodal discretization $y^n \approx y$ with $y_i^n \approx y(x_i^n)$ and the above discretization of the differential operator, a second-order approximation of (35) is obtained by using a midpoint quadrature rule:

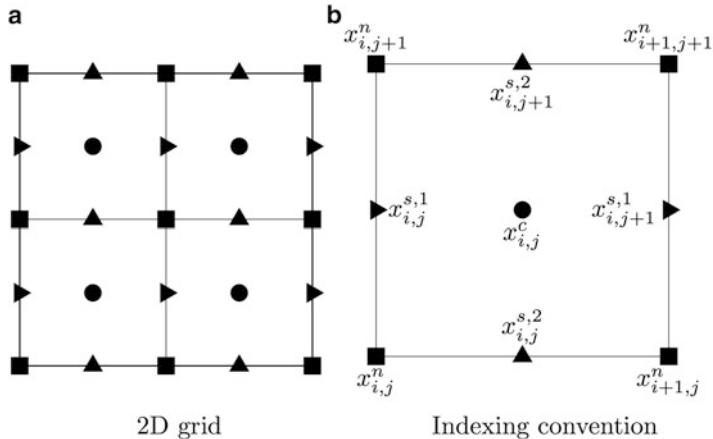

Fig. 4 Overview of grids and indexing convention in 2D as also used in [55]. A cell-centered grid x^c a nodal grid x^n and staggered grids $x^{s,1}$ and $x^{s,2}$ are depicted in (a). The indexing convention for the (i, j) th cell is illustrated in (b)

$$S[y^n] := \frac{h}{2} (y^n)^\top (\partial_m^h)^\top \partial_m^h y^n.$$

Note that both the finite difference operator and the quadrature rule are of second order which is essential for a consistent approximation.

Finite Differences in 2D

Already in 2D, the situation gets far more interesting. Let the rectangular domain $\Omega = [0, 1]^2$ be divided into (m, m) cells of uniform edge length $h = 1/m$. Similar as above, cell-centered and nodal grids are defined as

$$\begin{aligned} x^c &= ((i - 0.5)h, (j - 0.5)h)_{i,j=1,\dots,m} \\ x^n &= ((i - 1)h, (j - 1)h)_{i,j=1,\dots,m+1}. \end{aligned}$$

See Fig. 4 for an overview of grids and indexing conventions. For ease of presentation of finite difference operators to higher dimensions, the concept of *Kronecker products* is convenient; see also [9].

Definition 4 (Kronecker Product). Given two matrices $A \in \mathbb{R}^{p_1 \times p_2}$ and $B \in \mathbb{R}^{q_1 \times q_2}$, the *Kronecker product* is defined by

$$A \otimes B = \begin{pmatrix} a_{1,1}B & \dots & a_{1,p_2}B \\ \vdots & \ddots & \vdots \\ a_{p_1,1}B & \dots & a_{p_1,p_2}B \end{pmatrix} \in \mathbb{R}^{p_1 q_1 \times p_2 q_2}.$$

As the following discussion illustrates, it is impossible to give a second order approximation to all components of the Jacobian matrix of $y = [y_1, y_2] \in C^2(\Omega, \mathbb{R}^2)$ on a cell-centered grid by using short differences. To illustrate this, consider the first component y_1 of the transformation. Second order approximations to the partial derivatives of a nodal discretization $y_1^n \in \mathbb{R}^{(m+1)^2}$ can be obtained using the finite difference operators

$$\partial_{m,1}^h = I_{m+1} \otimes \partial_m^h \text{ and } \partial_{m,2}^h = \partial_m^h \otimes I_{m+1} \in \mathbb{R}^{m(m+1) \times (m+1)^2}.$$

In contrast to the 1D case, partial derivatives are not approximated on a cell-centered grid, but on *staggered grids*. Here, the first partial derivatives $\partial_{m,1}^h y_1^n$ and $\partial_{m,2}^h f^n$ are approximated at different locations

$$\begin{aligned} x^{s,1} &= ((i-1)h, (j+.5)h)_{i=1,\dots,m+1, j=1,\dots,m}, \\ x^{s,2} &= ((i+.5)h, (j-1)h)_{i=1,\dots,m, j=1,\dots,m+1}, \end{aligned}$$

see also Fig. 4. As in the 1D case, grid changes are inevitable when using short differences. Furthermore, different partial derivatives are approximated at different positions. This also holds for other choices of discretization. For example, discretizing y_1 on the staggered grid $x^{s,1}$ and using the operators

$$\partial_{m,1}^h = I_m \otimes \partial_m^h \text{ and } \partial_{m,2}^h = \partial_{m-1}^h \otimes I_{m+1},$$

approximates $\partial_1 y_1$ on a cell-centered grid and $\partial_2 y_1$ on a subset of a nodal grid. Note that for all combinations of the above grids and finite difference operators the components of the gradient of y_1 are approximated at different locations. This is a major source of difficulty when discretizing regularization functionals based on coupled partial differential operators such as the determinant of the Jacobian (34).

Finite Volume Discretization

The above presentation indicates that second order approximations of the partial derivatives at the cell-centered grid with short differences are impossible. Averaging derivatives to the cell-centers is not a remedy as it annihilates oscillatory functions. One way to overcome this limitation is to approximate $\det \nabla y$ in a finite volume approach by measuring volume changes as it has been proposed [36]. In [36], the volume of a deformed cell V is approximated by the sum over of the volume of two triangles spanned by its vertices V_i , see also Fig. 5:

$$\begin{aligned} \int_V \det \nabla y(x) dx &= \int_{y(V)} dx \\ &= (V_3 - V_2) \times (V_2 - V_1)/2 + (V_4 - V_1) \times (V_3 - V_4)/2 + \mathcal{O}(h^2). \end{aligned} \tag{38}$$

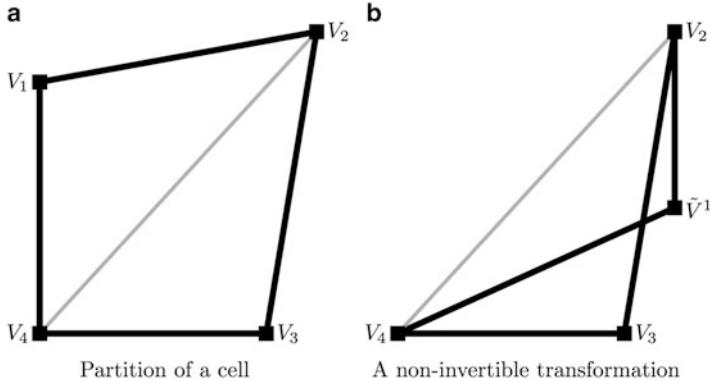

Fig. 5 Measuring the volume of a transformed cell as in [36]. The volume of the transformed cell is approximated by the sum of the volumes of the two triangles spanned by its vertices; see (a). In (b), a non-invertible transformation is applied to the cell. Note that although the volume of the triangle spanned by V_4 , V_2 and \tilde{V}^1 is negative, the volume of V is positive. This motivates to individually control volume changes of the triangles in order to detect twists

Assuming $y \in C^2(\Omega, \mathbb{R}^3)$, this approximation is second order; see also section “Images and Transformation”. The first equality requires that y is invertible due to the transformation theorem, which is to be ensured by hyperelastic regularization. An advantage of this approach is that transformations that are not one-to-one can be detected. Note that for a non-invertible transformation and a sufficiently fine spacing of control points there is a sign change of the volume of a triangle; see Fig. 5. This approach was also used for hyperelastic image registration in [14].

Note that using this discretization, the constraint $\det \nabla y > 0$ is controlled only approximately and on a tetrahedral partition rather than point-wise. In order to ensure $\det \nabla y > 0$ almost everywhere, additional assumptions on the behavior of y between the control points are required. In [14] it is shown that based on the above discretization the volume constraint can be ensured almost everywhere for continuous and piecewise linear transformations. Motivated by this observation, the next section presents a Galerkin Finite Element approach that operates on this finite dimensional space.

Galerkin Finite Element Discretization

This section presents a *Galerkin finite element method* based on the general framework presented in [32]. The idea is to discretize the variational problem (2) with regularization functional $\mathcal{S}^{\text{hyper}}$ using globally continuous and piecewise linear transformations on a tetrahedral mesh. For these functions, the constraint $\det \nabla y > 0$ is fulfilled everywhere if it holds on each element. In accordance with the theory, our discrete solutions will share this important quality.

Let $V_1, \dots, V_{n_V} \in \mathbb{R}^3$ denote vertices and T_1, \dots, T_{n_T} tetrahedra, where it is assumed that $\text{vol}(T_i) > 0$ for all $i = 1, \dots, n_T$. This builds a finite dimensional subspace

$$\mathcal{A}_h := \{y \in \mathcal{C}(\Omega, \mathbb{R}^3) : y|_{T_i} \in \Pi^1(T, \mathbb{R}^3) \text{ for } i = 1, \dots, n_T\} \subset \mathcal{A}, \quad (39)$$

where h is related to n_V and denotes order of the approximation, Π_1 denotes the space of first order vector-valued polynomials. Standard nodal Lagrange basis functions $b^1, \dots, b^{n_V} : \Omega \rightarrow \mathbb{R}$ are used as a basis of \mathcal{A}_h . The coefficients \mathbf{y} of $y^h \in \mathcal{A}_h$ with respect to that basis are stored component-wise in a column vector of size $3n_V$, $\mathbf{y}_j = (\mathbf{y}_j^1, \mathbf{y}_j^2, \mathbf{y}_j^3)^\top$, $j = 1, \dots, n_V$:

$$y^h(x) = \sum_{j=1}^{n_V} \mathbf{y}_j b^j(x), \quad (40)$$

where $\mathbf{y}_j = y^h(V_j)$ and analogously a discretization of a reference transformation \mathbf{y}_{ref} is obtained as $(\mathbf{y}_{\text{ref}})_j = y_{\text{ref}}(V_j)$. The discretized hyperelastic registration problem then reads

$$J : \mathbb{R}^{3n_V} \rightarrow \mathbb{R}^+, \quad J(\mathbf{y}) = D(\mathbf{y}) + \alpha \mathcal{S}^{\text{hyper}}(\mathbf{y} - \mathbf{y}_{\text{ref}}). \quad (41)$$

The discretization of the distance and hyperelastic regularization functional are derived as follows.

Let $I_k \in \mathbb{R}^{k \times k}$ denote the identity matrix, $\mathbf{1}_k \in \mathbb{R}^k$ the vector of all ones, \otimes the Kronecker product, and \odot the Hadamard product. The entries of the Jacobian matrix ∇y^h are piecewise constant on each triangle. The nine components of the Jacobi matrix are stored in a column vector $(By) \in \mathbb{R}^{9n_T}$, where B is the discrete vector gradient operator formed essentially from the discrete partial derivatives $\partial_k^h \in \mathbb{R}^{n_T \times n_V}$ with $(\partial_k^h)_{i,j} = \partial_k b^i(V_j)$:

$$B = I_3 \otimes \nabla^h, \quad \text{with } (\nabla^h)^\top = ((\partial_1^h)^\top, (\partial_2^h)^\top, (\partial_3^h)^\top). \quad (42)$$

Interpolation from nodes to barycenters of the tetrahedra is accomplished by applying the averaging matrix

$$\mathbf{A} = I_3 \otimes A \in \mathbb{R}^{n_T \times n_V} \text{ with } A_{i,j} = \begin{cases} 1/4 & \text{if } V_j \text{ is node of } T_i \\ 0 & \text{otherwise} \end{cases}. \quad (43)$$

Assembling the volumes of the tetrahedra in

$$\mathbf{v} \in \mathbb{R}^{n_T}, \quad \text{with } \mathbf{v}_i := \text{vol}(T_i) \text{ and setting } \mathbf{V} := \text{diag}(\mathbf{v}), \quad (44)$$

the SSD distance functional (5) is approximated by using a midpoint quadrature rule

$$D(\mathbf{y}) \approx \frac{1}{2} \text{res}(\mathbf{y})^\top \mathbf{V} \text{res}(\mathbf{y}), \text{ where } \text{res}(\mathbf{y}) = \mathcal{T}(\mathbf{A}\mathbf{y}) - \mathcal{R}(\mathbf{x}). \quad (45)$$

Since the Jacobian matrix of $\mathbf{y}^h \in \mathcal{A}_h$ is piecewise constant, the hyperelastic regularization functional is evaluated exactly by

$$\begin{aligned} \mathcal{S}^{\text{hyper}}(\mathbf{y}) &= \frac{\alpha_\ell}{2} (\mathbf{y} - \mathbf{y}_{\text{ref}})^\top \mathbf{B}^\top (I_9 \otimes \mathbf{V}) \mathbf{B} (\mathbf{y} - \mathbf{y}_{\text{ref}}) \\ &\quad + \alpha_a \mathbf{v}^\top \phi(\text{cof} \mathbf{B} \mathbf{y}) + \alpha_v \mathbf{v}^\top \psi(\det \mathbf{B} \mathbf{y}). \end{aligned} \quad (46)$$

In line with the organization of the gradient, the entries of the cofactor matrix are stored in a column-vector of length $9n_T$. The first derivatives of the discretized objective function is

$$dJ(\mathbf{y}) = d\mathcal{D}(\mathbf{y}) + d\mathcal{S}^{\text{length}}(\mathbf{y}) + d\mathcal{S}^{\text{area}}(\mathbf{y}) + d\mathcal{S}^{\text{vol}}(\mathbf{y}). \quad (47)$$

Using the chain rule yields

$$dD(\mathbf{y}) = \text{res}(\mathbf{y})^\top \mathbf{V} (\nabla \mathcal{T}(\mathbf{A}\mathbf{y})) \mathbf{A}, \quad (48)$$

$$d\mathcal{S}^{\text{length}}(\mathbf{y}) = \alpha_\ell (\mathbf{y} - \mathbf{y}_{\text{ref}})^\top \mathbf{B}^\top (I_9 \otimes \mathbf{V}) \mathbf{B}, \quad (49)$$

$$d\mathcal{S}^{\text{area}}(\mathbf{y}) = \alpha_a ((I_9 \otimes \mathbf{v}) \odot \phi'(\text{cof} \mathbf{B} \mathbf{y}))^\top d \text{cof} \mathbf{B} \mathbf{y}, \quad (50)$$

$$d\mathcal{S}^{\text{vol}}(\mathbf{y}) = \alpha_v \mathbf{v}^\top \psi'(\det \mathbf{B} \mathbf{y}) d \det \mathbf{B} \mathbf{y}. \quad (51)$$

Setting $D_i^j = \text{diag}(\partial_i \mathbf{y}^j) \in \mathbb{R}^{n_T \times n_T}$, one gets

$$d \text{cof} \mathbf{B} \mathbf{y} = \left(\begin{array}{ccc} D_3^3 & -D_2^3 & -D_3^2 D_2^2 \\ D_3^3 & -D_2^3 & -D_3^1 D_1^2 \\ D_2^3 & -D_1^3 & -D_2^2 D_1^2 \\ D_3^3 & -D_3^2 & -D_3^1 D_2^1 \\ D_3^2 & -D_1^3 & -D_3^1 D_1^2 \\ D_3^2 & -D_1^2 & -D_1^2 D_1^1 \\ D_2^2 & -D_1^2 & -D_3^1 D_2^1 \\ D_2^2 & -D_1^2 & D_1^1 \\ D_2^2 & D_1^1 & D_1^1 \end{array} \right) B \in \mathbb{R}^{9n_T \times 3n_V}. \quad (52)$$

With the abbreviation $C_i^j = \text{diag}((\text{cof} \mathbf{B} \mathbf{y})_{i,j}) \in \mathbb{R}^{n_T \times n_T}$, the derivative of the Jacobi determinant can be compactly written as

$$d \det \mathbf{B} \mathbf{y} = (C_1^1, C_1^2, C_1^3, C_2^1, C_2^2, C_2^3, C_3^1, C_3^2, C_3^3) B \in \mathbb{R}^{n_T \times 3n_V}. \quad (53)$$

Following the guidelines of [55], the Hessian of the objective functional is approximated to ensure positive semi-definiteness and avoid computations of second derivatives of the (generally noisy) template image as follows

$$H(\mathbf{y}) \approx d_2 D(\mathbf{y}) + d_2 \mathcal{S}^{\text{length}} + d_2 \mathcal{S}^{\text{area}}(\mathbf{y}) + d_2 \mathcal{S}^{\text{vol}}(\mathbf{y}) \quad (54)$$

with the summands

$$d_2 D(\mathbf{y}) = \mathbf{A}^\top (\nabla \mathcal{T}(\mathbf{Ay}))^\top \mathbf{V} \nabla \mathcal{T}(\mathbf{Ay}) \mathbf{A}, \quad (55)$$

$$d_2 \mathcal{S}^{\text{length}} = \alpha_\ell B^\top (I_9 \otimes \mathbf{V}) B, \quad (56)$$

$$d_2 \mathcal{S}^{\text{area}}(\mathbf{y}) = \alpha_a (d \operatorname{cof} B \mathbf{y})^\top (\operatorname{diag}(1_9 \otimes \mathbf{v}) \phi''(\operatorname{cof} B \mathbf{y})) d \operatorname{cof} B \mathbf{y}, \quad (57)$$

$$d_2 \mathcal{S}^{\text{vol}}(\mathbf{y}) = \alpha_v (d \det B \mathbf{y})^\top \operatorname{diag}(\mathbf{v} \odot \psi''(\det B \mathbf{y})) d \det B \mathbf{y}. \quad (58)$$

Note that for this distance functional the dependency of the first summand on \mathbf{y} is only low order and the second summand is constant with respect to \mathbf{y} . In contrast, the Hessian of the area and volume regularization functionals strongly depend on \mathbf{y} .

Multi-level Optimization Strategy

Using the above presented Galerkin method translates the variational image registration problem into a finite dimensional optimization problem. Solving the discrete problem is not straightforward as it is typically large, nonlinear and non-convex. However, state-of-the-art tools from numerical optimization can be used to obtain accurate and efficient schemes. This section describes a multi-level strategy using Gauss–Newton optimization.

Multi-level Idea

In image registration, challenges arise from the non-convex dependence of the objective functional on the transformation to be determined. Thus, many local minima have to be expected; for an example, see [55, p. 112]. A typical solution strategy is to approximately solve the variational problem (2) on a coarse-to-fine hierarchy of discretizations often referred to as *multi-level* strategy [55] or *cascadic multigrid* [7]. The key motivation is to reduce the risk of being trapped in a local minimum and to obtain good starting guesses for the correction steps on finer discretization levels. A positive side effect is a reduction of computational costs.

Generically, a nested series of finite dimensional spaces \mathcal{A}_{h_i} with

$$\mathcal{A}_{h_1} \subset \mathcal{A}_{h_2} \subset \dots \subset \mathcal{A}$$

is constructed, where h_i refers to the approximation order. The idea then is to compute a minimizer y^1 of \mathcal{J} in \mathcal{A}_{h_1} first. This is relatively simple, as it is assumed that the space \mathcal{A}_{h_1} is smooth and the problem is of small size. Note that y^1 is in S_{h_2} and can thus be used as starting guess. In practice, only the coefficients of the basis functions in S_{h_2} at the new vertices need to be computed. For Lagrange basis functions, weights are easily obtained by evaluating y^1 at the nodes of the mesh

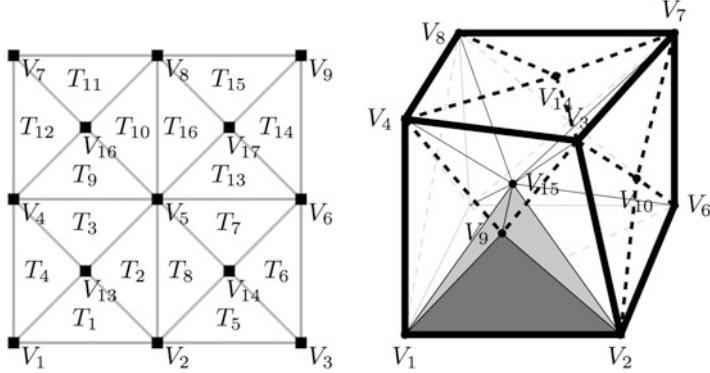

Fig. 6 Subdivision used for generating nested families of structured meshes as in [14]. *Left:* triangulation of an $m = [2, 2]$ grid. *Right:* tetrahedral subdivision of a voxel

of S_{h_2} . With this excellent starting guess, computing a solution in \mathcal{A}_{h_2} is relatively simple, particularly with a second order schemes. This procedure is repeated until the finest level is reached.

There are many ways to construct a nested sequence of triangular meshes. A simple but powerful method is to use nested rectangular meshes and decompose each cell into tetrahedra as depicted in Fig. 6. However, more efficient strategies using local refinements based on error estimates exist; see, e.g., [39].

Commonly, the representation of the images are simplified on a coarse level by reducing the data; see [55]. Thereby, only essential image features are considered and consequently the danger of being trapped in a local minima is reduced further.

Gauss Newton Optimization

On each level, a Gauss–Newton scheme [57] can be used to compute a minimizer of the discretized objective function J in (41). Until convergence, the objective function $J(\mathbf{y})$, its gradient $dJ(\mathbf{y})$, and an approximation $H(\mathbf{y})$ to its Hessian are computed. The search direction v is then obtained by solving the linear system

$$H(\mathbf{y}) v = -dJ(\mathbf{y}). \quad (59)$$

As outlined in section “Galerkin Finite Element Discretization”, a symmetric and positive definite approximation of the Hessian is computed. Solving the above linear system is one of the most computationally expensive parts of the scheme. Recall (54) that the Hessian consists of four summands

$$H(\mathbf{y}) \approx d_2 D(\mathbf{y}) + d_2 \mathcal{S}^{\text{length}} + d_2 \mathcal{S}^{\text{area}}(\mathbf{y}) + d_2 \mathcal{S}^{\text{vol}}(\mathbf{y}).$$

The Hessian of the length regularizer $\mathcal{S}^{\text{length}}$ is simply a discrete Laplacian for each component of the transformation and does not depend on \mathbf{y} unlike the other

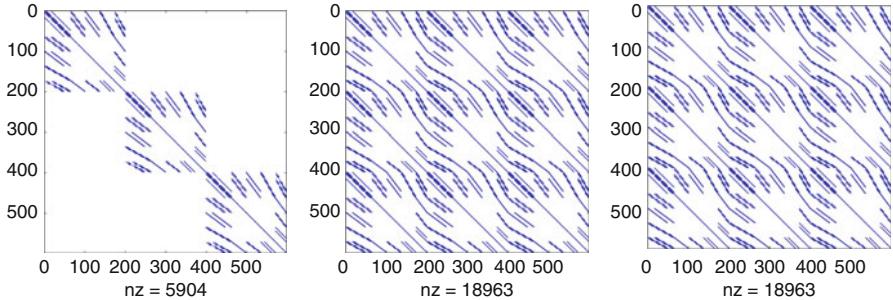

Fig. 7 Nonzero patterns of the Hessians of length (left), area (middle), and volume regularization functionals (right) for a tetrahedra mesh based on (3,3,3) cells. The mesh has 199 nodes and a number of nonzero elements in the Hessians are 5,904, 18,963, and 18,963, respectively

summands, which need to be updated in each iteration. Recall that a tight coupling between the components of the transformation is introduced by the area and volume regularizer and that the effective weight of $d^2\mathcal{S}^{\text{vol}}$ depends on the current iterate. A visualization of the nonzero patterns of the four blocks is presented in Fig. 7.

Since H is symmetric and positive semi-definite by design, a conjugate gradient (CG) method [44] can be used to approximate v . Conjugate gradient methods become even more efficient when being combined with preconditioning; see, e.g., [8]. Suppose there is an approximation $C \in \mathbb{R}^{N \times N}$ to H that is positive definite and easily invertible. Given a starting guess $v_0 \in \mathbb{R}^N$ consider the iteration

$$v_1 = v_0 - \alpha C^{-1}(H[y]v_0 + d\mathcal{J}[y])$$

with some step length α . Using $C = H$ and $\alpha = 1$, this would yield the result in one iteration. However, it is equivalent to directly solving (59). Thus, the idea is to use a “sufficient” approximation of C to H that is considerably easier to invert than H itself.

There are many preconditioning techniques for conjugate gradient methods. A computational attractive option is *Jacobi preconditioning*, i.e., $C = D$, where $D = \text{diag}(H)$. More expensive but also more effective preconditioning is offered by *Gauss-Seidel preconditioning*, i.e., $C = (D + L)D^{-1}(D + L^\top)$, where L is the lower triangular matrix of H and D the diagonal of H ; see [8, Ch.4] for more details.

The step length is determined by a standard Armijo line search in combination with a backtracking that ensures $\det \nabla y > 0$; see [57]. Standard stopping rules based on the value of the objective functional, the norm of the gradient, and the norm of the update can be used as discussed in detail in [55].

5 Applications of Hyperelastic Image Registration

This section outlines the potential of hyperelastic image registration for real-world applications. Exemplarily, two registration problems from medical imaging are considered. In both applications mass-preserving distance functionals are required and hyperelastic regularization is used to yield mathematically sound formulations.

Motion Correction of Cardiac PET

Positron Emission Tomography (PET) can provide useful information about the metabolism of the human heart, which is useful for the diagnosis of coronary artery diseases. To this end, a radioactive glucose tracer is administered and emission events are recorded by a detector ring during its decay. Finally, a tomographic image representing the spatial distribution of the tracer is reconstructed. Typically, a large fraction of the tracer is metabolized by the left ventricular muscle of the heart, which is thus visible in the images; see Fig. 8.

A key problem in PET reconstruction is the severe degradation of the images due to respiratory and cardiac motion during image acquisition. In principle, the more emission events are recorded, the better the expected image quality. Thus,

acquisition times are typically in the order of minutes and motion is inevitable. The so-called gating techniques are typically used to compensate for these motion artifacts [21]. The idea is that recorded emission events are grouped into a number of gates, which relate to particular phases in the respiratory and cardiac cycle. For each gate, a reconstruction is computed which shows less motion blur, but is also based on fewer counts and consequently of degraded quality as signal to noise has been reduced. To take full advantage of all measurements, the individual reconstructions are aligned using image registration and finally fused [30, 61].

Mass-Preservation

PET images represent the distribution of the density of the radioactive tracer, in this case, the distribution of a glucose tracer measured 1 h after injection. Therefore, it can be assumed the amount of tracer per given tissue unit to be constant. Thus the mass-preserving distance measure, as defined in section “Distance Functionals”, is used

$$\mathcal{D}^{\text{MP}}[y] = \mathcal{D}^{\text{MP}}[\mathcal{T}, \mathcal{R}; y] = \frac{1}{2} \int_{\Omega} (\mathcal{T}[y] \cdot \det \nabla y - \mathcal{R})^2 dx.$$

As mentioned in section “Distance Functionals”, the mass-preserving distance functional \mathcal{D}^{MP} is not convex in ∇y and mass-preservation requires that transformations satisfy $\det \nabla y > 0$. Also, large strains for cardiac motion correction are expected and images will be of relatively poor quality when using fine gating schemes. Thus, hyperelastic regularization is used since Theorem 1 guarantees existence of minimizers with positive Jacobian determinants.

The mass-preserving distance functional is discretized following the guidelines of section “Galerkin Finite Element Discretization”. As for the SSD distance, a midpoint quadrature rule is employed and computation of the Jacobian determinant and its derivatives are reused.

Registration Results and Impact on Image Quality

Registration results for a 3D PET data set of a human heart are visualized in Fig. 8. More precisely, Fig. 8 only presents results for the registration of diastolic and systolic phases which is the most difficult scenario. Data courtesy by Fabian Gigengack, European Institute for Molecular Imaging, University of Münster, Germany. It turns out that the mass-preserving hyperelastic registration approach accurately deforms the contracted systolic gate such that is very similar to the diastolic gate. The smooth and invertible transformation is visualized using a slice projection.

The image quality that can dramatically improved by registration and subsequent averaging of the transformed images as shown in Fig. 9. Here, a dual gating into five respiratory gates each being divided into five cardiac gates is performed, yielding 25 image volumes. Each single gate contains only a small fraction of the signal, however, is less affected by motion; cf. Fig. 9a. Reconstruction without registration yields a smoother image degraded by motion blurr; cf. Fig. 9b. A smooth and

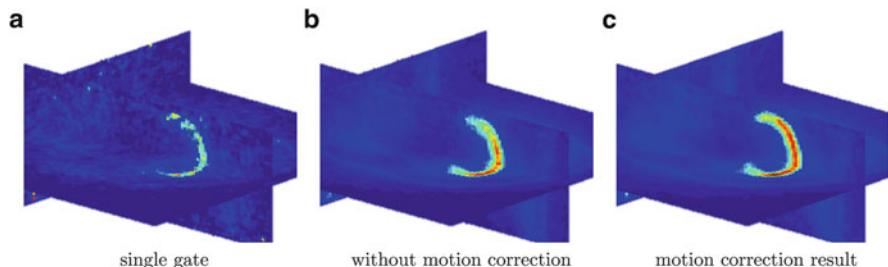

Fig. 9 Motion Correction result for PET data of a human heart. Slice projections of a single gate (*left*) a blurred reconstruction without motion correction (*center*) and motion-corrected reconstruction (*right*) are shown. Image data provided by Fabian Gigengack, European Institute of Molecular Imaging, University of Münster, Germany

motion-corrected reconstruction is obtained by following the pipeline suggested in [61] and averaging the aligned images. Here a much sharper and clearer image can be reconstructed; cf. Fig. 9c.

Summary and Further Literature

Mass-preserving hyperelastic image registration reduces motion artifacts in cardiac PET. The transformation model respects the density property of PET. Hyperelastic regularization is used to ensure existence of solutions that satisfy the mass-preserving constraint. The mass-preserving transformation model was validated in [30] and a pipeline for practical motion correction is suggested in [61].

Susceptibility Artefact Correction of Echo-Planar MRI

Echo Planar Imaging (EPI) is a commonly available ultrafast MRI acquisition technique; see [66]. It is routinely used for key investigation techniques in modern neuroscience such as diffusion tensor imaging (DTI) or functional MRI (fMRI).

While offering considerable reduction of acquisition time, a drawback of EPI is its high sensitivity against small perturbations of the magnetic field. Field inhomogeneities are inevitably caused by different magnetic susceptibilities of soft tissue, bone, and air and thus present in any practical setting. Inhomogeneities result in geometrical distortions and intensity modulations that complicate the interpretation of EPI data and their fusion with anatomical T1- or T2-weighted MR images obtained using conventional acquisition techniques with negligible distortions.

This section summarized the tailored variational image registration method for the correction of distortions presented in [62]. The method can be seen as a special case of mass-preservation hyperelastic registration for transformations that are restricted along one a priori known spatial direction.

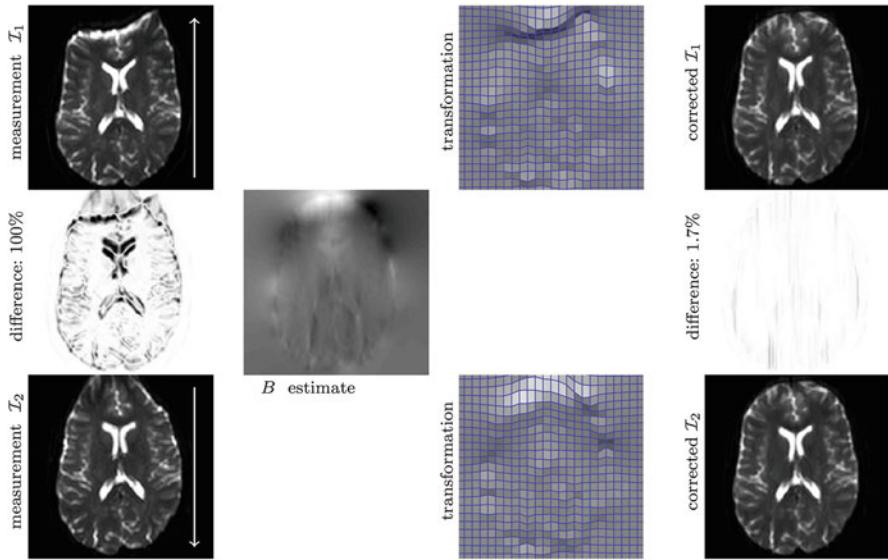

Fig. 10 Illustration of the Reversed Gradient Approach [15]. The initial measurements (*first column*) are distorted in opposite directions, depicted as *white arrows*. The estimated field inhomogeneity B (*second column*) gives rise to two geometric transformations (*third column*) that can be used to approximately correct the data (*right column*). Data courtesy by Harald Kugel, Department for Radiology, University of Münster, Germany

Reversed Gradient Method

The *Reversed Gradient Method* was firstly described by Chang and Fitzpatrick in 1992 [15] to correct for distortions due to field inhomogeneities. They derived a physical model for the distortions, which shows that measurements are distorted along one a priori known spatial direction. Interestingly, the direction of distortion v is not only known, but can also be controlled by parameters settings on the scanner. It is thus possible to acquire a pair of images, denoted by \mathcal{I}_1 and \mathcal{I}_2 , that are oppositely affected by distortions; see also Fig. 10.

The Variational Problem

The measurements \mathcal{I}_1 and \mathcal{I}_2 represent density distributions of protons. Therefore, there is a mass-preserving property [15] assumed. Due to field inhomogeneities, the signal is wrongly localized along the distortion direction v and the image intensities are modulated depending on the determinant of the Jacobian of the transformation (Fig. 11). Chang and Fitzpatrick describe the relation of the distorted measurements to the undistorted image \mathcal{I} by

$$I(x) = \mathcal{I}_1(x + vB(x))(1 + \partial_v B) = \mathcal{I}_2(x - vB(x))(1 + \partial_v B), \quad (60)$$

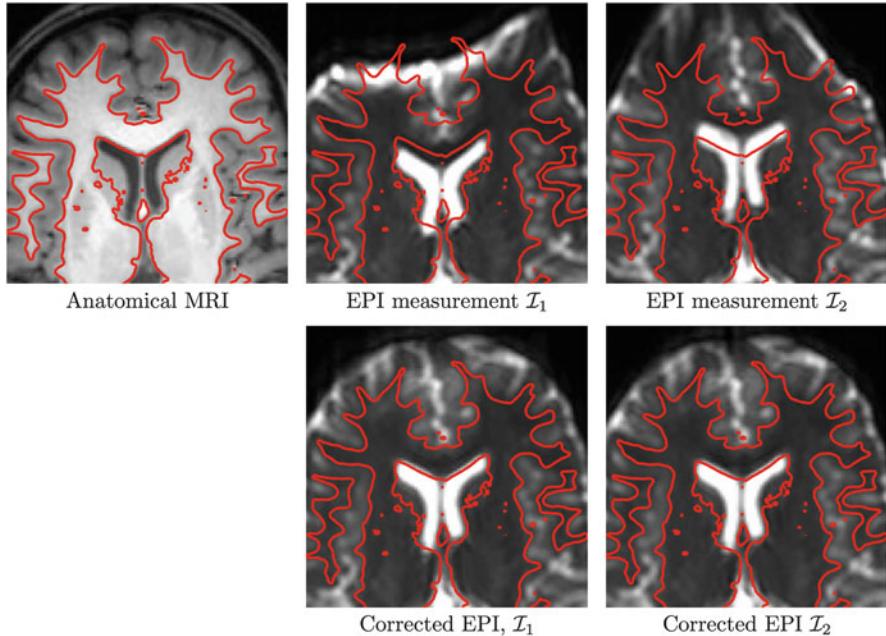

Fig. 11 Improved correspondence of corrected EPI measurements to anatomical MRI. Data courtesy by Harald Kugel, Department for Radiology, University of Münster, Germany

where $B : \Omega \rightarrow \mathbb{R}$ denotes the field inhomogeneity that needs to be measured or estimated numerically. Note that for distortion directions $\pm v$, there are two transformations $y^\pm = x \pm vB(x)$ and hence $\det \nabla y = 1 \pm \partial_v B$.

Considerable progress has been made in the numerical treatment of the reversed gradient method in the last decade; see, for instance [2, 47, 62, 64]. These numerical schemes are based on a tailored mass-preserving distance functional

$$\mathcal{D}^{\text{EPI}}[B] = \frac{1}{2} \int_{\Omega} (\mathcal{I}_1(x + vB(x))(1 + \partial_v B) - \mathcal{I}_2(x - vB(x))(1 - \partial_v B))^2 \, dx.$$

A notable difference to image registration problems is that there is no template and reference image relationship. The displacement is applied to images, but in opposite directions. Further, intensity modulations are applied to ensure mass-preservation.

Regularization Because of the mass-preservation component invertibility of the geometrical transformations in (60) is required as has been already stressed in [15]. However, simplifications of the hyperelastic regularization functional $\mathcal{S}^{\text{hyper}}$ arise, since displacements are restricted in one direction. Thus the field inhomogeneity B needs to satisfy

$$0 < (1 + \partial_v B) \text{ and } 0 < (1 - \partial_v B) \Leftrightarrow -1 < \partial_v B < 1. \quad (61)$$

This motivates using the following regularizer

$$\mathcal{S}^{\text{EPI}}[B] = \frac{\alpha}{2} \int_{\Omega} \|\nabla B\|^2 dx + \beta \int_{\Omega} \psi(\partial_v B) dx.$$

The first summand is a diffusion term that ensures smoothness as commonly used and suggested by the forward model; see [22]. The convex penalty function

$$\psi(v) = \frac{v^4}{(v-1)(v+1)}$$

has singularities at ± 1 and ensures $\partial_v B \in L^2$. This is essential to ensure positivity of the intensity modulations. It is shown in [62] that this regularizer ensures existence of solutions and that solutions satisfy (61).

Numerical Implementation Numerical discretization of the reversed gradient can be done using a nodal grid for the field inhomogeneity and a finite volume approach. Intensity modulations are thus approximated by monitoring volume changes. Note that no coupling between the components of the Jacobian matrix is present since displacements are restricted along $\pm v$. A Matlab implementation is available as an extension to the FAIR toolbox [55] and integrated into the toolbox Statistical Parametric Mapping (SPM) [63].

Correction Results

Figure 10 illustrates the correction method for EPI data of the brain of a healthy volunteer; see [62] for more results. Data courtesy by Harald Kugel, Department for Radiology, University of Münster, Germany. The distance between the images \mathcal{I}_1 and \mathcal{I}_2 with respect to \mathcal{D}^{EPI} is reduced considerably by the estimated transformation.

Figure 10 shows the improvement of spatial correspondence between the distorted EPI data and an anatomical T1-weighted MRI which can be assumed to be free of distortions. An axial slice zoomed into the frontal brain region is shown. Superimposed contour lines representing a white matter segmentation obtained from the anatomical image data are depicted in all subplots. Geometrical mismatch of the uncorrected EPI measurements and the anatomical data is most pronounced in frontal regions and around the Corpus Callosum. After correction, the geometrical correspondence improves considerably.

6 Conclusion

Image registration is an essential task in a variety of areas involving imaging techniques. This chapter presented a comprehensive overview of mathematical techniques used for nonlinear image registration. Emphasis was on regularization

techniques that ensure a mathematically sound formulation of the problem, allow stable and fast numerical solution, and favor solutions that are realistic for the application in mind.

Starting out from one of the most commonly used linear elastic model [10, 55], its limitations and extensions to nonlinear regularization functionals based on the theory of hyperelastic materials were discussed. A detailed overview of the available theoretical results was given. Insight into the existence theory of hyperelastic image registration problems was given and a state-of-the-art numerical scheme is presented. Finally, the potential of hyperelastic image registration for real-life medical imaging applications was outlined in two case studies.

Abstract

We begin with traditional source detection algorithms in astronomy. We then introduce the sparsity data model. The starlet wavelet transform serves as our main focus in this article. Sparse modeling and noise modeling are described. Applications to object detection and characterization, and to image filtering and deconvolution, are discussed. The multiscale vision model is a further development of this work, which can allow for image reconstruction when the point spread function is not known or not known well. Bayesian and other algorithms are described for image restoration. A range of examples is used to illustrate the algorithms.

1 Introduction

Data analysis is becoming more and more important in astronomy. This can be explained by detector evolution, which concerns all wavelengths. In the 1980s, CCD (charge-coupled device) images had a typical size of 512×512 pixels, while astronomers now have CCD mosaics with $16,000 \times 16,000$ pixels or even more. At the same time, methods of analysis have become much more complex, and the human and financial efforts to create and process the data can sometimes be of the same order as for the construction of the instrument itself. As an example, for the ISOCAM camera of the Infrared Space Observatory (ISO), the command software of the instrument, and the online and offline data processing, required altogether 70 person years of development, while 200 person years were necessary for the construction of the camera. The data analysis effort for the PLANCK project is even larger. Furthermore, the quantity of outputs requires the use of databases, and in parallel sophisticated tools are needed to extract ancillary astrophysical information, generally now through the web. From the current knowledge, new questions emerge, and it is necessary to proceed to new observations of a given object or a part of the sky. The acquired data need to be calibrated prior to useful information for the scientific project being extracted.

Data analysis acts during the calibration, the scientific information extraction process, and the database manipulation. The calibration phase consists of correcting various instrumental effects, such as the dark current (i.e., in the absence of any light, the camera does not return zero values, and the measured image is called the dark image and needs to be subtracted from any observation) or the flat-field correction (i.e., for uniform light, the detector does not return the same value for each pixel, and a normalization needs to be performed by dividing the observed image by the “flat” image). Hence, it is very important to know well the parameters of the detector (flat-field image, dark image, etc.), because any error on these parameters will propagate to the measurements. Other effects can also be corrected during this phase, such as the removal of the cosmic ray impacts or the field distortion (the pixel surface for each pixel does not correspond to the same surface on the sky). Depending on the knowledge of the instrument, each of these tasks may be more or less difficult.

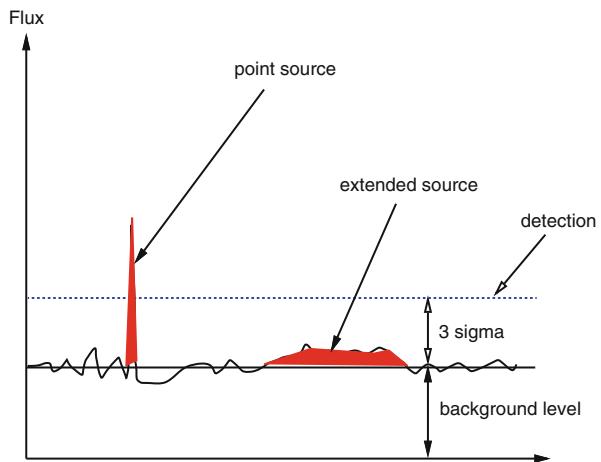

Once the data are calibrated, the analysis phase can start. Following the scientific objectives, several kinds of information can be extracted from the data, such as the detection of stars and galaxies, the measurement of their position, intensity, and various morphological parameters. The results can be compared to existing catalogs, obtained from previous observations. It is obviously impossible to cite all operations we may want to carry through on an astronomical image, and we have just mentioned the most common. In order to extract the information, it is necessary to take into account noise and point spread function. Noise is the random fluctuation which is added to the CCD data and comes partially from the detector and partially from the data. In addition to the errors induced by the noise on the different measurements, noise also limits the detection of objects and can be responsible for false detections. The point spread function is manifested in how the image of a star, for example, is generally spread out on several pixels, caused by the atmosphere’s effect on the light path. The main effect is a loss of resolution, because two sufficiently close objects cannot be separated. Once information has been extracted, such details can be compared to our existing knowledge. This comparison allows us to validate or reject our understanding of the universe.

In this chapter, we will discuss in detail how to detect objects in astronomical images and how to take into account the point spread function through the deconvolution processing.

Source Detection

As explained above, source (i.e., object) extraction from images is a fundamental step for astronomers. For example, to build catalogs, stars and galaxies must be identified and their position and photometry must be estimated with good accuracy. Catalogs comprise a key result of astronomical research. Various methods have been proposed to support the construction of catalogs. One of the now most widely used software packages is SExtractor [6], which is capable of handling very large images. A standard source detection approach, such as in SExtractor, consists of the following steps:

Fig. 1 Example of astronomical data: a point source and an extended source are shown, with noise and background. The extended object, which can be detected by eye, is undetected by a standard detection approach

1. Background estimation.
2. Convolution with a mask.
3. Detection.
4. Deblending/merging.
5. Photometry.
6. Classification.

These different steps are described in the next section. Astronomical images contain typically a large set of point-like sources (the stars), some quasi point-like objects (faint galaxies, double stars), and some complex and diffuse structures (galaxies, nebulae, planetary stars, clusters, etc.). These objects are often hierarchically organized: a star in a small nebula, itself embedded in a galaxy arm, itself included in a galaxy, and so on.

The standard approach, which is presented in detail in Sect. 2, presents some limits, when we are looking for faint extended objects embedded in noise. Figure 1 shows a typical example where a faint extended object is under the detection limit. In order to detect such objects, more complex data modeling needs to be defined. Section 3 presents another approach to model and represent astronomical data, by using a sparse model in a wavelet dictionary. A specific wavelet transform, called the *starlet transform* or the isotropic undecimated wavelet transform, is presented. Based on this new modeling, several approaches are proposed in Sects. 4 and 5.

2 Standard Approaches to Source Detection

We describe here the most popular way to create a catalog of galaxies from astronomical images.

The Traditional Data Model

The observed data Y can be decomposed into two parts, the signal X and the noise N :

$$Y[k, l] = X[k, l] + N[k, l] \quad (1)$$

The imaging system can also be considered. If it is linear, the relation between the data and the image in the same coordinate frame is a convolution:

$$Y[k, l] = (HX)[k, l] + N[k, l] \quad (2)$$

where H is the matrix related to the point spread function (PSF) of the imaging system.

In most cases, objects of interest are superimposed on a relatively flat signal B , called *background signal*. The model becomes

$$Y[k, l] = (HX)[k, l] + B[k, l] + N[k, l] \quad (3)$$

PSF Estimation

The PSF H can be estimated from the data or from an optical model of the imaging telescope. In astronomical images, the data may contain stars, or one can point towards a reference star in order to reconstruct a PSF. The drawback is the “degradation” of this PSF because of unavoidable noise or spurious instrument signatures in the data. So, when reconstructing a PSF from experimental data, one has to reduce very carefully the images used (background removal for instance). Another problem arises when the PSF is highly variable with time, as is the case for adaptive optics (AO) images. This means usually that the PSF estimated when observing a reference star, after or before the observation of the scientific target, has small differences from the perfectly correct PSF.

Another approach consists of constructing a synthetic PSF. Various studies [11, 21, 38, 39] have suggested a radially symmetric approximation to the PSF:

$$P(r) \propto \left(1 + \frac{r^2}{R^2}\right)^{-\beta} \quad (4)$$

The parameters β and R are obtained by fitting the model with stars contained in the data.

In the case of AO systems, this model can be used for the tail of the PSF (the so-called *seeing* contribution), while in the central region, the system provides an approximation of the diffraction-limited PSF. The quality of the approximation is measured by the Strehl ratio (SR), which is defined as the ratio of the observed peak

intensity in the image of a point source to the theoretical peak intensity of a perfect imaging system.

Background Estimation

The background must be accurately estimated; otherwise it will introduce bias in flux estimation. In [7, 28], the image is partitioned into blocks, and the local sky level in each block is estimated from its histogram. The pixel intensity histogram $p(Y)$ is modeled using three parameters, the true sky level B , the RMS (root mean square) noise σ , and a parameter describing the asymmetry in $p(Y)$ due to the presence of objects, and is defined by [7]:

$$p(Y) = \frac{1}{a} \exp\left(\sigma^2/2a^2\right) \exp[-(Y - B)/a] \operatorname{erfc}\left(\frac{\sigma}{a} - \frac{(Y - B)}{\sigma}\right) \quad (5)$$

Median filtering can be applied to the 2D array of background measurements in order to correct for spurious background values. Finally the background map is obtained by a bilinear or a cubic interpolation of the 2D array. The block size is a crucial parameter. If it is too small, the background estimation map will be affected by the presence of objects, and if too large it will not take into account real background variations.

In [6, 15], the local sky level is calculated differently. A 3-sigma clipping around the median is performed in each block. If the standard deviation is changed by less than 20 % in the clipping iterations, the block is uncrowded, and the background level is considered to be equal to the mean of the clipped histogram. Otherwise, it is calculated by $c_1 \times \text{median} - c_2 \times \text{mean}$, where $c_1 = 3, c_2 = 2$ in [15] and $c_1 = 2.5, c_2 = 1.5$ in [6]. This approach has been preferred to histogram fitting for two reasons: it is more efficient from the computation point of view and more robust with small sample size.

Convolution

In order to optimize the detection, the image must be convolved with a filter. The shape of this filter optimizes the detection of objects with the same shape. Therefore, for star detection, the optimal filter is the PSF. For extended objects, a larger filter size is recommended. In order to have optimal detection for any object size, the detection must be repeated several times with different filter sizes, leading to a kind of multiscale approach.

Detection

Once the image is convolved, all pixels $Y[k, l]$ at location (k, l) with a value larger than $T[k, l]$ are considered as significant, i.e., belonging to an object. $T[k, l]$ is

generally chosen as $B[k, l] + K\sigma$, where $B[k, l]$ is the background estimate at the same position, σ is the noise standard deviation, and K is a given constant (typically chosen between 3 and 5). The thresholded image is then segmented, i.e., a label is assigned to each group of connected pixels. The next step is to separate the blended objects which are connected and have the same label.

An alternative to the thresholding/segmentation procedure is to find peaks. This is only well suited to star detection and not to extended objects. In this case, the next step is to merge the pixels belonging to the same object.

Deblending/Merging

This is the most delicate step. Extended objects must be considered as single objects, while multiple objects must be well separated. In SExtractor, each group of connected pixels is analyzed at different intensity levels, starting from the highest down to the lowest level. The pixel group can be seen as a surface, with mountains and valleys. At the beginning (highest level), only the highest peak is visible. When the level decreases, several other peaks may become visible, defining therefore several structures. At a given level, two structures may become connected, and the decision whether they form only one (i.e., merging) or several objects (i.e., deblending) must be taken. This is done by comparing the integrated intensities inside the peaks. If the ratio between them is too low, then the two structures must be merged.

Photometry and Classification

Photometry

Several methods can be used to derive the photometry of a detected object [7, 29]. Adaptive aperture photometry uses the first image moment to determine the elliptical aperture from which the object flux is integrated. Kron [29] proposed an aperture size of twice the radius of the first image moment radius r_1 , which leads to recovery of most of the flux (>90%). In [6], the value of $2.5r_1$ is discussed, leading to loss of less than 6 % of the total flux. Assuming that the intensity profiles of the faint objects are Gaussian, flux estimates can be refined [6, 35]. When the image contains only stars, specific methods can be developed which take the PSF into account [18, 42].

Star–Galaxy Separation

In the case of star–galaxy classification, following the scanning of digitized images, Kurtz [30] lists the following parameters which have been used:

1. Mean surface brightness;
2. Maximum intensity and area;
3. Maximum intensity and intensity gradient;

4. Normalized density gradient;
5. Areal profile;
6. Radial profile;
7. Maximum intensity, 2nd and 4th order moments, and ellipticity;
8. The fit of galaxy and star models;
9. Contrast versus smoothness ratio;
10. The fit of a Gaussian model;
11. Moment invariants;
12. Standard deviation of brightness;
13. 2nd order moment;
14. Inverse effective squared radius;
15. Maximum intensity and intensity-weighted radius;
16. 2nd and 3rd order moments, number of local maxima, and maximum intensity.

References for all of these may be found in the cited work. Clearly there is room for differing views on parameters to be chosen for what is essentially the same problem. It is of course the case also that aspects such as the following will help to orientate us towards a particular set of parameters in a particular case: the quality of the data; the computational ease of measuring certain parameters; the relevance and importance of the parameters measured relative to the data analysis output (e.g., the classification, or the planar graphics); and, similarly, the importance of the parameters relative to theoretical models under investigation.

Galaxy Morphology Classification

The inherent difficulty of characterizing spiral galaxies especially when not face-on has meant that most work focuses on ellipticity in the galaxies under study. This points to an inherent bias in the potential multivariate statistical procedures. In the following, it will not be attempted to address problems of galaxy photometry per se [17,44], but rather to draw some conclusions on what types of parameters or features have been used in practice.

From the point of view of multivariate statistical algorithms, a reasonably homogeneous set of parameters is required. Given this fact, and the available literature on quantitative galaxy morphological classification, two approaches to parameter selection appear to be strongly represented:

1. The luminosity profile along the major axis of the object is determined at discrete intervals. This may be done by the fitting of elliptical contours, followed by the integrating of light in elliptical annuli [33]. A similar approach was used in the ESO–Uppsala survey. Noisiness and faintness require attention to robustness in measurement: the radial profile may be determined taking into account the assumption of a face-on optically thin axisymmetric galaxy and may be further adjusted to yield values for circles of given radius [64]. Alternatively, isophotal contours may determine the discrete radial values for which the profile is determined [62].

2. Specific morphology-related parameters may be derived instead of the profile. The integrated magnitude within the limiting surface brightness of 25 or 26 mag. arcsec⁻² in the visual is popular [33, 61]. The logarithmic diameter (D_{26}) is also supported by Okamura [43]. It may be interesting to fit to galaxies under consideration model bulges and disks using, respectively, $r^{\frac{1}{4}}$ or exponential laws [62], in order to define further parameters. Some catering for the asymmetry of spirals may be carried out by decomposing the object into octants; furthermore, the taking of a Fourier transform of the intensity may indicate aspects of the spiral structure [61].

The following remarks can be made relating to image data and reduced data:

- The range of parameters to be used should be linked to the subsequent use to which they might be put, such as to underlying physical aspects.
- Parameters can be derived from a carefully constructed luminosity profile, rather than it being possible to derive a profile from any given set of parameters.
- The presence of both partially reduced data such as luminosity profiles, and more fully reduced features such as integrated flux in a range of octants, is of course not a hindrance to analysis. However, it is more useful if the analysis is carried out on both types of data separately.

Parameter data can be analyzed by clustering algorithms, by principal component analysis, or by methods for discriminant analysis. Profile data can be sampled at suitable intervals and thus analyzed also by the foregoing procedures. It may be more convenient in practice to create dissimilarities between profiles and analyze these dissimilarities: this can be done using clustering algorithms with dissimilarity input.

3 Mathematical Modeling

Different models may be considered to represent the data. One of the most effective is certainly the sparsity model, especially when a specific wavelet dictionary is chosen to represent the data. We introduce here the sparsity concept as well as the wavelet transform decomposition, which is the most used in astronomy.

Sparsity Data Model

A signal X , $X = [x_1, \dots, x_N]^T$, is sparse if most of its entries are equal to zero. For instance, a k -sparse signal is a signal where only k samples have a nonzero value. A less strict definition is to consider a signal as weakly sparse or compressible when only a few of its entries have a large magnitude, while most of them are close to zero.

If a signal is not sparse, it may be *sparsified* using a given data representation. For instance, if X is a sine, it is clearly not sparse but its Fourier transform is extremely sparse (i.e., 1-sparse). Hence, we say that a signal X is sparse in the Fourier domain if its Fourier coefficients $\hat{X}[u]$, $\hat{X}[u] = \frac{1}{N} \sum_{k=-\infty}^{+\infty} X[k] e^{2i\pi \frac{uk}{N}}$, are sparse. More generally, we can model a vector signal $X \in \mathbb{R}^N$ as the linear combination of T elementary waveforms, also called *signal atoms*: $X = \Phi\alpha = \sum_{i=1}^T \alpha[i]\phi_i$, where $\alpha[i] = \langle X, \phi_i \rangle$ are called the decomposition coefficients of X in the dictionary $\Phi = [\phi_1, \dots, \phi_T]$ (the $N \times T$ matrix whose columns are the atoms normalized to a unit ℓ_2 -norm, i.e., $\forall i \in [1, T], \|\phi_i\|_{\ell^2} = 1$).

Therefore, to get a sparse representation of our data, we need first to define the dictionary Φ and then to compute the coefficients α . x is sparse in Φ if the sorted coefficients in decreasing magnitude have fast decay, i.e., most coefficients α vanish except for a few.

The best dictionary is the one which leads to the sparsest representation. Hence, we could imagine having a huge overcomplete dictionary (i.e., $T \gg N$), but we would be faced with prohibitive computation time cost for calculating the α coefficients. Therefore, there is a trade-off between the complexity of our analysis step (i.e., the size of the dictionary) and the computation time. Some specific dictionaries have the advantage of having fast operators and are very good candidates for analyzing the data.

The Isotropic Undecimated Wavelet Transform (IUWT), also called *starlet wavelet transform*, is well known in the astronomical domain because it is well adapted to astronomical data where objects are more or less isotropic in most cases [54, 57]. For most astronomical images, the starlet dictionary is very well adapted.

The Starlet Transform

The starlet wavelet transform [53] decomposes an $n \times n$ image c_0 into a coefficient set $W = \{w_1, \dots, w_J, c_J\}$, as a superposition of the form

$$c_0[k, l] = c_J[k, l] + \sum_{j=1}^J w_j[k, l],$$

where c_J is a coarse or smooth version of the original image c_0 and w_j represents the details of c_0 at scale 2^{-j} (see Starck et al. [56, 58] for more information). Thus, the algorithm outputs $J + 1$ sub-band arrays of size $N \times N$. (The present indexing is such that $j = 1$ corresponds to the finest scale or high frequencies.)

The decomposition is achieved using the filter bank ($h_{2D}, g_{2D} = \delta - h_{2D}, \tilde{h}_{2D} = \delta, \tilde{g}_{2D} = \delta$), where h_{2D} is the tensor product of two 1D filters h_{1D} and δ is the Dirac function. The passage from one resolution to the next one is obtained using the “à trous” (“with holes”) algorithm [58]:

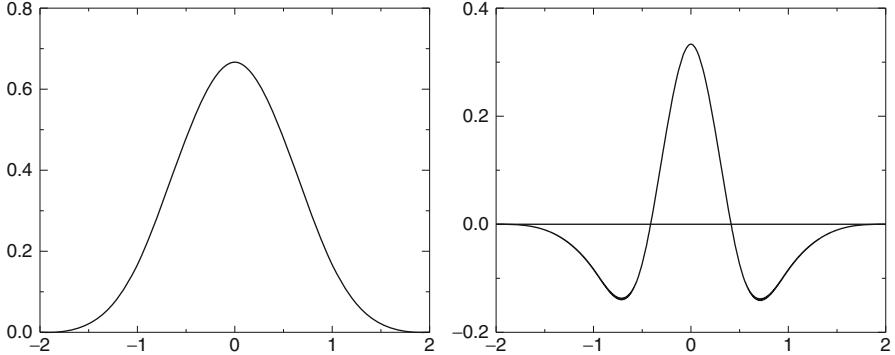

Fig. 2 Left, the cubic spline function ϕ ; right, the wavelet ψ

$$c_{j+1}[k, l] = \sum_m \sum_n h_{1D}[m] h_{1D}[n] c_j[k + 2^j m, l + 2^j n], \quad (6)$$

$$w_{j+1}[k, l] = c_j[k, l] - c_{j+1}[k, l],$$

If we choose a B_3 -spline for the scaling function,

$$\phi(x) = B_3(x) = \frac{1}{12}(|x-2|^3 - 4|x-1|^3 + 6|x|^3 - 4|x+1|^3 + |x+2|^3) \quad (7)$$

the coefficients of the convolution mask in one dimension are $h_{1D} = \{\frac{1}{16}, \frac{1}{4}, \frac{3}{8}, \frac{1}{4}, \frac{1}{16}\}$, and in two dimensions,

$$h_{2D} = (1/16 \ 1/4 \ 3/8 \ 1/4 \ 1/16) \begin{pmatrix} \frac{1}{16} \\ \frac{1}{4} \\ \frac{3}{8} \\ \frac{1}{4} \\ \frac{1}{16} \end{pmatrix} = \begin{pmatrix} \frac{1}{256} & \frac{1}{64} & \frac{3}{128} & \frac{1}{64} & \frac{1}{256} \\ \frac{1}{64} & \frac{1}{16} & \frac{3}{32} & \frac{1}{16} & \frac{1}{64} \\ \frac{3}{128} & \frac{3}{32} & \frac{9}{64} & \frac{3}{32} & \frac{1}{128} \\ \frac{1}{128} & \frac{1}{32} & \frac{3}{64} & \frac{1}{32} & \frac{1}{128} \\ \frac{1}{64} & \frac{1}{16} & \frac{3}{32} & \frac{1}{16} & \frac{1}{64} \\ \frac{1}{256} & \frac{1}{64} & \frac{3}{128} & \frac{1}{64} & \frac{1}{256} \end{pmatrix}$$

Figure 2 shows the scaling function and the wavelet function when a cubic spline function is chosen as the scaling function ϕ .

The most general way to handle the boundaries is to consider that $c[k + N] = c[N - k]$ (“mirror”). But other methods can be used such as periodicity ($c[k + N] = c[N]$) or continuity ($c[k + N] = c[k]$).

The starlet transform algorithm is:

1. We initialize j to 0 and we start with the data $c_j[k, l]$.
2. We carry out a discrete convolution of the data $c_j[k, l]$ using the filter (h_{2D}), using the separability in the two-dimensional case. In the case of the B_3 -

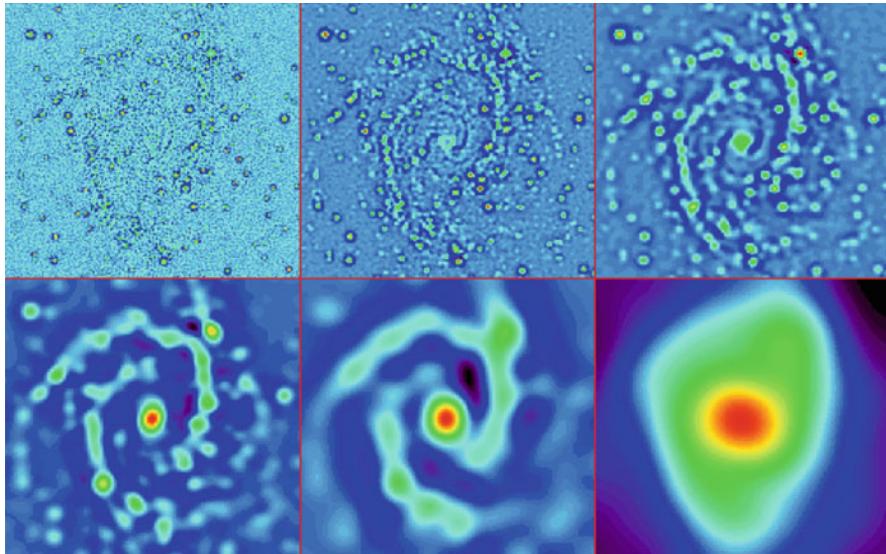

Fig. 3 Wavelet transform of NGC 2997 by the IUWT. The co-addition of these six images reproduces exactly the original image

spline, this leads to a row-by-row convolution with $(\frac{1}{16}, \frac{1}{4}, \frac{3}{8}, \frac{1}{4}, \frac{1}{16})$, followed by column-by-column convolution. The distance between the central pixel and the adjacent ones is 2^j .

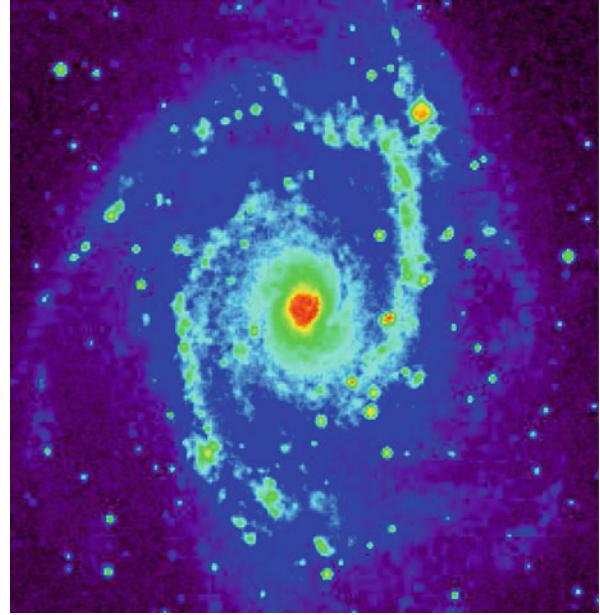

3. After this smoothing, we obtain the discrete wavelet transform from the difference $c_j[k, l] - c_{j+1}[k, l]$.
4. If j is less than the number J of resolutions we want to compute, we increment j and then go to step 2.
5. The set $\alpha = \{w_1, \dots, w_J, c_J\}$ represents the wavelet transform of the data.

This starlet transform is very well adapted to the detection of isotropic features, and this explains its success for astronomical image processing, where the data contain mostly isotropic or quasi-isotropic objects, such as stars, galaxies, or galaxy clusters.

Figure 3 shows the starlet transform of the galaxy NGC 2997 displayed in Fig. 4. Five wavelet scales and the final smoothed plane (lower right) are shown. The original image is given exactly by the sum of these six images.

The Starlet Reconstruction

The reconstruction is straightforward. A simple co-addition of all wavelet scales reproduces the original map: $c_0[k, l] = c_J[k, l] + \sum_{j=1}^J w_j[k, l]$. But because the transform is non-subsampled, there are many ways to reconstruct the original image

Fig. 4 Galaxy NGC 2997

from its wavelet transform [53]. For a given wavelet filter bank (h, g) , associated with a scaling function ϕ and a wavelet function ψ , any synthesis filter bank (\tilde{h}, \tilde{g}) , which satisfies the following reconstruction condition

$$\hat{h}^*(v)\hat{\tilde{h}}(v) + \hat{g}^*(v)\hat{\tilde{g}}(v) = 1 , \quad (8)$$

leads to exact reconstruction. For instance, for isotropic h , if we choose $\tilde{h} = h$ (the synthesis scaling function $\tilde{\phi} = \phi$), we obtain a filter \tilde{g} defined by [53]

$$\tilde{g} = \delta + h .$$

If h is a positive filter, then g is also positive. For instance, if $h_{1D} = [1, 4, 6, 4, 1]/16$, then $\tilde{g}_{1D} = [1, 4, 22, 4, 1]/16$. That is, \tilde{g}_{1D} is positive. This means that \tilde{g} is no longer related to a wavelet function. The 1D detail synthesis function related to \tilde{g}_{1D} is defined by

$$\frac{1}{2}\tilde{\psi}_{1D}\left(\frac{t}{2}\right) = \phi_{1D}(t) + \frac{1}{2}\phi_{1D}\left(\frac{t}{2}\right) . \quad (9)$$

Note that by choosing $\tilde{\phi}_{1D} = \phi_{1D}$, any synthesis function $\tilde{\psi}_{1D}$ which satisfies

$$\hat{\tilde{\psi}}_{1D}(2v)\hat{\psi}_{1D}(2v) = \hat{\phi}_{1D}^2(v) - \hat{\phi}_{1D}^2(2v) \quad (10)$$

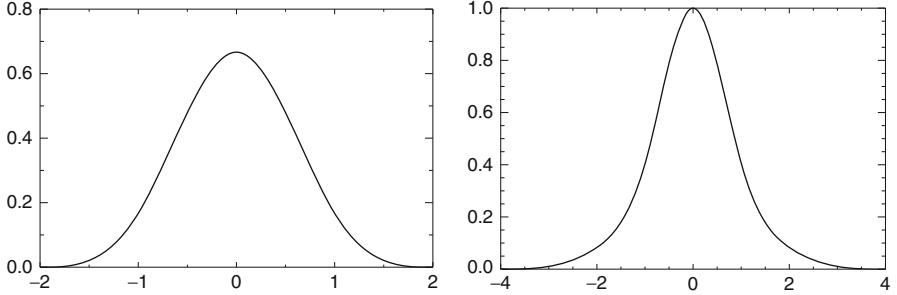

Fig. 5 Left, $\tilde{\phi}_{1D}$ the 1D synthesis scaling function and right, $\tilde{\psi}_{1D}$ the 1D detail synthesis function

leads to an exact reconstruction [36] and $\hat{\psi}_{1D}(0)$ can take any value. The synthesis function $\tilde{\psi}_{1D}$ does not need to verify the admissibility condition (i.e., to have a zero mean).

Figure 5 shows the two functions $\tilde{\phi}_{1D}$ ($= \hat{\phi}_{1D}$) and $\tilde{\psi}_{1D}$ used in the reconstruction in 1D, corresponding to the synthesis filters $\tilde{h}_{1D} = h_{1D}$ and $\tilde{g}_{1D} = \delta + h_{1D}$. More details can be found in [53].

Starlet Transform: Second Generation

A particular case is obtained when $\hat{\phi}_{1D} = \hat{\phi}_{1D}$ and $\hat{\psi}_{1D}(2\nu) = \frac{\hat{\phi}_{1D}^2(\nu) - \hat{\phi}_{1D}^2(2\nu)}{\hat{\phi}_{1D}(\nu)}$, which leads to a filter g_{1D} equal to $\delta - h_{1D} * h_{1D}$. In this case, the synthesis function $\tilde{\psi}_{1D}$ is defined by $\frac{1}{2}\tilde{\psi}_{1D}(\frac{t}{2}) = \phi_{1D}(t)$, and the filter $\tilde{g}_{1D} = \delta$ is the solution to (8).

We end up with a synthesis scheme where only the smooth part is convolved during the reconstruction.

Deriving h from a spline scaling function, for instance $B_1(h_1 = [1, 2, 1]/4)$ or $B_3(h_3 = [1, 4, 6, 4, 1]/16)$ (note that $h_3 = h_1 * h_1$), since h_{1D} is even-symmetric (i.e., $H(z) = H(z^{-1})$), the z -transform of g_{1D} is then

$$\begin{aligned} G(z) &= 1 - H^2(z) = 1 - z^4 \left(\frac{1 + z^{-1}}{2} \right)^8 \\ &= \frac{1}{256} (-z^4 - 8z^3 - 28z^2 - 56z + 186 - 56z^{-1} - 28z^{-2} - 8z^{-3} - z^{-4}), \end{aligned} \quad (11)$$

which is the z -transform of the filter

$$g_{1D} = [-1, -8, -28, -56, 186, -56, -28, -8, -1]/256.$$

We get the following filter bank:

$$\begin{aligned} h_{1D} &= h_3 = \tilde{h} = [1, 4, 6, 4, 1]/16 \\ g_{1D} &= \delta - h \star h = [-1, -8, -28, -56, 186, -56, -28, -8, -1]/256 \\ \tilde{g}_{1D} &= \delta . \end{aligned} \quad (12)$$

The second-generation starlet transform algorithm is:

1. We initialize j to 0 and we start with the data $c_j[k]$.
2. We carry out a discrete convolution of the data $c_j[k]$ using the filter h_{1D} . The distance between the central pixel and the adjacent ones is 2^j . We obtain $c_{j+1}[k]$.
3. We do exactly the same convolution on $c_{j+1}[k]$ and we obtain $c'_{j+1}[k]$.
4. After this two-step smoothing, we obtain the discrete starlet wavelet transform from the difference $w_{j+1}[k] = c_j[k] - c'_{j+1}[k]$.
5. If j is less than the number J of resolutions we want to compute, we increment j and then go to step 2.
6. The set $\alpha = \{w_1, \dots, w_J, c_J\}$ represents the starlet wavelet transform of the data.

As in the standard starlet transform, extension to 2D is trivial. We just replace the convolution with h_{1D} by a convolution with the filter h_{2D} , which is performed efficiently by using the separability.

With this specific filter bank, there is a no convolution with the filter \tilde{g}_{1D} during the reconstruction. Only the low-pass synthesis filter \tilde{h}_{1D} is used.

The reconstruction formula is

$$c_j[l] = (h_{1D}^{(j)} \star c_{j+1})[l] + w_{j+1}[l], \quad (13)$$

and denoting $L^j = h^{(0)} \star \dots \star h^{(j-1)}$ and $L^0 = \delta$, we have

$$c_0[l] = (L^J \star c_J)[l] + \sum_{j=1}^J (L^{j-1} \star w_j)[l]. \quad (14)$$

Each wavelet scale is convolved with a low-pass filter.

The second-generation starlet reconstruction algorithm is:

1. The set $\alpha = \{w_1, \dots, w_J, c_J\}$ represents the input starlet wavelet transform of the data.
2. We initialize j to $J - 1$ and we start with the coefficients $c_j[k]$.
3. We carry out a discrete convolution of the data $c_{j+1}[k]$ using the filter (h_{1D}) . The distance between the central pixel and the adjacent ones is 2^j . We obtain $c'_{j+1}[k]$.
4. Compute $c_j[k] = c'_{j+1}[k] + w_{j+1}[k]$.

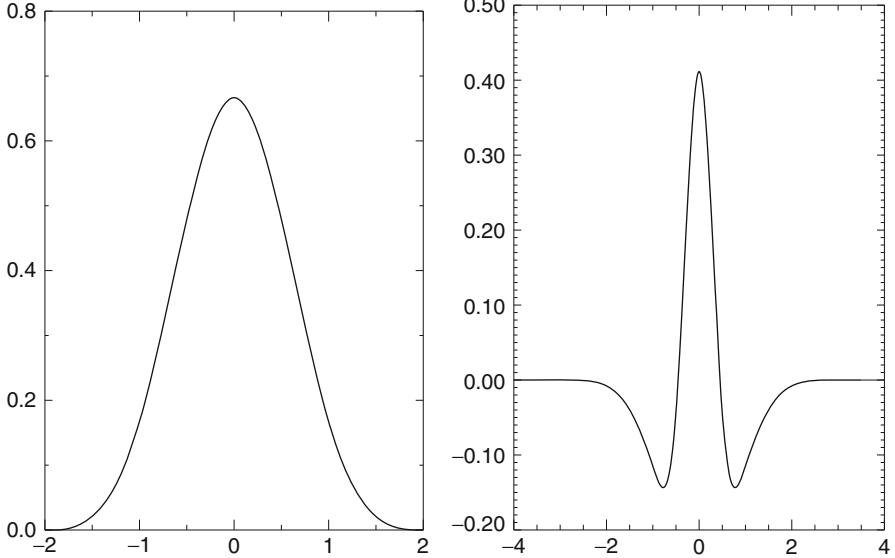

Fig. 6 *Left*, the ϕ_{ID} analysis scaling function and *right*, the ψ_{ID} analysis wavelet function. The synthesis functions $\tilde{\phi}_{\text{ID}}$ and $\tilde{\psi}_{\text{ID}}$ are the same as those in Fig. 5

5. If j is larger than 0, $j = j - 1$ and then go to step 3.
6. c_0 contains the reconstructed data.

As for the transformation, the 2D extension consists just in replacing the convolution by $h_{1\text{D}}$ with a convolution by $h_{2\text{D}}$.

Figure 6 shows the analysis scaling and wavelet functions. The synthesis functions $\tilde{\phi}_{\text{ID}}$ and $\tilde{\psi}_{\text{ID}}$ are the same as those in Fig. 5. As both are positive, we have a decomposition of an image X on positive scaling functions $\tilde{\phi}_{\text{ID}}$ and $\tilde{\psi}_{\text{ID}}$, but the coefficients α are obtained with the starlet wavelet transform and have a zero mean (except for c_J), as a regular wavelet transform.

In 2D, similarly, the second-generation starlet transform leads to the representation of an image $X[k, l]$:

$$X[k, l] = \sum_{m,n} \phi_{j,k,l}^{(1)}(m, n) c_J[m, n] + \sum_{j=1}^J \sum_{m,n} \phi_{j,k,l}^{(2)}(m, n) w_j[m, n], \quad (15)$$

where $\phi_{j,k,l}^{(1)}(m, n) = 2^{-2j} \tilde{\phi}_{\text{ID}}(2^{-j}(k-m)) \tilde{\phi}_{\text{ID}}(2^{-j}(l-n))$ and $\phi_{j,k,l}^{(2)}(m, n) = 2^{-2j} \tilde{\psi}_{\text{ID}}(2^{-j}(k-m)) \tilde{\psi}_{\text{ID}}(2^{-j}(l-n))$.

$\phi^{(1)}$ and $\phi^{(2)}$ are positive, and w_j are zero mean 2D wavelet coefficients.

The advantage of the second-generation starlet transform will be seen in section “Sparse Positive Decomposition” below.

Sparse Modeling of Astronomical Images

Using the sparse modeling, we now consider that the observed signal X can be considered as a linear combination of a few atoms of the wavelet dictionary $\Phi = [\phi_1, \dots, \phi_T]$. The model of Eq. 3 is then replaced by the following:

$$Y = H\Phi\alpha + N + B \quad (16)$$

and $X = \Phi\alpha$, and $\alpha = \{w_1, \dots, w_J, c_J\}$. Furthermore, most of the coefficients α will be equal to zero. Positions and scales of active coefficients are unknown, but they can be estimated directly from the data Y . We define the multiresolution support M of an image Y by

$$M_j[k, l] = \begin{cases} 1 & \text{if } w_j[k, l] \text{ is significant} \\ 0 & \text{if } w_j[k, l] \text{ is not significant} \end{cases} \quad (17)$$

where $w_j[k, l]$ is the wavelet coefficient of Y at scale j and at position (k, l) . Hence, M describes the set of active atoms in Y . If H is compact and not too extended, then M describes also well the active set of X . This is true because the background B is generally very smooth, and therefore, a wavelet coefficient $w_j[k, l]$ of Y , which does not belong to the coarsest scale, is only dependent on X and N (the term $\langle \phi_i, B \rangle$ being equal to zero).

Selection of Significant Coefficients Through Noise Modeling

We need now to determine when a wavelet coefficient is significant. Wavelet coefficients of Y are corrupted by noise, which follows in many cases a Gaussian distribution, a Poisson distribution, or a combination of both. It is important to detect the wavelet coefficients which are “significant,” i.e., the wavelet coefficients which have an absolute value too large to be due to noise.

For Gaussian noise, it is easy to derive an estimation of the noise standard deviation σ_j at scale j from the noise standard deviation, which can be evaluated with good accuracy in an automated way [55]. To detect the significant wavelet coefficients, it suffices to compare the wavelet coefficients $w_j[k, l]$ to a threshold level t_j . t_j is generally taken equal to $K\sigma_j$, and K , as noted in Sect. 2, is chosen between 3 and 5. The value of 3 corresponds to a probability of false detection of 0.27 %. If $w_j[k, l]$ is small, then it is not significant and could be due to noise. If $w_j[k, l]$ is large, it is significant:

$$\begin{aligned} \text{if } |w_j[k, l]| \geq t_j & \text{ then } w_j[k, l] \text{ is significant} \\ \text{if } |w_j[k, l]| < t_j & \text{ then } w_j[k, l] \text{ is not significant} \end{aligned} \quad (18)$$

When the noise is not Gaussian, other strategies may be used:

- **Poisson noise:** if the noise in the data Y is Poisson, the transformation [1] $\mathcal{A}(Y) = 2\sqrt{Y + \frac{3}{8}}$ acts as if the data arose from a Gaussian white noise model, with $\sigma = 1$, under the assumption that the mean value of Y is sufficiently large. However, this transform has some limits, and it has been shown that it cannot be applied for data with less than 20 counts (due to photons) per pixel. So for X-ray or gamma ray data, other solutions have to be chosen, which manage the case of a reduced number of events or photons under assumptions of Poisson statistics.
- **Gaussian + Poisson noise:** the generalization of variance stabilization [40] is

$$\mathcal{G}(Y[k, l]) = \frac{2}{\alpha} \sqrt{\alpha Y[k, l] + \frac{3}{8}\alpha^2 + \sigma^2 - \alpha g}$$

where α is the gain of the detector and g and σ are the mean and the standard deviation of the readout noise.

- **Poisson noise with few events using the MS-VST:** for images with very few photons, one solution consists in using the Multi-Scale Variance Stabilization Transform (MS-VST) [66]. The MS-VST combines both the Anscombe transform and the starlet transform in order to produce *stabilized* wavelet coefficients, i.e., coefficients corrupted by a Gaussian noise with a standard deviation equal to 1. In this framework, wavelet coefficients are now calculated by

$$\begin{array}{c} \text{Starlet} \\ + \\ \text{MS-VST} \end{array} \left\{ \begin{array}{l} c_j = \sum_m \sum_n h_{1D}[m] h_{1D}[n] \\ c_{j-1}[k + 2^{j-1}m, l + 2^{j-1}n] \\ w_j = \mathcal{A}_{j-1}(c_{j-1}) - \mathcal{A}_j(c_j) \end{array} \right. \quad (19)$$

where \mathcal{A}_j is the VST operator at scale j defined by

$$\mathcal{A}_j(c_j) = b^{(j)} \sqrt{|c_j + e^{(j)}|} \quad (20)$$

where the variance stabilization constants $b^{(j)}$ and $e^{(j)}$ only depend on the filter h_{1D} and the scale level j . They can all be precomputed once for any given h_{1D} [66]. The multiresolution support is computed from the MS-VST coefficients, considering a Gaussian noise with a standard deviation equal to 1. This stabilization procedure is also invertible as we have

$$c_0 = \mathcal{A}_0^{-1} \left[\mathcal{A}_J(a_J) + \sum_{j=1}^J w_j \right] \quad (21)$$

For other kinds of noise (correlated noise, nonstationary noise, etc.), other solutions have been proposed to derive the multiresolution support [57].

Sparse Positive Decomposition

Many astronomical images can be modeled as a sum of positive features, like stars and galaxies, which are more or less isotropic. The previous representation, based on the starlet transform, is well adapted to the representation of isotropic objects, but does not introduce any prior relative to the positivity of the features contained in our image. A positive and sparse modeling of astronomical images is similar to Eq. 16:

$$Y = H\Phi\alpha + N + B \quad (22)$$

or

$$Y = \Phi\alpha + N + B \quad (23)$$

if we do not take into account the point spread function. All coefficients in α are now positive, and all atoms in the dictionary Φ are positive functions. Such a decomposition normally requires computationally intensive algorithms such as matching pursuit [37]. The second-generation starlet transform offers us a new way to perform such a decomposition. Indeed, we have seen in section “Starlet Transform: Second Generation” that, using a specific filter bank, we can decompose an image Y on a positive dictionary Φ (see Fig. 5) and obtain a set of coefficients $\alpha^{(Y)}$, where $\alpha^{(Y)} = \mathbf{W}Y = \{w_1, \dots, w_J, c_J\}$, \mathbf{W} being the starlet wavelet transform operator. α coefficients are positive and negative and are obtained using the standard starlet wavelet transform algorithm. Hence, by thresholding all negative (respectively, positive) coefficients, the reconstruction is always positive (respectively, negative), since Φ contains only positive atoms.

Hence, we would like to have a sparse set of positive coefficients $\tilde{\alpha}$ which verify $\Phi\tilde{\alpha} = Y$. But in order to take into account the background and the noise, we need to define the constraint in the wavelet space (i.e., $\mathbf{W}\Phi\tilde{\alpha} = \mathbf{W}Y = \alpha^{(Y)}$), and this constraint must be applied only to the subset of coefficients in $\alpha^{(Y)}$ which are larger than the detection level. Therefore, to get a sparse positive decomposition on Φ , we need to minimize

$$\tilde{\alpha} = \min_{\alpha} \|\alpha\|_1 \quad \text{s.t. } M\mathbf{W}\Phi\alpha = M\alpha^{(Y)}, \quad (24)$$

where M is the multiresolution support defined in the previous section (i.e., $M_j[k, l] = 1$ if a significant coefficient is detected at scale j and at position (k, l) , and zero otherwise). To remove the background, we have to set $M_{J+1}[k, l] = 0$ for all (k, l) .

It was shown that such optimization problems can be efficiently solved through an iterative soft thresholding (IST) algorithm [14, 24, 52]. The following algorithm, based on the IST, allows to take into account the noise modeling through the multiresolution support and force the coefficients to be all positive:

1. Taking the second-generation starlet wavelet transform of the data Y , we obtain $\alpha^{(Y)}$.
2. From a given noise model, determine the multiresolution support M .
3. Set the number of iterations N_{iter} , the first threshold, $\lambda^{(0)} = \text{MAX}(\alpha^{(Y)})$, and the solution $\tilde{\alpha}^{(0)} = 0$.
4. For $0 = 1, N_{\text{iter}}$ do:

- Reconstruct the image $\tilde{Y}^{(i)}$ from $\tilde{\alpha}^{(i)}$: $\tilde{Y}^{(i)} = \Phi \tilde{\alpha}^{(i)}$.
- Taking the second-generation starlet wavelet transform of the data $\tilde{Y}^{(i)}$, we obtain $\alpha^{\tilde{Y}^{(i)}} = \mathbf{W} \Phi \tilde{\alpha}^{(i)}$.
- Compute the significant residual $r^{(i)}$:

$$r^{(i)} = M (\alpha^{(Y)} - \alpha^{\tilde{Y}^{(i)}}) = M (\alpha^{(Y)} - \mathbf{W} \Phi \tilde{\alpha}^{(i)}) \quad (25)$$

- Calculate the value $\lambda^{(i)} = \lambda^{(0)}(1 - i/N_{\text{iter}})$
- Update the solution, by adding the residual, applying a soft thresholding on positive coefficients using the threshold level $\lambda^{(i)}$, and setting all negative coefficients to zero.

$$\begin{aligned} \tilde{\alpha}^{(i+1)} &= (\tilde{\alpha}^{(i)} + r^{(i)} - \lambda^{(i)})_+ \\ &= (\tilde{\alpha}^{(i)} + M (\alpha^{(Y)} - \mathbf{W} \Phi \tilde{\alpha}^{(i)}) - \lambda^{(i)})_+ \end{aligned} \quad (26)$$

- $i = i + 1$.

5. The set $\tilde{\alpha} = \tilde{\alpha}^{(N_{\text{iter}})}$ represents the sparse positive decomposition of the data.

The threshold parameter $\lambda^{(i)}$ decreases with the iteration number, and it plays a role similar to the cooling parameter of the simulated annealing techniques, i.e., it allows the solution to escape from local minima.

Example 1: Sparse Positive Decomposition of NGC 2997

Figure 7 shows the positive starlet decomposition, using 100 iterations, and can be compared to Fig. 3.

Example 2: Sparse Positive Starlet Decomposition of a Simulated Image

The next example compares the standard starlet transform to the positive starlet decomposition (PSD) on a simulated image.

Figure 8 shows respectively from top to bottom and left to right (a) the original simulated image, (b) the noisy data, (c) the reconstruction from the PSD coefficients, and (d) the residual between the noisy data and the PSD reconstructed image (i.e., image b–image c). Hence, the PSD reconstructed image gives a very good approximation of the original image. No structures can be seen in the residual, and all sources are well detected.

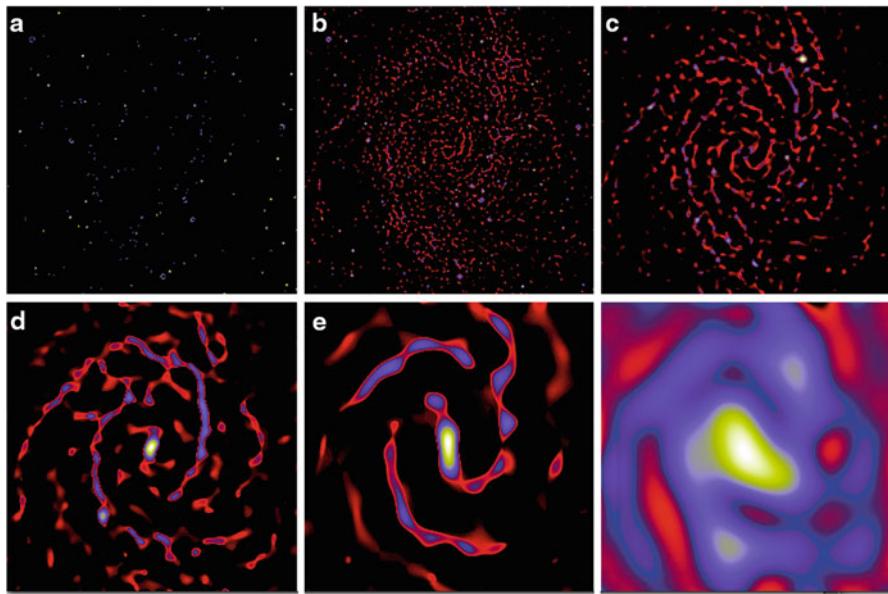

Fig. 7 Positive starlet decomposition of the galaxy NGC 2997 with six scales

The first PSD scale does not contain any nonzero coefficient. Figure 9, top, shows the first four scales of the wavelet transform, and Fig. 9, bottom, the first four scales of the PSD.

4 Source Detection Using a Sparsity Model

As described in the previous section, the wavelet coefficients of Y which do not belong to the coarsest scale c_J are not dependent on the background. This is a serious disadvantage, since the background estimation can be sometimes very problematic.

Two approaches have been proposed to detect sources, assuming the signal is sparse in the wavelet domain. The first consists in first removing the noise and the background and then applying the standard approach described in Sect. 2. It has been used for many years for X-ray source detection [45, 59]. The second approach, called Multiscale Vision Model [8], attempts to define directly an astronomical object in the wavelet space.

Detection Through Wavelet Denoising

The most commonly used filtering method is hard thresholding, which consists of setting to 0 all wavelet coefficients of Y which have an absolute value lower than a

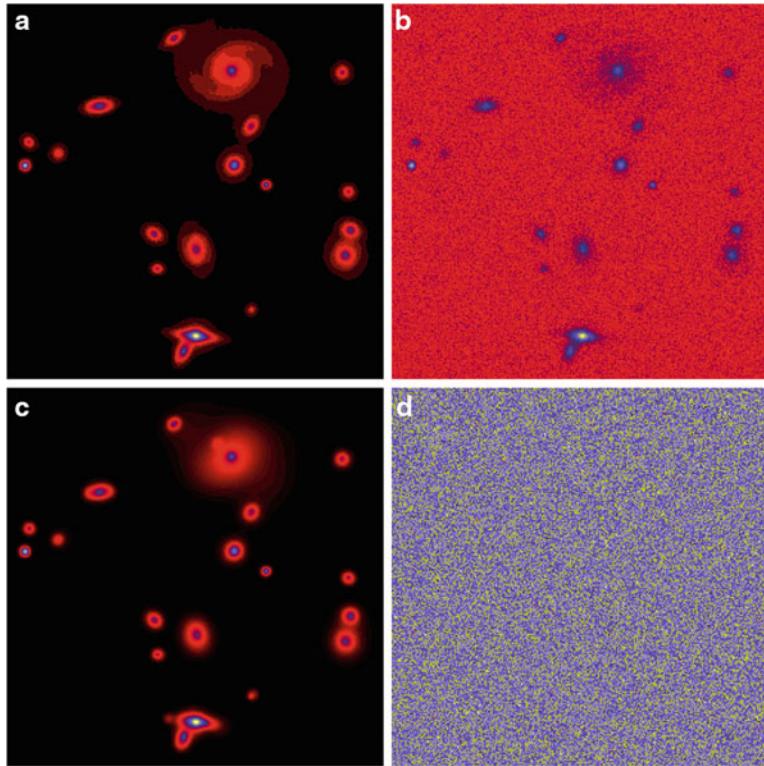

Fig. 8 (a and b) Original simulated image and the same image contaminated by a Gaussian noise. (c and d) Reconstructed image for the positive starlet coefficients of the noisy image using 50 iterations, and residual (i.e., noisy image – reconstructed image)

threshold t_j :

$$\tilde{w}_j[k, l] = \begin{cases} w_j[k, l] & \text{if } |w_j[k, l]| > t_j \\ 0 & \text{otherwise} \end{cases} \quad (27)$$

More generally, for a given sparse representation (i.e., wavelet) with its associated fast transform \mathbf{W} and fast reconstruction \mathbf{R} , we can derive a hard threshold denoising solution X from the data Y , by first estimating the multiresolution support M using a given noise model, and then calculating

$$X = \mathbf{R} M \mathbf{W} Y. \quad (28)$$

We transform the data, multiply the coefficients by the support, and reconstruct the solution.

The solution can however be improved by considering the following optimization problem, $\min_X \|M(\mathbf{W}Y - \mathbf{W}X)\|_2^2$, where M is the multiresolution support of Y .

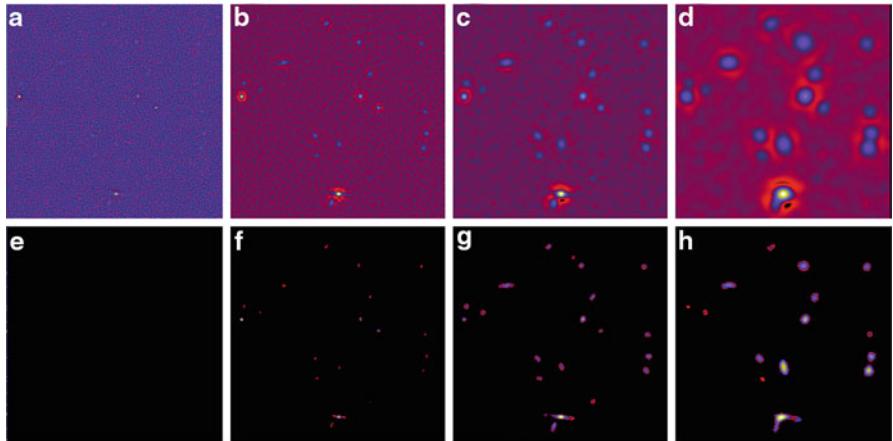

Fig. 9 Top, starlet transform, and bottom, positive starlet decomposition of a simulated astronomical image

A solution can be obtained using the Landweber iterative scheme [51, 58]:

$$X^{n+1} = X^n + \mathbf{R}M [\mathbf{W}Y - \mathbf{W}X^n] \quad (29)$$

If the solution is known to be positive, the positivity constraint can be introduced using the following equation:

$$X^{n+1} = P_+ (X^n + \mathbf{R}M [\mathbf{W}Y - \mathbf{W}X^n]) \quad (30)$$

where P_+ is the projection on the cone of nonnegative images.

This algorithm allows us to constrain the residual to have a zero value within the multiresolution support [58]. For astronomical image filtering, iterating improves significantly the results, especially for the photometry (i.e., the integrated number of photons in a given object).

Removing the background in the solution is straightforward. The algorithm does not need to be modified. We only need to set to zero the coefficients related to the coarsest scale in the multiresolution support: $\forall k \ M_J[k, l] = 0$.

The Multiscale Vision Model

Introduction

The wavelet transform of an image Y by the starlet transform produces at each scale j a set $\{w_j\}$. This has the same number of pixels as the image. The original image I can be expressed as the sum of all the wavelet scales and the smoothed array c_J by the expression

$$Y[k, l] = c_J[k, l] + \sum_{j=1}^J w_j[k, l]. \quad (31)$$

Hence, we have a *multiscale pixel representation*, i.e., each pixel of the input image is associated with a set of pixels of the multiscale transform. A further step is to consider a *multiscale object representation*, which would associate with an object contained in the data a volume in the multiscale transform. Such a representation obviously depends on the kind of image we need to analyze, and we present here a model which has been developed for astronomical data. It may however be used for other kinds of data, to the extent that such data are similar to astronomical data. We assume that an image Y can be decomposed into a set of components:

$$Y[k, l] = \sum_{i=1}^{N_o} X_i[k, l] + B[k, l] + N[k, l] \quad (32)$$

where N_o is the number of components, X_i are the components contained in the data (stars, galaxies, etc.), B is the background image, and N is the noise.

To perform such a decomposition, we have to detect, to extract, to measure, and to recognize the significant structures. This is done by first computing the multiresolution support of the image (i.e., the set of significant active coefficients) and by applying a segmentation scale by scale. The wavelet space of a 2D direct space is a 3D volume. An object, associated with a component, has to be defined in this space. A general idea for object definition lies in the connectivity property. An object occupies a physical region, and in this region we can join any pixel to other pixels based on significant adjacency. Connectivity in direct space has to be transported into wavelet transform space. In order to define the objects, we have to identify the wavelet transform space pixels we can attribute to the objects. We describe in this section the different steps of this method.

Multiscale Vision Model Definition

The multiscale vision model, MVM [8], described an object as a hierarchical set of structures. It uses the following definitions:

- *Significant wavelet coefficient*: a wavelet coefficient is significant when its absolute value is above a given detection limit. The detection limit depends on the noise model (Gaussian noise, Poisson noise, and so on). See section “Sparse Modeling of Astronomical Images” for more details.
- *Structure*: a structure $S_{j,k}$ is a set of significant connected wavelet coefficients at the same scale j :

$$S_{j,k} = \{w_j[k_1, l_1], w_j[k_2, l_2], \dots, w_j[k_p, l_p]\} \quad (33)$$

where p is the number of significant coefficients included in the structure $S_{j,k}$ and $w_j[x_i, y_i]$ is a wavelet coefficient at scale j and at position (x_i, y_i) .

- *Object*: an object is a set of structures:

$$O_l = \{S_{j_1,k_1}, \dots, S_{j_n,k_n}\} \quad (34)$$

We define also the operator \mathcal{L} which indicates to which object a given structure belongs: $\mathcal{L}(S_{j,k}) = l$ if $S_{j,k} \in O_l$, and $\mathcal{L}(S_{j,k}) = 0$ otherwise.

- *Object scale*: the scale of an object is given by the scale of the maximum of its wavelet coefficients.
- *Interscale relation*: the criterion allowing us to connect two structures into a single object is called the “interscale relation.”
- *Sub-object*: a sub-object is a part of an object. It appears when an object has a local wavelet maximum. Hence, an object can be composed of several sub-objects. Each sub-object can also be analyzed.

From Wavelet Coefficients to Object Identification

Multiresolution Support Segmentation

Once the multiresolution support has been calculated, we have at each scale a Boolean image (i.e., pixel intensity equals 1 when a significant coefficient has been detected, and 0 otherwise). The segmentation consists of labeling the Boolean scales. Each group of connected pixels having a “1” value gets a label value between 1 and L_{\max} , L_{\max} being the number of groups. This process is repeated at each scale of the multiresolution support. We define a “structure” $S_{j,i}$ as the group of connected significant pixels which has the label i at a given scale j .

Interscale Connectivity Graph

An object is described as a hierarchical set of structures. The rule which allows us to connect two structures into a single object is called “interscale relation.” Figure 10 shows how several structures at different scales are linked together and form objects. We have now to define the interscale relation. Let us consider two structures at two successive scales, $S_{j,k}$ and $S_{j+1,l}$. Each structure is located in one of the individual images of the decomposition and corresponds to a region in this image where the signal is significant. Denoting (x_m, y_m) the pixel position of the maximum wavelet coefficient value of $S_{j,k}$, $S_{j,k}$ is said to be connected to $S_{j+1,l}$ if $S_{j+1,l}$ contains the pixel position (x_m, y_m) (i.e., the pixel position of the maximum wavelet coefficient of the structure $S_{j,k}$ must also be contained in the structure $S_{j+1,l}$). Several structures appearing in successive wavelet coefficient images can be connected in such a way, which we call an object in the interscale connectivity graph. Hence, we identify n_o objects in the wavelet space, each object O_i being defined by a set of structures, and we can assign to each structure a label i , with $i \in [1, n_o]$: $\mathcal{L}(S_{j,k}) = i$ if the structure $S_{j,k}$ belongs to the i th object.

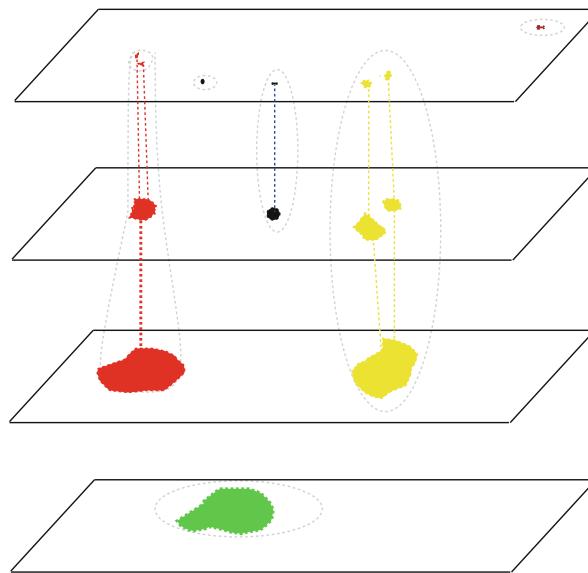

Fig. 10 Example of connectivity in wavelet space: contiguous significant wavelet coefficients form a structure, and following an interscale relation, a set of structures forms an object. Two structures S_j, S_{j+1} at two successive scales belong to the same object if the position pixel of the maximum wavelet coefficient value of S_j is included in S_{j+1}

Filtering

Statistically, some significant structures can be due to the noise. They contain very few pixels and are generally isolated, i.e., connected to no field at upper and lower scales. So, to avoid false detection, the isolated fields can be removed from the initial interscale connection graph. Structures at the border of the images may also have been detected because of the border problem and can be removed.

Merging/Deblending

As in the standard approach, true objects which are too close may generate a set of connected structures, initially associated with the same object, and a decision must be taken whether to consider such a case as one or two objects. Several cases may be distinguished:

- Two (or more) close objects, approximately of the same size, generate a set of structures. At a given scale j , two separate structures $S_{j,1}$ and $S_{j,2}$ are detected, while at the scale $j + 1$, only one structure is detected $S_{j+1,1}$, which is connected to the $S_{j,1}$ and $S_{j,2}$.
- Two (or more) close objects of different sizes generate a set of structures, from scale j to scale k ($k > j$).

In the wavelet space, the merging/deblending decision will be based on the local maxima values of the different structures belonging to this object. A new object (i.e., deblending) is derived from the structure $S_{j,k}$ if there exists at least one other structure at the same scale belonging to the same object (i.e., there exists one structure $S_{j+1,a}$ and at least one structure $S_{j,b}$ such that $\mathcal{L}(S_{j+1,a}) = \mathcal{L}(S_{j,b}) = \mathcal{L}(S_{j,k})$) and if the following relationship is verified: $w_j^m > w_{j-1}^m$ and $w_j^m > w_{j+1}^m$, where:

- w_j^m is the maximum wavelet coefficient of the structure $S_{j,k}$: $w_j^m = \text{Max}(S_{j,k})$:
 - $w_{j-1}^m = 0$ if $S_{j,k}$ is not connected to any structure at scale $j - 1$.
 - w_{j-1}^m is the maximum wavelet coefficient of the structure $S_{j-1,l}$, where $S_{j-1,l}$ is such that $\mathcal{L}(S_{j-1,l}) = \mathcal{L}(S_{j,k})$ and the position of its highest wavelet coefficient is the closest to the position of the maximum of $S_{j,k}$.
- $w_{j+1}^m = \text{Max}\{w_{j+1,x_1,y_1}, \dots, w_{j+1,x_n,y_n}\}$, where all wavelet coefficients $w_{j+1,x,y}$ are at a position which belongs also to $S_{j,k}$ (i.e., $w_{j,x,y} \in S_{j,k}$).

When these conditions are verified, $S_{j,k}$ and all structures at smaller scales which are directly or indirectly connected to $S_{j,k}$ will define a new object.

Object Identification

We can now summarize this method allowing us to identify all the objects in a given image Y :

1. We compute the wavelet transform with the starlet algorithm, which leads to a set $\alpha = \mathbf{W}Y = \{w_1, \dots, w_J, c_J\}$. Each scale w_j has the same size as the input image.
2. We determine the noise standard deviation in w_1 .
3. We deduce the thresholds at each scale from the noise modeling.
4. We threshold scale by scale and we do an image labeling.
5. We determine the interscale relations.
6. We identify all the wavelet coefficient maxima of the wavelet transform space.
7. We extract all the connected trees resulting from each wavelet transform space maximum.

Source Reconstruction

Partial Reconstruction as an Inverse Problem

A set of structures \mathcal{S}_i ($\mathcal{S}_i = \{S_{j,k}, \dots, S_{j',k'}\}$) defines an object O_i which can be reconstructed separately from other objects, in order to provide the components X_i . The co-addition of all reconstructed objects is a filtered version of the input data. We will denote α_i the set of wavelet coefficients belonging to the object O_i . Therefore, α_i is a subset of the wavelet transform of X_i , $\tilde{\alpha}_i = \mathbf{W}X_i$. Indeed, the last scale of

$\tilde{\alpha}_i$ is unknown, as well as many wavelet coefficients which have not been detected. Then the reconstruction problem consists of searching for an image X_i such that its wavelet transform reproduces the coefficients α_i (i.e., they are the same as those of S_i , the detected structures). If \mathbf{W} describes the wavelet transform operator and P_w the projection operator in the subspace of the detected coefficients (i.e., having set to zero all coefficients at scales and positions where nothing was detected), the solution is found by minimization of

$$\min_{X_i} \| \alpha_i - P_w(\mathbf{W}X_i) \|^2 \quad (35)$$

The size of the restored image X_i is arbitrary, and it can be easily set greater than the number of known coefficients. It is certain that there exists at least one image X_i which gives exactly α_i , i.e., the original one. But generally we have an infinity of solutions, and we have to choose among them the one which is considered as correct. An image is always a positive function, which leads us to constrain the solution, but this is not sufficient to get a unique solution. More details on the reconstruction algorithm can be found in [8, 57].

Examples

Band Extraction

We simulated a spectrum which contains an emission band at $3.50\text{ }\mu\text{m}$ and a nonstationary noise superimposed on a smooth continuum. The band is a Gaussian of width $\text{FWHM} = 0.01\text{ }\mu\text{m}$ ($\text{FWHM} = \text{full width at half-maximum}$) and normalized such that its maximum value equals ten times the local noise standard deviation.

Figure 11 (top) contains the simulated spectrum. The wavelet analysis results in the detection of an emission band at $3.50\text{ }\mu\text{m}$ above 3σ . Figure 11 (middle) shows the reconstruction of the detected band in the simulated spectrum. The real feature is overplotted as a dashed line. Figure 11 (bottom) contains the original simulation with the reconstructed band subtracted. It can be seen that there are no strong residuals near the location of the band, which indicates that the band is well reconstructed. The center position of the band, its FWHM, and its maximum can then be estimated via a Gaussian fit. More details about the use of MVM for spectral analysis can be found in [60].

Star Extraction in NGC 2997

We applied MVM to the galaxy NGC 2997 (Fig. 12, top left). Two images were created by co-adding objects detected from scales 1 and 2 and from scales 3 to 6. They are displayed, respectively, in Fig. 12, top right and bottom left. Figure 12, bottom right, shows the difference between the input data and the image which contained the objects from scales 1 and 2. As we can see, all small objects have been removed, and the galaxy can be better analyzed.

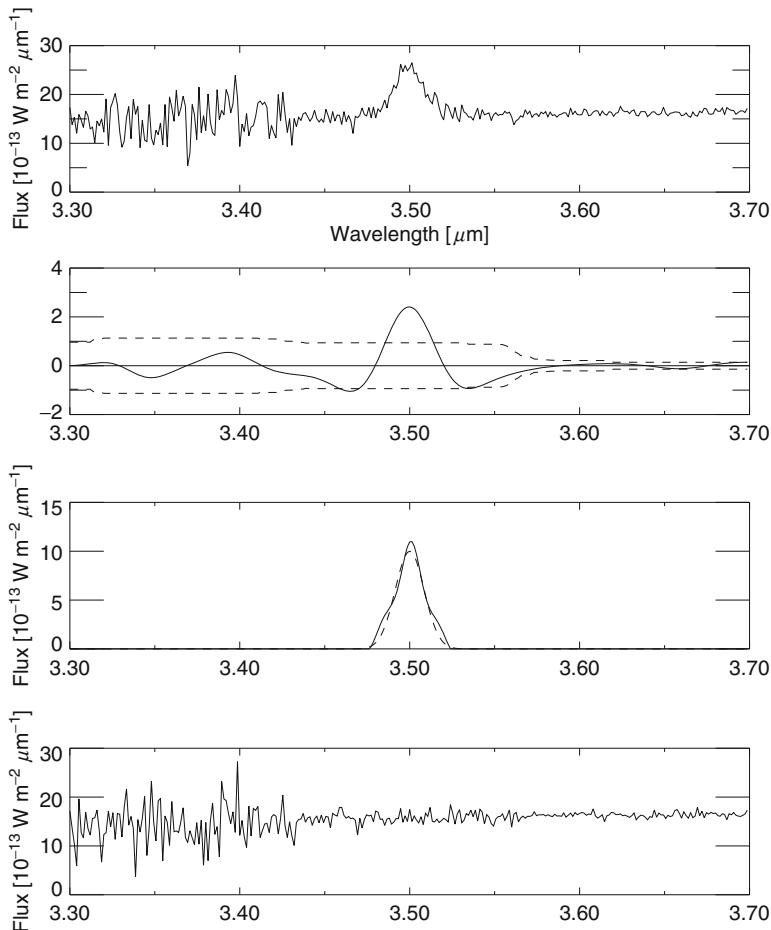

Fig. 11 *Top:* simulated spectrum. *Middle:* reconstructed simulated band (*full line*) and original band (*dashed line*). *Bottom:* simulated spectrum minus the reconstructed band

Galaxy Nucleus Extraction

Figure 13 shows the extracted nucleus of NGC 2997 using the MVM method and the difference between the galaxy image and the nucleus image.

5 Deconvolution

Up to now, the PSF H has not been considered in the source detection. This means that all morphological parameters (size, ellipticity, etc.) derived from the detected objects need to be corrected from the PSF. Very close objects may also be seen as a single object because H acts as a blurring operator on the data. A solution

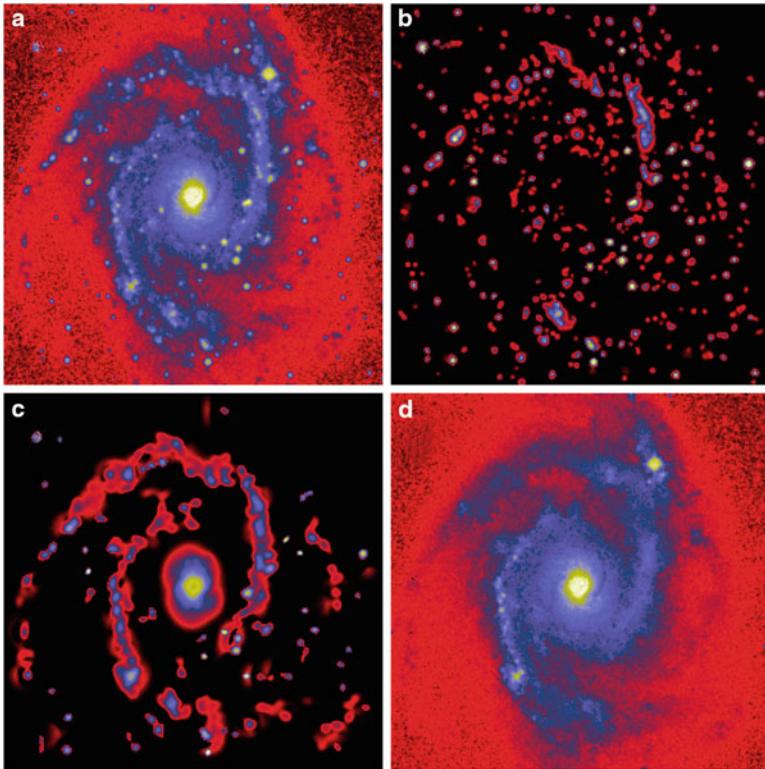

Fig. 12 (a) Galaxy NGC 2997, (b) objects detected from scales 1 and 2, (c) objects detected from scales 3 to 6, and (d) difference between (a) and (b)

may consist in deconvolving first the data and carrying out the source detection afterwards.

The problem of image deconvolution is ill-posed [3], and as a consequence, the matrix H modeling the imaging system is ill-conditioned. If Y is the observed image and X the unknown object, the equation $HX = Y$ has not a unique and stable solution. Therefore, one must look for approximate solutions of this equation that are also physically meaningful. One approach is Tikhonov regularization theory [23]; however, a more general approach is provided by the so-called Bayes paradigm [25], even if it is applicable only to discrete problems. In this framework one can both take into account statistical properties of the data (Tikhonov regularization is obtained by assuming additive Gaussian noise) and also introduce a priori information on the unknown object.

Statistical Approach to Deconvolution

We assume that the detected image Y is the realization of a multivalued random variable I corresponding to the (unknown) value X of another multivalued random variable, the object O . Moreover, we assume that the *conditional probability distribution* $p_I(Y|X)$ is known. Since the unknown object appears as a set of unknown parameters, the problem of image deconvolution can be considered as a classical problem of parameter estimation. The standard approach is the *maximum likelihood* (ML) method. In our specific application, for a given detected image Y , this consists of introducing the *likelihood function* defined by

$$L_Y(X) = p_I(Y; X) . \quad (36)$$

Then the ML estimate of the unknown object is any maximizer X^* of the likelihood function

$$X^* = \arg \max_{X \in \mathbb{R}^n} L_Y(X) , \quad (37)$$

if it exists.

In our applications the likelihood function is the product of a very large number of terms (the data components are assumed to be statistically independent), so that it is convenient to take the logarithm of this function; moreover, if we consider its negative logarithm, the maximization problem is transformed into a minimization one. Let us consider the function

$$J_0(X; Y) = -A \ln L_Y(X) + B , \quad (38)$$

where A, B are suitable constants. They are introduced in order to obtain a function which has a simple expression and is also nonnegative since, in our applications, the negative logarithm of the likelihood is bounded from below. Then, it is easy to verify that the problem of Eq. 37 is equivalent to the following one:

$$X^* = \arg \min_{X \in \mathbb{R}^n} J_0(X; Y) . \quad (39)$$

We consider now the model of Eq. 2 with three different examples of noise.

Example 1. In the case of additive white Gaussian noise, by a suitable choice of the constants A, B , we obtain (we assume here that the background B is not subtracted even if it must be estimated)

$$J_0(X; Y) = ||HX + B - Y||^2 , \quad (40)$$

and therefore, the ML approach coincides with the well-known least-squares (LS) approach. It is also well known that the function of Eq. 40 is convex and strictly convex if and only if the equation $HX = 0$ has only the solution $X = 0$. Moreover, it has always absolute minimizers, i.e., the LS problem has always a solution; but the problem is ill-conditioned because it is equivalent to the solution of the Euler equation:

$$H^T H X = H^T(Y - B) . \quad (41)$$

We remark that the ill-posedness of the LS problem is the starting point of *Tikhonov regularization theory* (see, for instance, [23, 63]), and therefore, this theory is based on the tacit assumption that the noise affecting the data is additive and Gaussian.

We remark that, in the case of object reconstruction, since objects are non-negative, we should consider the minimization of the function of Eq. 40 on the

nonnegative orthant. With such a constraint the problem is not treatable in the standard framework of regularization theory.

Example 2. In the case of Poisson noise, if we introduce the so-called generalized Kullback–Leibler (KL) divergence of a vector Z from a vector Y , defined by

$$D_{\text{KL}}(Y, Z) = \sum_{i=1}^m \left\{ y_i \ln \frac{Y_i}{Z_i} + Z_i - Y_i \right\} , \quad (42)$$

then, with a suitable choice of the constants A, B , the function $J_0(X; Y)$ is given by

$$\begin{aligned} J_0(X; Y) &= D_{\text{KL}}(Y; HX + B) \\ &= \sum_{i=1}^m \left\{ Y_i \ln \frac{y_i}{(HX + B)_i} + (HX + B)_i - y_i \right\} . \end{aligned} \quad (43)$$

It is quite natural to take the nonnegative orthant as the domain of this function. Moreover, it is well known that it is convex (strictly convex if the equation $HX = 0$ has only the solution $X = 0$), nonnegative, and coercive. Therefore, it has absolute minimizers. However, these minimizers are strongly affected by noise, and the specific effect of the noise in this problem is known as *checkerboard effect* [41], since many components of the minimizers are zero.

Example 3. In the case of Gauss+Poisson noise, the function $J_0(X; Y)$ is given by a much more complex form. This function is also convex (strictly convex if the equation $Hx = 0$ has the unique solution $x = 0$), nonnegative, and coercive [2]. Therefore, it also has absolute minimizer on the nonnegative orthant.

The previous examples demonstrate that, in the case of image reconstruction, ML problems are ill-posed or ill-conditioned. That means that one is not interested in computing the minimum points X^* of the functions corresponding to the different noise models because they do not provide sensible estimates \bar{X} of the unknown object.

The previous remark is not surprising in the framework of inverse problem theory. Indeed it is generally accepted that, if the formulation of the problem does not use some additional information on the object, then the resulting problem is ill-posed. This is what happens in the maximum likelihood approach because we only use information about the noise with, possibly, the addition of the constraint of non-negativity.

The additional information may consist, for instance, of prescribed bounds on the solution and/or its derivatives up to a certain order (in general not greater than two). These prescribed bounds can be introduced in the problem as additional constraints in the variational formulation provided by ML. However, in a quite natural

probabilistic approach, called the *Bayesian approach*, the additional information is given in the form of statistical properties of the object [25].

In other words, one assumes that the unknown object X is a realization of a vector-valued random variable O and that the probability distribution of O , the so-called prior denoted by $p_O(X)$, is also known or can be deduced from known properties of the object. The most frequently used priors are Markov random fields or, equivalently, Gibbs random fields, i.e., they have the following form:

$$p_O(X) = \frac{1}{Z} e^{-\mu \Omega(X)} , \quad (44)$$

where Z is a normalization constant, μ is a positive parameter (a hyperparameter in statistical language, a regularization parameter in the language of regularization theory), while $\Omega(X)$ is a function, possibly convex.

The previous assumptions imply that the joint probability density of the random variables O, I is given by

$$p_{OI}(X, Y) = p_I(Y|X)p_O(X) . \quad (45)$$

If we introduce the marginal probability density of the image I

$$p_I(Y) = \int p_{OI}(X, Y) dX , \quad (46)$$

from *Bayes' formula* we obtain the conditional probability density of O for a given value Y of I :

$$p_O(X|Y) = \frac{p_{OI}(X, Y)}{p_I(Y)} = \frac{p_I(Y|X)p_O(X)}{p_I(Y)} . \quad (47)$$

If in this equation we insert the detected value Y of the image, we obtain the a posteriori probability density of X :

$$P_Y(X) = p_O(X|Y) = L_Y(X) \frac{p_O(X)}{p_I(Y)} . \quad (48)$$

Then, a *maximum a posteriori* (MAP) estimate of the unknown object is defined as any object X^* that maximizes the a posteriori probability density:

$$X^* = \arg \max_{X \in \mathbb{R}^n} P_Y(X) . \quad (49)$$

As in the case of the likelihood, it is convenient to consider the negative logarithm of $P_Y(X)$. If we assume a Gibbs prior as that given in Eq. 44 and we take into account the definition of Eq. 38, we can introduce the following function:

$$\begin{aligned} J(X; Y) &= -A \ln P_Y(X) + B - A \ln Z \\ &\quad - A \ln p_I(Y) = J_0(X; Y) + \mu J_R(X), \end{aligned} \tag{50}$$

where $J_R(X) = A\Omega(X)$. Therefore, the MAP estimates are also given by

$$X^* = \arg \min_{X \in \mathbb{R}^n} J(X; Y) \tag{51}$$

and again one must look for the minimizers satisfying the non-negativity constraint.

The Richardson–Lucy Algorithm

One of the most frequently used methods for image deconvolution in astronomy is an iterative algorithm known as the *Richardson–Lucy* (RL) algorithm [34, 48]. In emission tomography it is also denoted as *expectation maximization* (EM) because, as shown in [49], it can be obtained by applying to the ML problem with Poisson noise a general EM method introduced in [19] for obtaining ML estimates.

In [49] it is shown that, if the iteration converges, then the limit is just an ML estimate in the case of Poisson data. Subsequently the convergence of the algorithm was proved by several authors in the case $B = 0$. An account can be found in [41].

The iteration is as follows: it is initialized with a positive image $X^{(0)}$ (a constant array, in general); then, given $X^{(n)}$, $X^{(n+1)}$ is computed by

$$X^{(n+1)} = X^{(n)} H^T \frac{Y}{H X^{(n)} + B}. \tag{52}$$

This algorithm has some nice features. First, the result of each iteration is automatically a positive array; second, in the case $B = 0$, the result of each iteration has the same flux of the detected image Y , and this property is interesting from the photometric point of view.

The limit of the RL iteration is, in general, very noisy and sparse in pixel space (see the remark at the end of Example 2 in the previous section) and can provide satisfactory results in the case of star systems (see [4], section 3.1); in the case of complex systems, a reasonable solution can be obtained by a suitable stopping of the algorithm before convergence. This can be seen as a kind of regularization, and this property is called *semi-convergence* [3], i.e., the iteration first approaches the correct solution and then goes away. An example of RL reconstruction is shown in Fig. 14 (lower left panel).

The main drawback of RL is that, in general, it is very slow and may require hundreds or thousands of iterations. The proposed acceleration approaches are based on the remark that RL is a scaled gradient method since it can be written in the

following form:

$$X^{(n+1)} = X^{(n)} - X^{(n)} \nabla_X J_0(X^{(n)}; Y) , \quad (53)$$

where ∇_X denotes the gradient with respect to X and $J_0(X; Y)$ is the data-fidelity function defined in Eq. 43. Therefore, a reduction of the number of iterations can be obtained by means of a suitable line search along the descent direction. This is the approach proposed by several authors. However, this structure of RL has inspired a recently proposed optimization method, known as *scaled gradient projection* (SGP) [10], which can be viewed as a general method for the constrained minimization of differentiable functions.

If $J(X)$ is the function to be minimized on the nonnegative orthant, then the method is based on the descent direction:

$$D^{(n)} = P_+ \left(X^{(n)} - \sigma_n S^{(n)} \nabla_X J(X^{(n)}) \right) - X^{(n)} \quad (54)$$

where P_+ is the projection on the nonnegative orthant, $S^{(n)}$ is the (diagonal) scaling matrix, and σ_n is a suitably chosen step length [10]. Then iteration $X^{(n+1)}$ is obtained by a line search along the descent direction based on the Armijo rule. We can add that the method can be easily extended to the case where the convex set of the admissible solutions is defined by box and equality constraints.

In the case of the minimization of the KL divergence, the diagonal scaling matrix is that suggested by RL, i.e., $S^{(n)} = X^{(n)}$ (with the addition of suitable upper and lower bounds), and the method shows the semi-convergence property as RL, but requires a much smaller number of iterations for obtaining a sensible reconstruction. In an application to the deconvolution of astronomical images [46], it has been shown that, even if the computational cost per iteration is about 30 % greater than that of RL, thanks to the reduction of the number of iterations it is possible to obtain a speedup, with respect to RL, ranging from 4 to more than 30, depending on the astronomical source and the noise level. Moreover, implementation on *graphics processing units* (GPU) allows to deconvolve a $2,048 \times 2,048$ image in a few seconds.

Several iterative methods, modeled on RL, have been introduced for computing MAP estimates corresponding to different kinds of priors. A recent account can be found in [4]. A nice feature of SGP, whose convergence is proved in [10], is that it can be easily applied to this problem, i.e., to the minimization of the function of Eq. 50 (again, with the addition of box and equality constraints). The scaling is taken from the *split-gradient method* (SGM), proposed in [31], since this scaling is always nonnegative, while the scaling proposed in [26] may take negative values. In general the choice of the scaling is as follows. If the gradient of $J_R(X)$ is split in the following way:

$$-\nabla_X J_R(X) = U_R(X) - V_R(X), \quad (55)$$

where U_R , V_R are nonnegative arrays, then the scaling is given by the array

$$S = \frac{X}{1 + \mu V_R(X)} . \quad (56)$$

Of course SGP can be applied if $J_R(X)$ is differentiable, and therefore, it can cover both smoothing regularization as given by Tikhonov and also edge-preserving regularization as given by smoothed TV (total variation) [12, 65]. Finally, a difficult problem in the case of regularized problems is the choice of the value of the regularization parameter. An attempt in the direction of solving this problem is provided by a recently proposed discrepancy principle for Poisson data deconvolution [5].

Blind Deconvolution

Blind deconvolution is the problem of image deblurring when the blur is unknown. In the case of a space-invariant model, the naive problem formulation is to solve the problem $Y = H * X$ where only Y is known, where $*$ denotes convolution. It is obvious that this problem is extremely undetermined and that there is an infinite set of pairs solving the equation. Among them also is the trivial solution $X = Y$, $H = \delta$, where δ denotes the usual delta function. Therefore, the problem must be formulated by introducing as far as possible all available constraints on both the object X and the PSF H .

In the case of Poisson noise, several iterative methods have been proposed, which consist of alternating updates of the object and PSF by means of RL iterations or accelerated RL iterations. For instance, in [27] one RL iteration is used both on the object and the PSF. This algorithm was investigated, in the context of *nonnegative matrix factorization* (NMF), by Lee and Seung [32], but their convergence proof is incomplete, since only the monotonic decrease of the objective function is shown while, for a general descent method to be convergent, strongest Armijo-like decreasing conditions have to be verified. In general, the proposed approaches to blind deconvolution with Poisson data could be classified as methods of inexact alternating minimization applied to the KL divergence, as a function of both object and PSF.

In a recent paper [9], in the context of NMF, convergence of inexact alternating minimization is proved if the iterative algorithm used for the inner iterations satisfies suitable conditions, which are satisfied by SGP. Therefore, this approach looks very suitable for the problem of blind deconvolution with Poisson data. The approach is applied in [47] using constraints both on the object and the PSF. The method applies to the imaging by ground-based telescopes since, as suggested in [20], one of the constraints on the PSF is provided by the Strehl ratio (SR; see Sect. 2), a parameter measuring the quality of the AO correction. Indeed we recall that the advantage of

SGP is not only fast convergence, if a suitable scaling of the gradient is used, but also the possibility of introducing suitable box and equality constraints on the solution. In particular the SR constraint excludes the trivial solution mentioned above. The method works well in the case of star systems.

Deconvolution with a Sparsity Prior

Another approach is to use the sparsity to model the data. A sparse model can be interpreted from a Bayesian standpoint, by assuming the coefficients α of the solution in the dictionary Φ follow a leptokurtic PDF with heavy tails such as the generalized Gaussian distribution form:

$$\text{pdf}_\alpha(\alpha_1, \dots, \alpha_K) \propto \prod_{k=1}^K \exp\left(-\lambda \|\alpha_i\|_p^p\right) \quad 0 \leq p < 2. \quad (57)$$

Between all possible solutions, we want the one which has the sparsest representation in the dictionary Φ . Putting together the log-likelihood function in the case of Gaussian noise σ and the priors on α , the MAP estimator leads to the following optimization problem:

$$\min_{\alpha_1, \dots, \alpha_K} \frac{1}{2\sigma} \|Y - \Phi\alpha\|^2 + \lambda \sum_{k=1}^K \|\alpha_k\|_p^p, \quad 0 \leq p < 2. \quad (58)$$

The sparsity can be measured through the $\|\alpha\|_0$ norm (i.e., $p = 0$). This counts in fact the number of nonzero elements in the sequence. It was also proposed to convexify the constraint by substituting the convex $\|\alpha\|_1$ norm for the $\|\alpha\|_0$ norm [13]. Depending on the H operator, there are several ways to obtain the solution of this equation.

A first iterative thresholding deconvolution method was proposed in [51] which consists of the following iterative scheme:

$$X^{(n+1)} = P_+ (X^{(n)} + H^T (\mathbf{WDen}_{M^{(n)}} (Y - HX^{(n)}))) \quad (59)$$

where P_+ is the projection on the cone of nonnegative images and **WDen** is an operator which performs a wavelet thresholding, i.e., applies the wavelet transform of the residual $R^{(n)}$ (i.e., $R^{(n)} = Y - HX^{(n)}$), thresholds some wavelet coefficients, and applies the inverse wavelet transform. Only coefficients that belong to the multiresolution support $M^{(n)}$ [51] are kept, while the others are set to zero. At each iteration, the multiresolution support $M^{(n)}$ is updated by selecting new coefficients in the wavelet transform of the residual which have an absolute value larger than a given threshold. The threshold is automatically derived assuming a given noise distribution such as Gaussian or Poisson noise.

More recently, it was shown [14, 16, 24] that a solution of Eq. 58 for $p = 1$ can be obtained through a thresholded Landweber iteration:

$$X^{(n+1)} = P_+(\mathbf{WDen}_\lambda(X^{(n)} + H^T(Y - HX^{(n)}))) , \quad (60)$$

with $\|H\| = 1$. In the framework of monotone operator splitting theory, it was shown that for frame dictionaries, a slight modification of this algorithm converges to the solution [14]. Extension to constrained nonlinear deconvolution is proposed in [22].

Constraints in the Object or Image Domains

Let us define the *object domain* \mathcal{O} as the space in which the solution belongs and the *image domain* \mathcal{I} as the space in which the observed data belongs (i.e., if $X \in \mathcal{O}$ then $HX \in \mathcal{I}$). The constraint in (59) was applied in the image domain, while in (60) we have considered constraints on the solution. Hence, two different wavelet-based strategies can be chosen in order to regularize the deconvolution problem. The constraint in the image domain through the multiresolution support leads to a very robust way to control the noise. Indeed, whatever the nature of the noise, we can always derive robust detection levels in the wavelet space and determine scales and positions of the important coefficients. A drawback of the image constraints is that there is no guarantee that the solution is free of artifacts such as ringing around point sources. A second drawback is that image constraints can be used only if the point spread function is relatively compact, i.e., does not smear the information over the whole image.

The property of introducing robust noise modeling is lost when applying the constraint in the object domain. For example, in the case of Poisson noise, there is no way (except using time-consuming Monte Carlo techniques) to estimate the level of the noise in the solution and to adjust properly the thresholds. The second problem with this approach is that, in fact, we try to solve two problems simultaneously (noise amplification and artifact control in the solution) with one parameter (i.e., λ). The choice of this parameter is crucial, while such a parameter is implicit when using the multiresolution support.

Ideally, constraints should be added in both the object and image domains in order to better control the noise by using the multiresolution support and avoid such a ringing artifact.

Example

A simulated Hubble Space Telescope Wide Field Camera image of a distant cluster of galaxies is shown in Fig. 14, upper left. The simulated data are shown in Fig. 14, upper right. The Richardson–Lucy and the wavelet solutions are shown, respectively, in Fig. 14, lower left and right. The Richardson–Lucy method amplifies the noise, which implies that the faintest objects disappear in the deconvolved image, while the wavelet starlet solution is stable for any kind of PSF, and any kind of noise modeling can be considered.

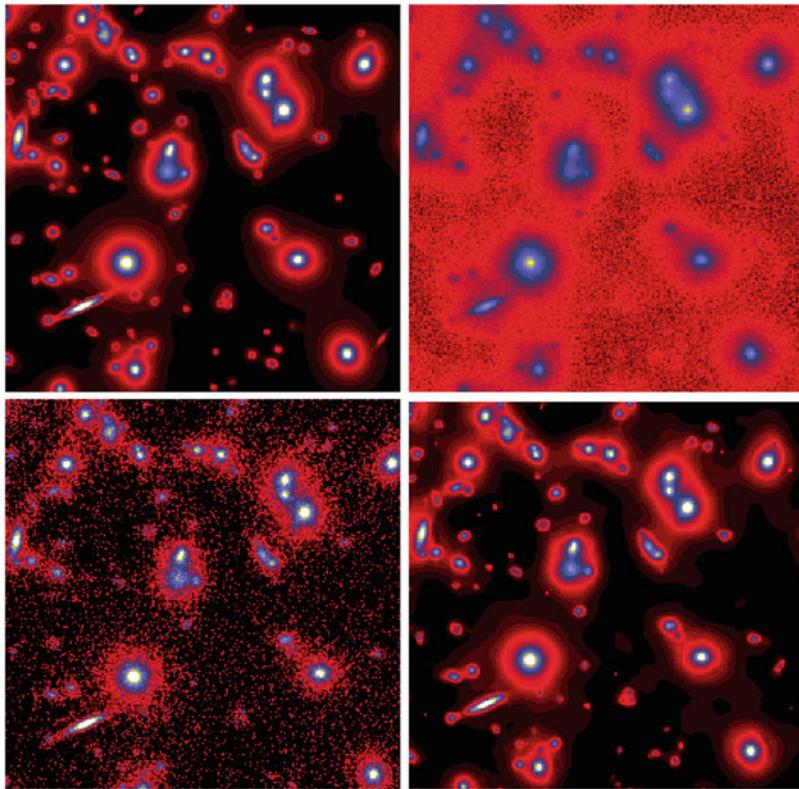

Fig. 14 Simulated Hubble Space Telescope Wide Field Camera image of a distant cluster of galaxies. *Upper left:* original, unaberrated, and noise-free. *Upper right:* input, aberrated, noise added. *Lower left:* restoration, Richardson–Lucy. *Lower right:* restoration starlet deconvolution

Detection and Deconvolution

The PSF is not needed with MVM. This is an advantage when the PSF is unknown or difficult to estimate, which happens relatively often when it is space variant. However, when the PSF is well determined, it becomes a drawback because known information is not used for the object reconstruction. This can lead to systematic errors in the photometry, which depends on the PSF and on the source signal-to-noise ratio. In order to preempt such a bias, a kind of calibration must be performed using simulations [50]. This section shows how the PSF can be used in the MVM, leading to a deconvolution.

Object Reconstruction Using the PSF

A reconstructed and deconvolved object X_i can be obtained by searching for a signal X_i such that the wavelet coefficients of $H X_i$ are the same as those of the

detected structures α_i . If \mathbf{W} describes the wavelet transform operator and P_w the projection operator in the subspace of the detected coefficients, the solution is found by minimization of

$$\min_{X_i} \| \alpha_i - P_w(\mathbf{W} H X_i) \|^2 \quad (61)$$

where α_i represents the detected wavelet coefficients of the object O_i and H is the PSF. In this approach, each object is deconvolved separately. The flux related to the extent of the PSF will be taken into account. For point sources, the solution will be close to that obtained by PSF fitting. This problem is also different from global deconvolution in the sense that it is well constrained. Except for the positivity of the solution which is always true and must be used, no other constraint is needed. This is due to the fact that the reconstruction is performed from a small set of wavelet coefficients (those above a detection limit). The number of objects is the same as those obtained by the MVM, but the photometry and the morphology are different. The astrometry may also be affected.

The Algorithm

Any minimizing method can be used to obtain the solution X_i . Since there is no problem of convergence, noise amplification, or ringing effect, the Van Cittert method was proposed on the grounds of its simplicity [57]. It leads to the following iterative scheme:

$$X_i^{(n+1)} = X_i^{(n)} + \mathbf{R}(\alpha_i - P_w(\mathbf{W} H X_i^{(n)})) \quad (62)$$

where \mathbf{R} is the inverse wavelet transform, and the algorithm is:

1. Set n to 0.
2. Find the initial estimation $X_i^{(n)}$ by applying an inverse wavelet transform to the set α_i corresponding to the detected wavelet coefficients in the data.
3. Convolve $X_i^{(n)}$ with the PSF H : $Y_i^{(n)} = H X_i^{(n)}$.
4. Determine the wavelet transform $\alpha^{(Y_i^{(n)})}$ of $Y_i^{(n)}$.
5. Threshold all wavelet coefficients in $\alpha^{(Y_i^{(n)})}$ at position and scales where nothing has been detected (i.e., P_w operator). We get $\alpha_t^{(Y_i^{(n)})}$.
6. Determine the residual $\alpha_r = \alpha_i - \alpha_t^{(Y_i^{(n)})}$.
7. Reconstruct the residual image $R^{(n)}$ by applying an inverse wavelet transform.
8. Add the residual to the solution: $X_i^{(n+1)} = X_i^{(n)} + R^{(n)}$.
9. Threshold negative values in $X_i^{(n+1)}$.
10. If $\sigma(R^{(n)})/\sigma(X_i^{(0)}) < \epsilon$, then $n = n + 1$ and go to step 3.
11. $X_i^{(n+1)}$ contains the deconvolved reconstructed object.

In practice, convergence is very fast (less than 20 iterations). The reconstructed image (not deconvolved) can also be obtained just by reconvolving the solution with the PSF.

Space-Variant PSF

Deconvolution methods generally do not take into account the case of a space-variant PSF. The standard approach when the PSF varies is to decompose the image into blocks and to consider the PSF constant inside a given block. Blocks which are too small lead to a problem of computation time (the FFT cannot be used), while blocks which are too large introduce errors due to the use of an incorrect PSF. Blocking artifacts may also appear. Combining source detection and deconvolution opens up an elegant way for deconvolution with a space-variant PSF. Indeed, a straightforward method is derived by just replacing the constant PSF at step 3 of the algorithm with the PSF at the center of the object. This means that it is not the image which is deconvolved, but its constituent objects.

Undersampled Point Spread Function

If the PSF is undersampled, it can be used in the same way, but results may not be optimal due to the fact that the sampled PSF varies depending on the position of the source. If an oversampled PSF is available, resulting from theoretical calculation or from a set of observations, it should be used to improve the solution. In this case, each reconstructed object will be oversampled. Equation 61 must be replaced by

$$\min_{X_i} \| \alpha_i - P_w (\mathbf{W} \mathcal{D}_l H X_i) \|^2 \quad (63)$$

where \mathcal{D}_l is the averaging-decimation operator, consisting of averaging the data in the window of size $l \times l$ and keeping only one average pixel for each $l \times l$ block.

Example: Application to Abell 1689 ISOCAM Data

Figure 15 (left) shows the detections (isophotes) obtained using the MVM method without deconvolution on ISOCAM data. The data were collected using the 6 arcsec lens at 6.75 μm . This was a raster observation with 10 s integration time, 16 raster positions, and 25 frames per raster position. The noise is nonstationary, and the detection of the significant wavelet coefficients was carried out using the root mean square error map $R_\sigma(x, y)$ by the method described in [50]. The isophotes are overplotted on an optical image (NTT, band V) in order to identify the infrared source. Figure 15 (right) shows the same treatment but using the MVM method with deconvolution. The objects are the same, but the photometry is improved, and it is clearly easier to identify the optical counterpart of the infrared sources.

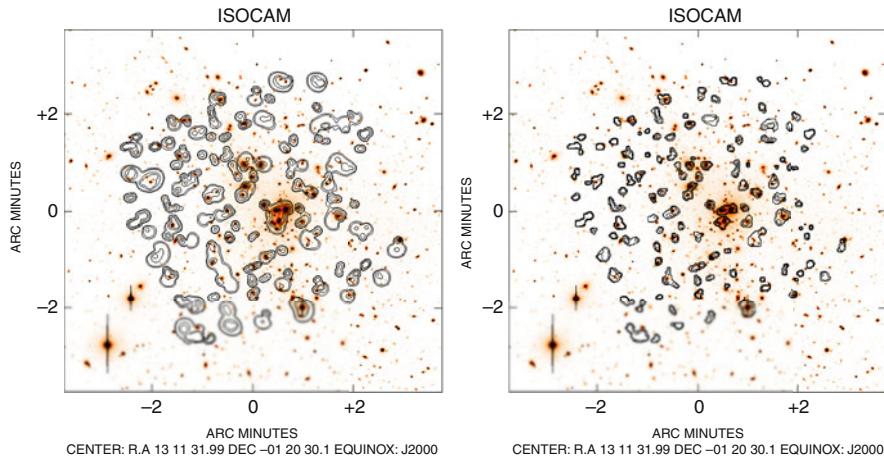

Fig. 15 Abell 1689: *left*, ISOCAM source detection (isophotes) overplotted on an optical image (NTT, band V). The ISOCAM image is a raster observation at $7\text{ }\mu\text{m}$. *Right*, ISOCAM source detection using the PSF (isophotes) overplotted on the optical image. Compared to the *left* panel, it is clearly easier to identify the detected infrared sources in the optical image

6 Conclusion

In this chapter we have used the sparsity principle that now occupies a very central role in signal processing. We have discussed the vision models within which the sparsity principle is applied. Finally, we have reviewed the use of the starlet wavelet transform as a prime technique in order to apply the sparsity principle in the context of vision models in various application domains. Among the latter are object detection coupled with denoising, deconvolution and Itering generally. Issues of algorithmic optimization and of statistical modeling entered into our discussion on various occasions. Many examples and case studies were used to demonstrate the powerfulness of the approaches described for astronomical data analysis and processing.

Abstract

Images in scientific visualization are the end product of data processing. Starting from higher-dimensional data sets such as scalar, vector, and tensor fields given on 2D, 3D, and 4D domains, the objective is to reduce this complexity to two-dimensional images comprehensible to the human visual system. Various mathematical fields such as in particular differential geometry, topology (theory of discretized manifolds), differential topology, linear algebra, Geometric Algebra, vector field and tensor analysis, and partial differential equations contribute to the data filtering and transformation algorithms used in scientific visualization. The application of differential methods is core to all these fields. The following chapter will provide examples from current research on the application of these mathematical domains to scientific visualization. Ultimately the use of these methods allows for a systematic approach for image generation resulting from the analysis of multidimensional datasets.

1 Introduction

Scientists need an alternative to numbers. The use of images is a technical reality nowadays and tomorrow it will be an essential requisite for knowledge. The ability of scientists to visualize calculations and complex simulations is absolutely essential to ensure the integrity of analyses, to promote scrutiny in depth and to communicate the result of such scrutiny to others... The purpose of scientific calculation is looking, not enumerating. It is estimated that 50 % of the brain's neurons are associated with vision. Visualization in a scientific calculation is aimed at putting this neurological machinery to work [56].

Since this visionary quote from an article in 1987, scientific visualization, benefiting from the affordable graphics hardware driven by the computer gaming industry, has grown rapidly. Beyond academic research interests it has become also a consumer market with practical applicability in industry and medicine. Still there are yet many gaps that are left open due to the unequal evolution velocities in different fields. Once, there is the human mind that is not able to keep up with the deluge of visual

information which can be produced with modern technology. Many scientists still prefer looking at numbers instead of utilizing modern display technology. At the same time, data can be produced by modern supercomputers that is far beyond the ability of even high-end graphics engines to be processed. Data sets originating from numerical simulations of physical processes will usually be three-dimensional or four-dimensional, with images just the final result of the process of scientific visualization. In this context images are the means to analyze data set of higher dimensions.

Reducing numerical data sets to images is known as the concept of the *visualization pipeline*. In its simplest form it consists of a data source (n -dimensional), a data filter (an algorithmic operation), and a data sink (an image). Data filters need to understand the structure and meaning of the multidimensional input data and to operate efficiently on them. This involves various mathematical fields such as in particular differential geometry, topology (theory of discretized manifolds), differential topology, linear algebra, Geometric Algebra, vector field and tensor analysis, and partial differential equations. Within a scientific visualization process, all these mathematical fields will work together, with more or less weighting. We subsume this set of mathematical domains as “differential methods” in this chapter as the concept of differentiation is fundamental to their approach of data analysis. The following sections will demonstrate the application of the respective mathematical fields to visual analysis by virtue of examples of ongoing research.

In Sect. 2 we discuss the general issue of how to lay out data to model the structure of space and time, as we know it from mathematics as foundation for further operations. Frequently visualization algorithms are implemented ad hoc, given the problem, inventing the solution with highest performance. This allegedly reasonable approach comes with an unfortunate downside: incompatibility among independently developed solutions, which impacts data exchange and interfacing complementary implementations. However, when keeping a common data model in mind right from the earliest steps of conceiving some algorithm, interoperability can be achieved at no cost with same performance as solitary solutions.

Given a solid foundation for data structures, Sect. 3 demonstrates how to formulate differential operators using the concepts of chains, cochains, homology, and cohomology. Since in computer graphics and visualization we have to deal with discretized spaces, we arrive in the mathematical field of topology, as an essential descriptive tool for meshes and all nontrivial grid structures.

When considering mathematics as a language unifying computer science, we need to even more think about a common denominator within mathematics itself. Geometric Algebra is a relatively new – or, rather, rediscovered – branch of mathematics that is very promising. It is extraordinarily visually intuitive while covering the abstractions of Clifford algebra as used in quantum mechanics equally well as the formulations of curved space in general relativity. However, even independent of such physics-oriented applications, Geometric Algebra has found its merits within computer graphics itself. Section 4 will talk about the elegant usage of five-dimensional projective conformal Geometric Algebra to handle primitives in

computer graphics and eventually implement the ray-tracing algorithm with a few, well-defined algebraic operations.

The general goal of visualization is to give insight into large and complex data sets. Due to the sheer size of the data sets alone, it is favorable if not necessary to automate at least parts of the analysis. A way to achieve this is by extracting features. Features can either be certain quantities derived from a data set or a mathematically well-defined, geometric object (point, line, surface, ...) with its definition and interpretation depending on the underlying application, but usually it represents important structures (e.g., vortex, stagnation point) or changes to such structures (events, bifurcations). A feature-based visualization aims at the reduction of information to guide a user to the most interesting parts of a data set. In Sect. 5 we describe some important approaches to feature-based visualization of vector fields. These include investigation of derived quantities such as vortices (section “Derived Measures of Vector Fields”) and the topology of vector fields (section “Topology of Vector Fields”). These approaches have become a standard tool for the analysis of vector fields.

Finally, in Sect. 6 we explore the capabilities of partial differential equations for the filtering and regularization of image data sets. Applications are enhancing image quality by reducing noise or similar artifacts, as well as the visualization of vector and tensor fields.

2 Modeling Data via Fiber Bundles

Purely numerical algorithms in C++ can be abstracted from concrete data structures using programming techniques such as generic programming [79]. However, generic algorithms still need to make certain assumptions about the data they operate on. The question remains what these *concepts* are that describe “data”: what properties should be expected by some algorithm from any kind of data provided for scientific visualization? Moreover, consistency among concepts shared by independent algorithms is also required to achieve *interoperability* among algorithms and eventually (independently developed) applications. While any particular problem can be addressed by some particular solution, a common concept allows to build a *framework* instead of just a collection of *tools*. Tools are what an end user needs to solve a particular problem with a known solution. However, when a problem is not yet clearly defined and a solution unknown, then a framework is required that allows exploration of various approaches and eventually adaption toward a specific direction that does not exist a priori.

The concept of how to lay out data to perform visualization operations in a common framework constitutes a *data model* for visualization. Many visualization applications are to a greater or lesser extent a collection of tools, even when bundled together within the same software library or binary. Consequently, interoperability between different applications and their corresponding file formats is hard or impossible. Only very few implementations adhere to the vision of a common data model across the various data types for visualization. The idea of a common data

model is frequently undervalued or even disregarded as being impossible. However, as D. Butler said, “The proper abstractions for scientific data are known. We just have to use them” [16].

D. Butler was following the mathematical concepts of fiber bundles [16], or more specific, vector bundles [15], to model data. The IBM Data Explorer, one of the earliest visualization applications, now open source and known as “OpenDX (<http://www.opendx.org>),” implemented this concept successfully [76]. These ideas have been revived and expanded by [7] leading to a hierarchical data structure consisting of a noncyclic graph in seven levels. It can be seen as largely keyword-free, hierarchical version of the OpenDX model, seeking to cast the information and relationships provided in original model into a grouping structure. This data model will be reviewed in the following, together with its mathematical background. Section “Differential Geometry: Manifolds, Tangential Spaces, and Vector Spaces” will review the basic mathematical structures that are used to describe space and time. Section “Topology: Discretized Manifolds” will introduce the mathematical formulation of discretized space. Based on this background, section “Ontological Scheme and Seven-Level Hierarchy” will present a scheme that is able to cover the described mathematical structures.

Differential Geometry: Manifolds, Tangential Spaces, and Vector Spaces

Space and time in physics is modeled via the concept of a differentiable manifold. As scientific visualization deals with data given in space and time, following these concepts is reasonable. In short, a manifold is a topological space that is locally homeomorphic to \mathbb{R}^n . However, not all data occurring in scientific visualization are manifolds. The more general case of topological spaces will be discussed in sections “Topology: Discretized Manifolds” and “Topology.”

A vector space over a field F (such as \mathbb{R}) is a set V together with two binary operations *vector addition* $+$: $V \times V \rightarrow V$ and *scalar multiplication* $\circ : F \times V \rightarrow V$. The mathematical concept of a *vector* is defined as an element $v \in V$. A vector space is closed under the operations $+$ and \circ , i.e., for all elements $u, v \in V$ and all elements $\lambda \in F$ there is $u + v \in V$ and $\lambda \circ u \in V$ (vector space axioms). The vector space axioms allow computing the differences of vectors and therefore defining the derivative of a vector-valued function $v(s) : \mathbb{R} \rightarrow V$ as

$$\frac{d}{ds}v(s) := \lim_{ds \rightarrow 0} \frac{v(s + ds) - v(s)}{ds} \quad (1)$$

A manifold in general is *not* a vector space. However, a differentiable manifold M allows to define a tangential space $T_P(M)$ at each point P which has vector space properties.

Tangential Vectors

In differential geometry, a tangential vector on a manifold M is the operator $\frac{d}{ds}$ that computes the derivative along a curve $q(s) : \mathbb{R} \rightarrow M$ for an arbitrary scalar-valued function $f : M \rightarrow \mathbb{R}$:

$$\frac{d}{ds} f \Big|_{q(s)} := \frac{df(q(s))}{ds} \quad (2)$$

Tangential vectors fulfill the vector space axioms and can therefore be expressed as linear combinations of derivatives along the n coordinate functions $x^\mu : M \rightarrow \mathbb{R}$ with $\mu = 0 \dots n - 1$, which define a basis of the tangential space $T_{q(s)}(M)$ on the n -dimensional manifold M at each point $q(s) \in M$:

$$\frac{d}{ds} f = \sum_{\mu=1}^{n-1} \frac{dx^\mu(q(s))}{ds} \frac{\partial}{\partial x^\mu} f =: \sum_{\mu=1}^{n-1} \dot{q}^\mu \partial_\mu f \quad (3)$$

where $\{q\}^\mu$ are the components of the tangential vector $\frac{d}{ds}$ in the chart $\{x^\mu\}$ and $\{\partial_\mu\}$ are the basis vectors of the tangential space in this chart. In the following text the Einstein sum convention is used, which assumes implicit summation over indices occurring on the same side of an equation. Often tangential vectors are used synonymous with the term “vectors” in computer graphics when a direction vector from point A to point B is meant. A tangential vector on an n -dimensional manifold is represented by n numbers in a chart.

Covectors

The set of operations $df : T(M) \rightarrow \mathbb{R}$ that map tangential vectors $v \in T(M)$ to a scalar value $v(f)$ for any function $f : M \rightarrow \mathbb{R}$ defines another vector space which is dual to the tangential vectors. Its elements are called *covectors*:

$$\langle df, v \rangle = df(v) := v(f) = v^\mu \partial_\mu f = v^\mu \frac{\partial f}{\partial x^\mu} \quad (4)$$

Covectors fulfill the vector space axioms and can be written as linear combination of covector basis functions dx^μ :

$$df =: \frac{\partial f}{\partial x^\mu} dx^\mu \quad (5)$$

whereby the dual basis vectors fulfill the duality relation

$$\langle dx^\nu, \partial_\mu \rangle = \begin{cases} \mu = \nu : & 1 \\ \mu \neq \nu : & 0 \end{cases} \quad (6)$$

The space of covectors is called the cotangential space $T_P^*(M)$. A covector on an n -dimensional manifold is represented by n numbers in a chart, same as a tangential vector. However, covectors transform inverse to tangential vectors when changing

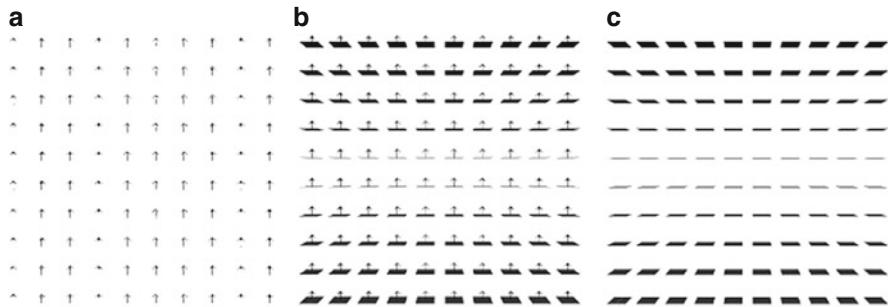

Fig. 1 The (trivial) constant vector field along the z -axis viewed as vector field ∂_z and as covector field dz . **(a)** Vector field ∂_z . **(b)** Duality relationship among ∂_z and dz . **(c)** Co-vector field dz

coordinate systems, as is directly obvious from Eq. (6) in the one-dimensional case: as $\langle dx^0, \partial_0 \rangle = 1$ must be sustained under coordinate transformation, dx^0 must shrink by the same amount as ∂_0 grows when another coordinate scale is used to represent these vectors. In higher dimensions this is expressed by an inverse transformation matrix.

In Euclidean three-dimensional space, a plane is equivalently described by a “normal vector,” which is orthogonal to the plane. While “normal vectors” are frequently symbolized by an arrow, similar to tangential vectors, they are not the same, rather they are dual to tangential vectors. It is more appropriate to visually symbolize them as a plane. This visual is also supported by (5), which can be interpreted as the total differential of a function f : a covector describes the change of a function f along a direction as specified by a tangential vector \vec{v} . A covector V can thus be visually imagined as a sequence of coplanar (locally flat) planes at distances given by the magnitude of the covector that count the number of planes which are crossed by a vector \vec{w} . This number is $V(w)$. For instance, for the Cartesian coordinate function x , the covector dx “measures” the “crossing rate” of a vector w in the direction along the coordinate line x ; see Figs. 1 and 2. On an n -dimensional manifold a covector is correspondingly symbolized by a $(n - 1)$ -dimensional subspace.

Tensors

A tensor T_n^m of rank $n \times m$ is a multi-linear map of n vectors and m covectors to a scalar

$$T_n^m : T(M) \times \dots T(M)_n \times T^*(M) \times \dots T^*(M)_m \rightarrow \mathbb{R} \quad (7)$$

Tensors are elements of a vector space themselves and form the tensor algebra. They are represented relative to a coordinate system by a set of k^{n+m} numbers for a k -dimensional manifold. Tensors of rank 2 may be represented using matrix notation. Tensors of type T_1^0 are equivalent to covectors and called co-variant; in

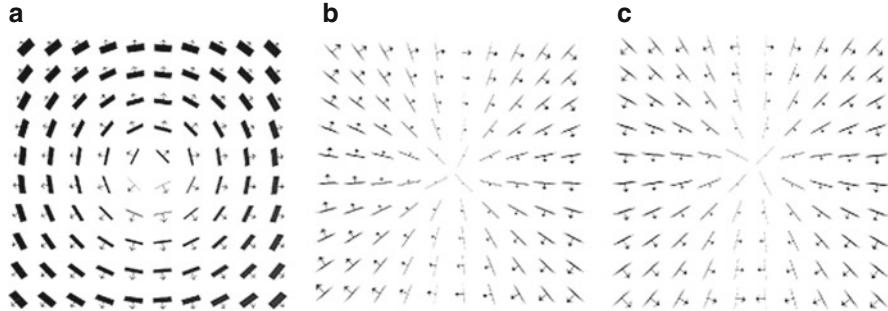

Fig. 2 The basis vector and covector fields induced by the polar coordinates $\{r, \vartheta, \phi\}$. (a) Radial field $d\mathbf{r}/\partial_r$. (b) Azimuthal field $d\phi/\partial_\phi$ view of the equatorial plane (z-axis towards eye). (c) Altitudinal field $d\theta/\partial_\theta$ slice along the z-axis

matrix notation (relative to a chart) they correspond to rows. Tensors of type T_0^1 are equivalent to a tangential vector and are called contra-variant, corresponding to columns in matrix notation. The duality relationship between vectors and covectors then corresponds to the matrix multiplication of a $1 \times n$ row with a $n \times 1$ column, yielding a single number

$$\langle a, b \rangle = \langle a^\mu \partial_\mu, b_\mu dx^\mu \rangle \equiv (a^0 a^1 \dots a^n) \begin{pmatrix} b^0 \\ b^1 \\ \dots \\ b^n \end{pmatrix} \quad (8)$$

By virtue of the duality relationship (6), the contraction of lower and upper indices is defined as the *interior product* ι of tensors, which reduces the dimensionality of the tensor:

$$\iota : T_n^m \times T_k^l \rightarrow T_{n-1}^{m-k} : u, v \mapsto \iota_{uv} \quad (9)$$

The interior product can be understood (visually) as a generalization of some “projection” of a tensor onto another one.

Of special importance are symmetric tensors of rank two $g \in T_2^0$ with $g : T(M) \times T(M) \rightarrow \mathbb{R} : u, v \mapsto g(u, v), g(u, v) = g(v, u)$, as they can be used to define a *metric* or *inner product* on the tangential vectors. Its inverse, defined by operating on the covectors, is called the co-metric. A metric, same as the co-metric, is represented as a symmetric $n \times n$ matrix in a chart for an n -dimensional manifold.

Given a metric tensor, one can define equivalence relationships between tangential vectors and covectors, which allow to map one into each other. These maps are called the “musical isomorphisms,” \flat and \sharp , as they raise or lower an index in the coordinate representation:

$$\flat : T(M) \rightarrow T^*(M) : v^\mu \partial_\mu \mapsto v^\mu g_{\mu\nu} dx^\nu \quad (10)$$

$$\sharp : T^*(M) \rightarrow T(M) : V_\mu dx^\mu \mapsto V_\mu g^{\mu\nu} \partial_\nu \quad (11)$$

As an example application, the “gradient” of a scalar function is given by $\nabla f = \sharp df$ using this notation. In Euclidean space, the metric is represented by the identity matrix and the components of vectors are identical to the components of covectors. As computer graphics usually is considered in Euclidean space, this justifies the usual negligence of distinction among vectors and covectors; consequently graphics software only knows about one type of vectors which is uniquely identified by its number of components. However, when dealing with coordinate transformations or curvilinear mesh types, distinguishing between tangential vectors and covectors is unavoidable. Treating them both as the same type within a computer program leads to confusions and is not safe.

Exterior Product

The *exterior product* $\wedge : V \times V \rightarrow \Lambda(V)$ is an algebraic construction generating vector space elements of higher dimensions from elements of a vector space V . The new vector space is denoted $\Lambda(V)$. It is alternating, fulfilling the property $v \wedge u = -u \wedge v \ \forall u, v \in V$ (which results in $v \wedge v = 0 \ \forall v \in V$). The exterior product defines an algebra on its elements, the exterior algebra (or Grassmann algebra). It is a sub-algebra of the tensor algebra consisting of the antisymmetric tensors. The exterior algebra is defined intrinsically by the vector space and does not require a metric. For a given n -dimensional vector space V , there can at most be n th power of an exterior product, consisting of n different basis vectors. The $(n+1)$ th power must vanish, because at least one basis vector would occur twice, and there is exactly one basis vector in $\Lambda^n(V)$.

Elements $v \in \Lambda^k(V)$ are called k -vectors, whereby two-vectors are also called bi-vectors and three-vectors tri-vectors. The number of components of a k -vector of an n -dimensional vector space is given by the binomial coefficient $\{n\}\{k\}$. For $n=2$ there are two one-vectors and one bi-vector, for $n=3$ there are three one-vectors, three bi-vectors, and one tri-vector. These relationships are depicted by the Pascal’s triangle, with the row representing the dimensionality of the underlying base space and the column the vector type:

$$\begin{array}{ccccccc} & & & & 1 & & \\ & & & & 1 & 1 & \\ & & & & 1 & 2 & 1 \\ & & & & 1 & 3 & 3 & 1 \\ & & & & 1 & 4 & 6 & 4 & 1 \end{array} \quad (12)$$

As can be easily read off, for a four-dimensional vector space, there will be four one-vectors, six bi-vectors, four tri-vectors, and one four-vector. The n -vector of

an n -dimensional vector space is also called a *pseudoscalar*, the $(n - 1)$ vector a *pseudo-vector*.

Visualizing Exterior Products

An exterior algebra is defined on both the tangential vectors and covectors on a manifold. A bi-vector v formed from tangential vectors is written in chart as

$$v = v^{\mu\nu} \partial_\mu \wedge \partial_\nu \quad (13)$$

and a bi-covector U formed from covectors is written in chart as

$$U = U_{\mu\nu} dx^\mu \wedge dx^\nu \quad (14)$$

They both have $\{n\}\{2\}$ independent components, due to $v^{\mu\nu} = -v^{\nu\mu}$ and $U_{\mu\nu} = -U_{\nu\mu}$ (three components in 3D, six components in 4D). A bi-tangential vector (13) can be understood visually as an (oriented, i.e., signed) plane that is spun by the two defining tangential vectors, independently of the dimensionality of the underlying base space. A bi-covector (14) corresponds to the subspace of an n -dimensional hyperspace where a plane is “cut out.” In three dimensions these visualizations overlap: both a bi-tangential vector and a covector correspond to a plane, and both a tangential vector and a bi-covector correspond to one-dimensional direction (“arrow”). In four dimensions, these visuals are more distinct but still overlap: a covector corresponds to a three-dimensional volume, but a bi-tangential vector is represented by a plane same as a bi-covector, since cutting out a 2D plane from four-dimensional space yields a 2D plane again. Only in higher dimensions these symbolic representations become unique. However, both a co-vector and a pseudo-vector will always correspond to (i.e., appear as) an $(n - 1)$ -dimensional hyperspace.

$$V_\mu dx^\mu \iff v_{\alpha_0\alpha_1\dots\alpha_{n-1}} \partial_{\alpha_0} \wedge \partial_{\alpha_1} \wedge \dots \wedge \partial_{\alpha_{n-1}} \quad (15)$$

$$v^\mu \partial_\mu \iff V_{\alpha_0\alpha_1\dots\alpha_{n-1}} dx^{\alpha_0} \wedge dx^{\alpha_1} \wedge \dots \wedge dx^{\alpha_{n-1}} \quad (16)$$

A tangential vector – lhs of (16) – can be understood as one specific direction. Equivalently, it can be seen as “cutting off” all but one $(n - 1)$ -dimensional hyperspaces from the full n -dimensional space. This equivalence is expressed via the interior product of a tangential vector v with a pseudo-co-scalar Ω yielding a pseudo-covector V (17). Similarly, the interior product of a pseudo-vector with a pseudo-co-scalar yields a tangential vector (17):

$$\iota_\Omega : T(M) \rightarrow (T^*)^{(n-1)}(M) : V \mapsto \iota_\Omega v \quad (17)$$

$$\iota_\Omega : T^{(n-1)}(M) \rightarrow T^*(M) : V \mapsto \iota_\Omega v \quad (18)$$

Pseudoscalars and pseudo-co-scalars will always be scalar multiples of the basis vectors $\partial_{\alpha 0} \wedge \partial_{\alpha 1} \wedge \dots \wedge \partial_{\alpha n}$ and $dx_0^\alpha \wedge dx_1^\alpha \wedge \dots \wedge dx_n^\alpha$. However, when inverting a coordinate $x^\mu \rightarrow -x^\mu$, they flip sign, whereas a “true” scalar does not. An example known from Euclidean vector algebra is the allegedly scalar value constructed from the dot and cross product of three vectors $V(u, v, w) = u \cdot (v \times w)$ which is the negative of when its arguments are flipped:

$$V(u, v, w) = -V(-u, -v, -w) = -u \cdot (-v \times -w) \quad (19)$$

which is actually more obvious when (19) is written as exterior product:

$$V(u, v, w) = u \wedge v \wedge w = V \partial_0 \wedge \partial_1 \wedge \partial_2 \quad (20)$$

The result (20) actually describes the multiple of a volume element span by the basis tangential vectors ∂_μ – any volume must be a scalar multiple of this basis volume element but can flip sign if another convention on the basis vectors is used. This convention depends on the choice of a right-handed versus left-handed coordinate system and is expressed by the orientation tensor $\Omega = \pm \partial_0 \wedge \partial_1 \wedge \partial_2$. In computer graphics, both left-handed and right-handed coordinate systems occur, which may lead to lots of confusions.

By combining (18) and (11) – requiring a metric – we get a map from pseudo-vectors to vectors and reverse. This map is known as the *Hodge star operator* “*”:

$$*: T^{(n-1)}(M) \rightarrow T(M) : V \mapsto \sharp \iota_\Omega V \quad (21)$$

The same operation can be applied to the covectors accordingly and generalized to all vector elements of the exterior algebra on a vector space, establishing a correspondence between k -vectors and $n-k$ -vectors. The Hodge star operator allows to identify vectors and pseudo-vectors, similar to how a metric allows to identify vectors and covectors. The Hodge star operator requires a metric and an orientation Ω .

A prominent application in physics using the hodge star operator are the Maxwell equations, which, when written based on the four-dimensional potential $A = V_0 dx^0 + A_k dx^k$ (V_0 the electrostatic, A_k the magnetic vector potential), take the form

$$d_* dA = J \quad (22)$$

with J the electric current and magnetic flow, which is zero in vacuum. The combination $d * d$ is equivalent to the Laplace operator “ \square ,” which indicates that (22) describes electromagnetic waves in vacuum.

Geometric Algebra

Geometric Algebra is motivated by the intention to find a closed algebra on a vector space with respect to multiplication, which includes existence of an inverse

operation. There is no concept of dividing vectors in “standard” vector algebra. Neither the inner or outer product has provided vectors of the same dimensionality as their arguments, so they do not provide a closed algebra on the vector space.

Geometric Algebra postulates a product on elements of a vector space $u, v, w \in \mathcal{V}$ that is associative $(uv)w = u(vw)$, left distributive $u(v + w) = uv + uw$, and right distributive $(u + v)w = uw + vw$ and reduces to the inner product as defined by the metric $v^2 = g(v, v)$. It can be shown that the sum of the outer product and the inner product fulfill these requirements; this defines the *geometric product* as the sum of both:

$$uv := u \wedge v + u \cdot v \quad (23)$$

Since $u \wedge v$ and $u \cdot v$ are of different dimensionalities ($\{n\} \{\{2\}\}$ and $\{n\} \{\{0\}\}$, respectively), the result must be in a higher-dimensional vector space of dimensionality $\{n\} \{\{2\}\} + \{n\} \{\{0\}\}$. This space is formed by the linear combination of k -vectors; its elements are called *multivectors*. Its dimensionality is $\sum_{k=0}^{n-1} \binom{n}{k} \equiv 2^n$.

For instance, in two dimensions, the dimension of the space of multivectors is $2^2 = 4$. A multivector V , constructed from tangential vectors on a two-dimensional manifold, is written as

$$V = V^0 + V^1 \partial_0 + V^2 \partial_1 + V^3 \partial_0 \wedge \partial_1 \quad (24)$$

with V^μ the four components of the multivector in a chart. For a three-dimensional manifold, a multivector on its tangential space has $2^3 = 8$ components and is written as

$$\begin{aligned} V = & V^0 + \\ & V^1 \partial_0 + V^2 \partial_1 + V^3 \partial_2 + \\ & V^4 \partial_0 \wedge \partial_1 + V^5 \partial_1 \wedge \partial_2 + V^6 \partial_2 \wedge \partial_0 + \\ & V^7 \partial_0 \wedge \partial_1 \wedge \partial_2 \end{aligned} \quad (25)$$

with V^μ the eight components of the multivector in a chart. The components of a multivector have a direct visual interpretation, which is one of the key features of Geometric Algebra. In 3D, a multivector is the sum of a scalar value, three directions, three planes, and one volume. These basis elements span the entire space of multivectors. Geometric Algebra provides intrinsic graphical insight to the algebraic operations. Its application for computer graphics will be discussed in Sect. 4.

Vector and Fiber Bundles

The concept of a fiber bundle data model is inspired by its mathematical correspondence. In short, a fiber bundle is a topological space that looks locally like a product space $B \times F$ of a base space B and a fiber space F .

The *fibers* of a function $f: X \rightarrow Y$ are the pre-images or inverse images of the points $y \in Y$, i.e., the sets of all elements $x \in X$ with $f(x) = y$:

$$f^{-1}(y) = \{x \in X \mid f(x) = y\}$$

is a fiber of f (at the point y). A fiber can also be the empty set. The union set of all fibers of a function is called the *total space*. The definition of a fiber bundle makes use of a *projection map* pr_1 , which is a function that maps each element of a product space to the element of the first space:

$$\begin{aligned} pr_1 : X \times Y &\rightarrow X \\ (x, y) &\mapsto x \end{aligned}$$

Let E, B be topological spaces and $f: E \rightarrow B$ a continuous map. (E, B, f) is called a *(fiber) bundle* if there exists a space F such that the union of fibers of a neighborhood $U_b \subset B$ of each point $b \in B$ is homeomorphic to $U_b \times F$ such that the projection pr_1 of $U_b \times F$ is U_b again:

$$(E, B, f : E \rightarrow B) \text{ bundle} \iff \exists F : \forall b \in B : \exists U_b : f^{-1}(U_b) \xrightarrow{\text{hom}} U_b \times F \text{ and } pr_1(U_b \times F) = U_b$$

E is called the *total space*, B is called the *base space*, and $f : E \rightarrow B$ the *projection map*. The space F is called the *fiber type* of the bundle or simply the *fiber* of the bundle. In other words, the total space can be written locally as a product space of the base space with some space F . The notation $\mathcal{F}(B) = (E, B, f)$ will be used to denote a fiber bundle over the base space B . It is also said that the *space F fibers over the base space B* .

An important case is the *tangent bundle*, which is the union of all tangent spaces $T_p(M)$ on a manifold M together with the manifold $\mathcal{T}(M) := \{(p, v) : p \in M, v \in T_p(M)\}$. Every differentiable manifold possesses a tangent bundle $\mathcal{T}(M)$. The dimension of $\mathcal{T}(M)$ is twice the dimension of the underlying manifold M , its elements are points plus tangential vectors. $T_p(M)$ is the fiber of the tangent bundle over the point p .

If a fiber bundle over a space B with fiber F can be written as $B \times F$ globally, then it is called a *trivial bundle* $(B \times F, B, pr_1)$. In scientific visualization, usually only trivial bundles occur. A well-known example for a nontrivial fiber bundle is the Möbius strip.

Topology: Discretized Manifolds

For computational purposes, a topological space is modeled by a finite set of points. Such a set of points intrinsically carries a discrete topology by itself, but one usually

considers embeddings in a space that is homeomorphic to Euclidean space to define various structures describing their spatial relationships.

A subset $c \subset X$ of a Hausdorff space X is a *k-cell* if it is homeomorphic to an open k -dimensional ball in \mathbb{R}^n . The dimension of the cell is k . Zero-cells are called vertices, one-cells are edges, two-cells are faces or polygons, and three-cells are polyhedra – see also section “Chains.” An n -cell within an n -dimensional space is just called a “cell.” $(n - 1)$ -cells are sometimes called “facets” and $(n - 2)$ -cells are known as “ridges.” For k -cells of arbitrary dimension, incidence and adjacency relationships are defined as follows: two cells c_1, c_2 are *incident* if $c_1 \subseteq \partial c_2$, where ∂c_2 denotes the border of the cell c_2 . Two cells of the same dimension can never be incident because $\dim(c_1) \neq \dim(c_2)$ for two incident cells c_1, c_2 . c_1 is a *side* of c_2 if $\dim(c_1) < \dim(c_2)$, which may be written as $c_1 < c_2$. The special case $\dim(c_1) = \dim(c_2) - 1$ may be denoted by $c_1 \prec c_2$. Two k -cells c_1, c_2 with $k > 0$ are called *adjacent* if they have a common side, i.e.,

$$\text{cell } c_1, c_2 \quad \text{adjacent} \iff \exists \quad \text{cell } f : f < c_1, f < c_2$$

For $k = 0$, two zero-cells (i.e., vertices) v_1, v_2 are said to be adjacent if there exists a one-cell (edge) e which contains both, i.e., $v_1 < e$ and $v_2 < e$. Incidence relationships form an incidence graph. A path within an incidence graph is a cell tuple: a *cell-tuple* \mathcal{C} within an n -dimensional Hausdorff space is an ordered sequence of k -cells $(c_n, c_{n-1}, \dots, c_1, c_0)$ of decreasing dimensions such that $\forall 0 < i \leq n : c_{i-1} \prec c_i$. These relationships allow to determine topological neighborhoods: adjacent cells are called *neighbors*. The set of all $k + 1$ cells which are incident to a k -cell forms a neighborhood of the k -cell. The cells of a Hausdorff space X constitute a topological base, leading to the following definition: a (“closure-finite, weak-topology”) *CW-complex* \mathcal{C} , also called a *decomposition* of a Hausdorff space X , is a hierarchical system of spaces $X^{(-1)} \subseteq X^{(0)} \subseteq X^{(1)} \subseteq \dots \subseteq X^{(n)}$, constructed by pairwise disjoint open cells $c \subset X$ with the Hausdorff topology $\cup_{c \in \mathcal{C}}^c$, such that $X^{(n)}$ is obtained from $X^{(n-1)}$ by attaching adjacent n -cells to each $(n-1)$ -cell and $X^{(-1)} = \emptyset$. The respective subspaces $X^{(n)}$ are called the n -skeletons of X . A CW complex can be understood as a set of cells which are glued together at their subcells. It generalizes the concept of a graph by adding cells of dimension greater than 1.

Up to now, the definition of a cell was just based on a homeomorphism of the underlying space X and \mathbb{R}^n . Note that a cell does not need to be “straight,” such that, e.g., a two-cell may be constructed from a single vertex and an edge connecting the vertex to itself, as, e.g., illustrated by J. Hart [34]. Alternative approaches toward the definition of cells are more restrictively based on isometry to Euclidean space, defining the notion of “convexity” first. However, it is recommendable to avoid the assumption of Euclidean space and treating the topological properties of a mesh purely based on its combinatorial relationships.

Ontological Scheme and Seven-Level Hierarchy

The concept of the fiber bundle data model builds on the paradigm that numerical data sets occurring for scientific visualization can be formulated as trivial fiber bundles (see section “Vector and Fiber Bundles”). Hence, data sets may be distinguished by their properties in the base space and the fiber space. At each point of the – discretized – base space, there are some data in the fiber space attached. Basically a fiber bundle is a set of points with neighborhood information attached to each of them. An n -dimensional array is a very simple case of a fiber bundle with neighborhood information given implicitly.

The structure of the base space is described as a CW complex, which categorizes the topological structure of an n -dimensional base space by a sequence of k -dimensional skeletons, with $0 < k < n$. These skeletons carry certain properties of the data set: the zero-skeleton describes vertices, the one-skeleton refers to edges, two-skeleton to the faces, etc., of some mesh (a triangulation of the base space). Structured grids are triangulations with implicitly given topological properties. For instance, a regular n -dimensional grid is one where each point has 2^n neighbors.

The structure of the fiber space is (usually) not discrete and given by the properties of the geometrical object residing there, such as a scalar, vector, covector, and tensor. Same as the base space, the fiber space has a specific dimensionality, though the dimensionality of the base space and fiber space is independent. Figure 3 demonstrates example images from scientific visualization classified via their fiber bundle structure. If the fiber space has vector space properties, then the fiber bundle is a vector bundle and vector operations can be performed on the fiber space, such as addition, multiplication, and derivation.

The distinction between base space and fiber space is not common use in computer graphics, where topological properties (base space) are frequently intermixed with geometrical properties (coordinate representations). Operations in the fiber space can, however, be formulated independently from the base space, which leads to a more reusable design of software components. Coordinate information, formally part of the base space, can as well be considered as fiber, leading to further generalization. The data sets describing a fiber are ideally stored as contiguous arrays in memory or disk, which allows for optimized array and vector operations. Such a storage layout turns out to be particularly useful for communicating data with the GPU using vertex buffer objects: the base space is given by vertex arrays (e.g., OpenGL `glVertexPointer`), and fibers are attribute arrays (e.g., OpenGL `glVertexAttribPointer`), in the notation of computer graphics. While the process of hardware rendering in its early times had been based on procedural descriptions (cached in display lists), vertex buffer objects are much faster in state-of-the-art technology. Efficient rendering routines are thus implemented as *maps* from fiber bundles in RAM to fiber bundles in GPU memory (eventually equipped with a GPU shader program).

A complex data structure (such as some color-coded time-dependent geometry) will be built from many data arrays. The main question that needs to be answered by

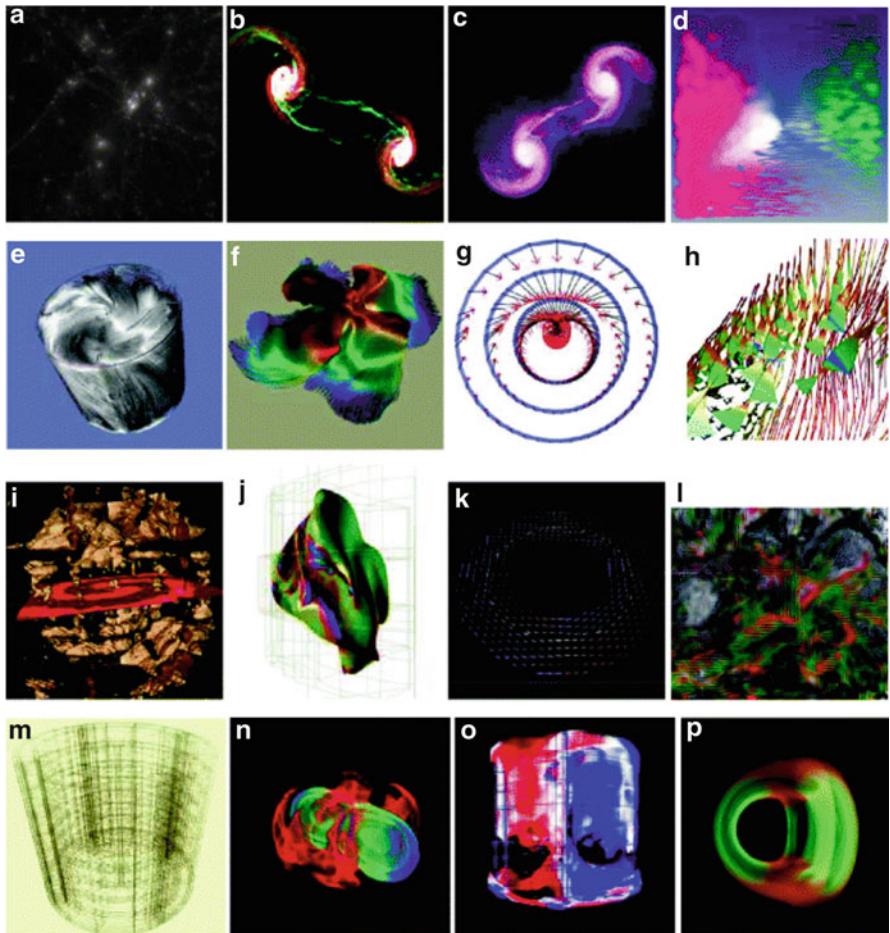

Fig. 3 Fiber bundle classification scheme for visualization methods: dimensionality of the base space (involving the k -skeleton of the discretized manifold) and dimensionality of the fiber space (involving the number of field quantities per element, zero referring to display of the mere topological structure). **(a)** Zero-cells, 0D. **(b)** Zero-cells, 1D. **(c)** Zero-cells, 3D. **(d)** Zero-cells, 6D. **(e)** One-cells, 0D. **(f)** One-cells, 1D. **(g)** One-cells, 3D. **(h)** One-cells, 6D. **(i)** Two-cells, 0D. **(j)** Two-cells, 1D. **(k)** Two-cells, 3D. **(l)** Two-cells, 6D. **(m)** Three-cells, 0D. **(n)** Three-cells, 1D. **(o)** Three-cells, 3D. **(p)** Three-cells, 6D

a data model is how to assign a semantic meaning to each of these data arrays – what do the numerical values actually *mean*? It is always possible to introduce a set of keywords with semantics attached to them. In addition, the introduction of keywords also reduces the number of possible identifiers available for user-specific purpose. This problem is also known as “name space pollution”. The approach followed in the data model presented in [7] is to avoid use of keywords as much as possible. Instead, it assigns the semantics of an element of the data structure into the placement of

this element. The objective is to describe all data types that occur in an algorithm (including file reader and rendering routines) within this model. It is formulated as a graph of up to seven levels (two of them optional). Each level represents a certain property of the entire data set, the *Bundle*. These levels are called:

1. *Slice*
2. *Grid*
3. *Skeleton*
4. *Representation*
5. *Field*
6. (Fragment)
7. (Compound Elements)

Actual data arrays are stored only below the “*Field*” level. Given one hierarchy level, the next one is accessed via some identifier. The type of this identifier differs for each level: numerical values within a *Skeleton* level are grouped into *Representation* objects, which hold all information that is *relative* to a certain “representer.” Such a representer may be a coordinate object that, for instance, refers to some Cartesian or polar chart, or it may well be another *Skeleton* object, either within the same *Grid* object or even within another one. An actual data set is described through the existence of entries in each level. Only two of these hierarchy levels are exposed to the end user; these are the *Grid* and *Field* levels. Their corresponding textual identifiers are arbitrary names specified by the user.

| Hierarchy object | Identifier type | Identifier semantic |
|-----------------------|------------------------|------------------------|
| <i>Bundle</i> | Floating point number | Time value |
| <i>Slice</i> | String | Grid name |
| <i>Grid</i> | Integer set | Topological properties |
| <i>Skeleton</i> | Reference | Relationship map |
| <i>Representation</i> | String | Field name |
| <i>Field</i> | Multidimensional index | Array index |

A *Grid* is subset of data within the Bundle that refers to a specific geometrical entity. A *Grid* might be a mesh carrying data such as a triangular surface, a data cube, a set of data blocks from a parallel computation, or many other data types. A *Field* is the collection of data sets given as numbers on a specific topological component of a Grid, for instance, floating point values describing pressure or temperature on a Grid’s vertices. All other levels of the data model describe the properties of the Bundle as construction blocks. The usage of these construction blocks constitutes a certain language to describe data sets. A *Slice* is identified by a single floating point number representing time (generalization to arbitrary-dimensional parameter spaces is possible). A *Skeleton* is identified by its dimensionality, index depth (relationship to the vertices of a Grid), and refinement

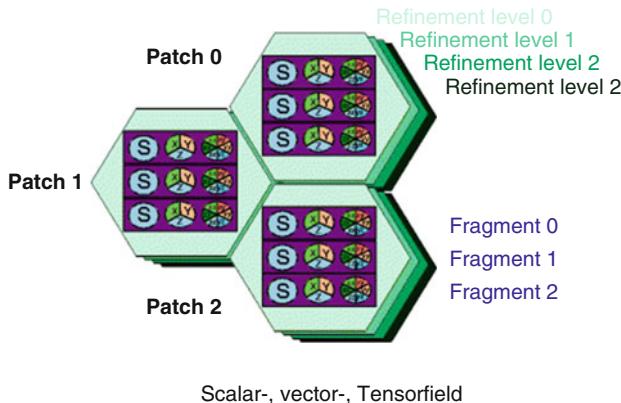

Fig. 4 Hierarchical structure of the data layout of the concept of a *field* in computer memory: (1) organization by multiple resolutions for same spatial domain; (2) multiple coordinate systems covering different spatial domains (arbitrary overlap possible); (3) fragmentation of fields into blocks (recombination from parallel data sources); and (4) layout of compound fields as components for performance reasons, indicated as *S* (scalar field), {*x*, *y*, *z*} for vector fields, and {*xx*, *xy*, *yy*, *yz*, *zz*, *zx*} for tensor fields

level. This will be explained in more detail in section “Topological Skeletons.” The scheme also extends to cases beyond the purely mathematical basis to also cover data sets that occur in praxis, which is described in section “Non-topological representations.” A representation is identified via some reference object, which may be some coordinate system or another *Skeleton*. The lowest levels of fragments and compounds describe the internal memory layout of a *Field* data set and are optional; some examples are described in [8,9].

Field Properties

A specific *Field* identifier may occur in multiple locations. All these locations together define the properties of a field. The following four properties are expressible in the data model:

1. *Hierarchical ordering*: For a certain point in space, there exist multiple data values, one for each *refinement* level. This property describes the topological structure of the base space.
2. *Multiple coordinate systems*: One spatial point may have multiple data representations relating to different coordinate systems. This property describes the geometrical structure of the base space.
3. *Fragmentation*: Data may stem from multiple sources, such as a distributed multiprocess simulation. The field then consists of multiple data blocks, each of them covering a subdomain of the field’s base space. Such field fragments may also overlap, known as “ghost zones.”
4. *Separated Compounds*: A compound data type, such as a vector or tensor, may be stored in different data layouts since applications have their own preferences. An

array of tensors may also be stored as a tensor of arrays, e.g., $XYZXYZXYZXYZ$ as $XXXXYYYYZZZZ$. This property describes the internal structure of the fiber space.

All of these properties are optional. In the most simple case, a field is just represented by an array of native data types; however, in the most general case (which the visualization algorithm must always support), the data are distributed over several such property elements and built from many arrays. With respect to quick transfer to the GPU, only the ability to handle multiple arrays per data set is of relevance.

Figure 4 illustrates the organization of the last four levels of the data model. These consist of Skeleton and Representation objects with optional fragmentation and compound levels. The ordering of these levels is done merely based on their semantic importance, with the uppermost level (1) embracing multiple resolutions of the spatial domain being the most visible one to the end user. Each of these resolution levels may come with different topological properties, but all arrays within the same resolution are required to be topologically compatible (i.e., share the same number of points). There might still be multiple coordinate representations required for each resolution, which constitutes the second hierarchy level (2) of multiple coordinate patches. Data per patch may well be distributed over various fragments (3), which is considered an internal structure of each patch, due to parallelization or numerical issues, but not fundamental to the physical setup. Last but not least, fields of multiple components such as vector or tensor fields may be separated into distinct arrays themselves [7]. This property, merely a performance issue of in-memory data representation, is not what the end user usually does not want to be bothered with and is thus set as the lowest level in among these four entries.

Topological Skeletons

The *Skeleton* level of the fiber bundle hierarchy describes a certain topological property. This can be the vertices, the cells, the edges, etc. Its primary purpose is to describe the skeletons of a CW complex, but they may also be used to specify mesh refinement levels and agglomerations of certain elements. All data fields that are stored within a *Skeleton* level provide the same number of elements. In other words they share their index space (a data space in HDF5 terminology). Each *Topology* object within a *Grid* object is uniquely identified via a set of integers, which are the *dimension* (e.g., the dimension of a k -cell), *index depth* (how many dereferences are required to access coordinate information in the underlying manifold), and *refinement level* (a multidimensional index, in general). Vertices – index depth 0 – of a topological space of dimension n define a Skeleton of type $(n, 0)$. Edges are one-dimensional sets of vertex indices; therefore, their index depth is 1 and their Skeleton type is $(1, 1)$. Faces are two-dimensional sets of vertex indices, hence Skeleton type $(2, 1)$. Cells – such as a tetrahedron or hexahedra – are described by a Skeleton type $(3, 1)$.

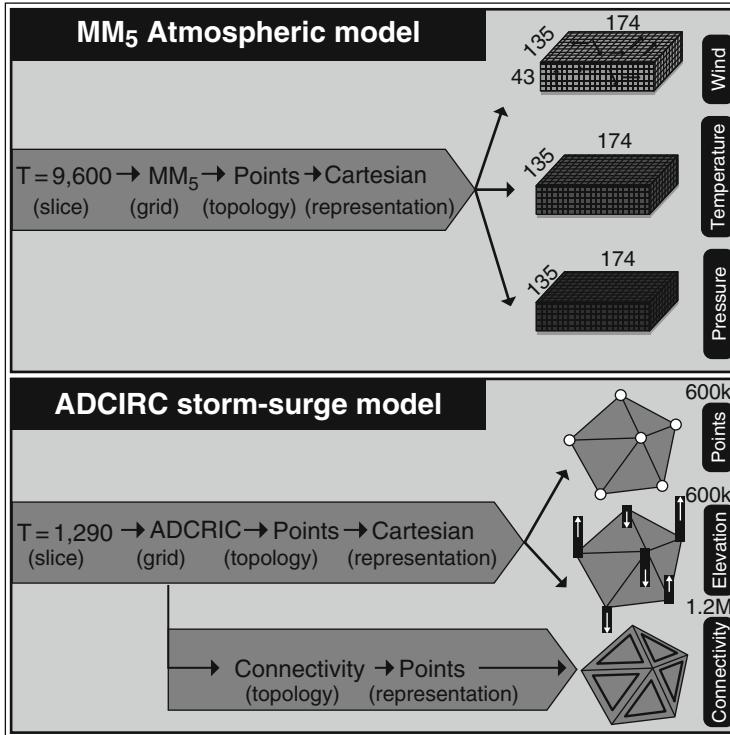

Fig. 5 The five-level organization scheme used for atmospheric data (MM5 model data) and surge data (ADCIRC simulation model), built upon common topological property descriptions with additional fields (From Venkataraman et al. [81])

All the Skeleton objects of index depth 1 build the k -skeletons of a manifold's triangulation.

Higher index depths describe sets of k -cells. For instance, a set of edges describes a line – a path along vertices in a Grid. Such a collection of edges will fit into a Skeleton of dimension 1 and depth 2, i.e., type (1, 2). It is a one-dimensional object of indices that refer to edges that refer to vertices.

Non-topological Representations

Polynomial coordinates, information on field fragments, histograms, and color maps can be formulated in the fiber bundle model as well. These quantities are no longer direct correspondences of the mathematical background, but they may still be cast into the given context.

Coordinates may be given procedurally, such as via some polynomial expression. The data for such expressions may be stored in a Skeleton of *negative* index depth – as these data are required to compute the vertex coordinates and more fundamental than these in this case.

A *fragment* of a Field given on vertices – the $(n, 0)$ -Skeleton of a Grid – defines an n -dimensional subset of the Grid, defined by the hull of the vertices corresponding to the fragments. These may be expressed as a $(n, 2)$ -Skeleton, where the Field object named “Positions” (represented relative to the vertices) refers to the (global) vertex indices of the respective fragments. The representation in coordinates corresponds to its range, known as the *bounding box*. Similarly, a field given on the vertices will correspond to the field’s numerical *minimum/maximum range* within this fragment.

A *histogram* is the representation of a field’s vertex complex in a “chart” describing the required discretization, depending on the min/max range and a number count. A *color map* (transfer function) can be interpreted as a chart object itself. It has no intrinsically geometrical meaning, but provides means to transform some data. For instance, some scalar value will be transformed to some RGB triple using some color map. A scalar field represented in a certain color map is therefore of type RGB values and could be stored as an array of RGB values for each vertex. In practice, this will not be done since such transformation is performed in real time by modern graphics hardware. However, this interpretation of a color map as a chart object tells how color maps may be stored in the fiber bundle data model.

3 Differential Forms and Topology

This section not only introduces the concepts of differential forms and their discrete counterparts but also illustrates that similar concepts are applied in several separate areas of scientific visualization. Since the available resources are discrete and finite, concepts mirroring these characteristics have to be applied to visualize complex data sets. The most distinguished algebraic structure is described by exterior algebra (or Grassmann algebra, see also section “Exterior Product”), which comes with two operations, the exterior product (or wedge product) and the exterior derivative.

Differential Forms

Manifolds can be seen as a precursor to model physical quantities of space. Charts on a manifold provide coordinates, which allows using concepts which are already well established. Furthermore, they are crucial for the field of visualization, as they are key components to obtain depictable expressions of abstract entities. Tangential vectors were already introduced in section “Tangential Vectors” as derivatives along a curve. Then a one-form α is defined as a linear mapping which assigns a value to each tangential vector v from the tangent space $T_p(M)$, i.e., $\alpha : T_p(M) \rightarrow \mathbb{R}$. They are commonly called co-varient vectors, covectors (see section “Tangential Vectors”), or Pfaff-forms. The set of one-forms generates the dual vector space or cotangential space $T_p^*(M)$. It is important to highlight that the tangent vectors $v \in T_p(M)$ are not contained in the manifold itself, so the differential forms also generate an additional space over $P \in M$. In the following, these one-forms are generalized to (alternating) differential forms.

An alternative point of view treats a tangential vector v as a linear mapping which assigns a scalar to each one-form α by $\langle \alpha, v \rangle \in \mathbb{R}$. By omitting one of the arguments of the obtained mappings, $\langle \alpha, . \rangle$ or $\alpha(v)$ and $\langle ., v \rangle$ or $v(\alpha)$, linear objects are defined. Multi-linear mappings depending on multiple vectors or covectors appear as an extension of this concept and are commonly called tensors

$$\gamma : T^{*m} \times T^n \rightarrow \mathbb{R} \quad (26)$$

where n and m are natural numbers and T^n and T^{*m} represent the n and m powered Cartesian product of the tangential space or the dual vector space (cotangential space). A tensor γ is called an (n, m) -tensor which assigns a scalar value to a set of m covectors and n vectors. All tensors of a fixed type (n, m) generate a tensor space attached at the point $P \in M$. The union of all tensor spaces at the points $P \in M$ is called a *tensor bundle*. The tangential and cotangential bundles are specialized cases for $(1, 0)$ and $(0, 1)$ tensor bundles, respectively. Fully antisymmetric tensors of type $(0, m)$ may be identified with *differential forms of degree m* . For $m > \dim(M)$, where $\dim(M)$ represents the dimension of the manifold, differential forms vanish.

The *exterior derivative* or Cartan derivative of differential forms generates a $p + 1$ -form df from a p -form f and conforms to the following requirements:

1. Compatibility with the wedge product (product rule): $d(\alpha \wedge \beta) = d\alpha \wedge \beta + (-1)^m \alpha \wedge d\beta$
2. Nilpotency of the operation d , $d \circ d = 0$, depicted in Fig. 11
3. Linearity

A subset of one-forms is obtained as a differential df of zero-forms (functions) f at P and are called *exact differential forms*. For an n -dimensional manifold M , a one-form can be depicted by drawing $(n - 1)$ -dimensional surfaces, e.g., for the three-dimensional space, Fig. 6 depicts a possible graphical representation of a one-form attached to M . This depiction also enables a graphical representation on how to integrate differential forms, where only the number of surfaces which are intersected by the integration domain has to be counted:

$$\langle df, v \rangle = df(v) = \alpha(v) \quad (27)$$

A consequence of being exact includes the closeness property $d\alpha = 0$. Furthermore, the integral $\int_{C_p} df$ with C_p representing an integration domain, e.g., an interval x_1 and x_2 , results in the same value $f(x_2) - f(x_1)$. In the general case, a p -form is not always the exterior derivative of a p -one-form; therefore, the integration of p -forms is not independent of the integration domain. An example is given by the exterior derivative of a p -form β resulting in a $p + 1$ -form $\gamma = d\beta$. The structure of such a generated differential form can be depicted by a tube-like structure such as in Fig. 7. While the wedge product of an r -form and an s -form results in an $r + s$ -form, this resulting form is not necessarily representable as a derivative. Figure 7 depicts a two-form which is not constructed by the exterior

Fig. 6 Possible graphical representation of the topological structure of one-forms in three dimensions. Note that the graphical display of differential forms varies in different dimension and does not depend on the selected basis elements

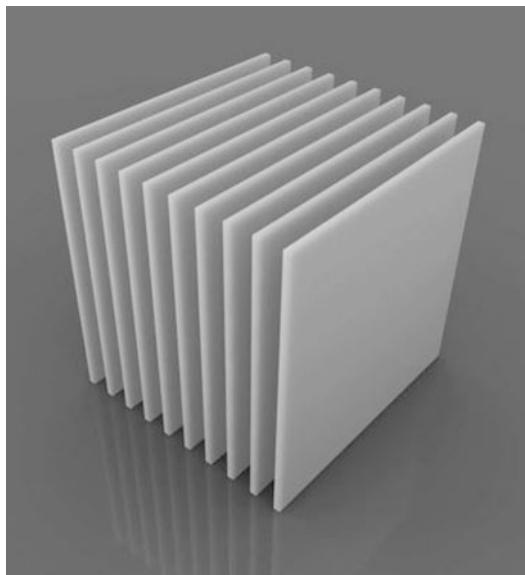

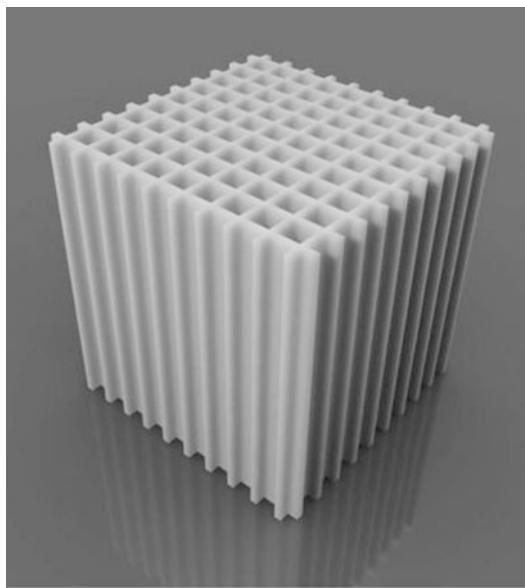

Fig. 7 Possible graphical representation of a general two-form generated by $\alpha \wedge \beta$, where α and β are one-forms. The topologically tube-like structure of the two-forms is enclosed by the depicted planes

derivative but instead by $\alpha \wedge \beta$, where α and β are one-forms. In the general case, a p -form attached on an n -dimensional manifold M is represented by using $(n - p)$ -dimensional surfaces.

By sequentially applying the operation d to $(0, m)$ for $0 \leq m \leq \dim(M)$, the *de Rham complex* is obtained, which enables the investigation of the relation of closed and exact forms. The de Rham complex enables the transition from

the continuous differential forms to the discrete counterpart, so-called cochains. The already briefly mentioned topic of integration of differential forms is now mapped onto the integration of these cochains. To complete the description, the notion of chains, also modeled by multivectors (as used in Geometric Algebra, see section “Geometric Algebra” and Sect. 4) or fully antisymmetric $(n, 0)$ -tensors, as description of integration domains is presented, where a chain is a collection of n -cells.

The connection between chains and cochains is investigated in algebraic topology under the name of homology theory, where chains and cochains are collected in additive Abelian groups $C_p(M)$.

Chains

The de Rham complex collects cochains similar to a cell complex aggregating cells as elements of chains. To use these elements, e.g., all edges, in a computational manner, a mapping of the n -cells onto an algebraic structure is needed. An algebraic representation of the assembly of cells, an n -chain, over a cell complex \mathcal{K} and a vector space \mathcal{V} can be written by

$$c_n = \sum_{i=1}^j w_i \tau_n^i \quad \tau_n^i \in \mathcal{K}, w_i \in \mathcal{V}$$

which is closed under reversal of the orientation:

$$\forall \tau_n^i \in c_n \quad \text{there is } -\tau_n^i \in c_n$$

The different topological elements are called cells, and the dimensionality is expressed by adding the dimension such as a three-cell for a volume, a two-cell for surface elements, a one-cell for lines, and a zero-cell for vertices. If the coefficients are restricted to $\{-1, 0, 1\} \in \mathbb{Z}$, the following classification for elements of a cell complex is obtained:

- 0: if the cell is not in the complex
- 1: if the unchanged cell is in the complex
- -1 : if the orientation is changed

The so-called boundary operator is a map between sets of chains C_p on a cell complex K . Let us denote the i th p -cell as $\tau_p^i = k_0, \dots, k_p$, whereby $\tau_p^i \in K$. The boundary operator ∂_p defines a $(p - 1)$ -chain computed from a p -chain: $\partial_p : C_p(K) \dashrightarrow C_{p-1}(K)$. The boundary of a cell τ_p^j can be written as alternating sum over elements of dimension $p - 1$:

$$\partial_p \tau_p^i = \sum_i (-1)^i [k_0, k_1, \dots, \tilde{k}_i, \dots, k_p] \quad (28)$$

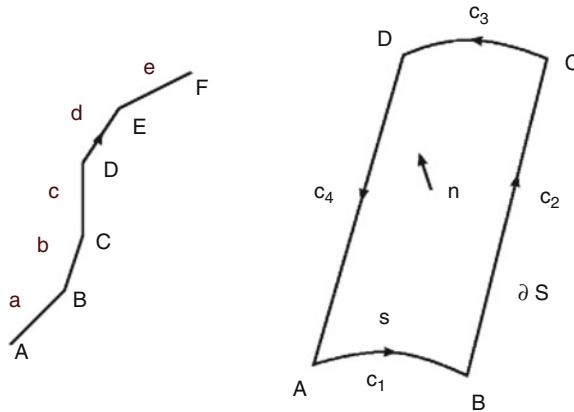

Fig. 8 Representation of a one-chain τ_1^i with zero-chain boundary τ_0^j (left) and a two-chain τ_2 with one-chain boundary τ_1^k (right)

where \tilde{k}_i indicates that k_i is deleted from the sequence. This map is compatible with the additive and the external multiplicative structure of chains and builds a linear transformation:

$$C_p \rightarrow C_{p-1} \quad (29)$$

Therefore, the boundary operator is linear

$$\partial \left(\sum_i w_i \tau_p^i \right) = \sum_i w_i (\partial \tau_p^i) \quad (30)$$

which means that the boundary operator can be applied separately to each cell of a chain. Using the boundary operator on a sequence of chains of different dimensions results in a chain complex $C_* = \{C_p, \partial_p\}$ such that the complex property

$$\partial_{p-1} \partial_p = 0 \quad (31)$$

is given. Homological concepts are visible here for the first time, as homology examines the connectivity between two immediately neighboring dimensions. Figure 8 depicts two examples of one-chains and two-chains and an example of the boundary operator.

Applying the appropriate boundary operator to the two-chain example reads

$$\begin{aligned} \partial_2 \tau_2 &= \tau_1^1 + \tau_1^2 + \tau_1^3 + \tau_1^4 \\ \partial_1(\tau_1^1 + \tau_1^2 + \tau_1^3 + \tau_1^4) &= \tau_0^1 + \tau_0^2 - \tau_0^2 + \tau_0^3 - \tau_0^3 + \tau_0^4 - \tau_0^4 - \tau_0^1 = 0 \end{aligned} \quad (33)$$

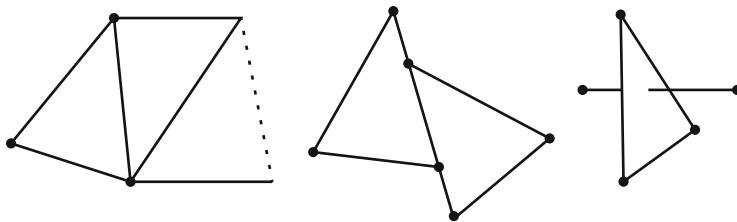

Fig. 9 Examples of violations of correct cell attachment. *Left*: missing zero-cell. *Middle*: cells do not intersect at vertices. *Right*: intersection of cells

A different view on chain complexes presents itself when the main focus is placed on the cells within a chain. To cover even the most abstract cases, a cell is defined as a subset $c \subset X$ of a Hausdorff space X if it is homeomorphic to the interior of the open n -dimensional ball $\mathbb{D}^n = \{x \in \mathbb{R}^n : |x| < 1\}$. The number n is unique due to the *invariance of domain* theorem [13] and is called the dimension of c , whereas homeomorphic means that two or more spaces share the same topological characteristics. The following list assigns terms corresponding to other areas of scientific computing:

- 0-cell: point
- 1-cell: edge
- 2-cell: facet
- n -cell: cell

A cell complex \mathcal{K} (see also section “Topology: Discretized Manifolds”) can be described by a set of cells that satisfy the following properties:

- The boundary of each p -cell τ_p^i is a finite union of $(p-1)$ -cells in \mathcal{K} : $\partial_p \tau_p^i = \cup^m \tau_{p-1}^m$.
- The intersection of any two cells τ_p^i, τ_p^j in \mathcal{K} is either empty or is a unique cell in \mathcal{K} .

The result of these operations are subspaces $X^{(n)}$ which are called the n -skeletons of the cell complex. Incidence and adjacence relations are then available. Examples for incidence can be given by vertex on edge relation and for adjacency by vertex to vertex relations. This cell complex with the underlying topological space guarantees that all interdimensional objects are connected in an appropriate manner. Although there are various possible attachments of cells, only one process results in a cell complex, see Fig. 9.

Cochains

In addition to chain and cell complices, scientific visualization requires the notation and access mechanisms to global quantities related to macroscopic n -dimensional

space-time domains. The differential forms which are necessary concepts to handle physical properties can also be projected onto discrete counterparts, which are called *cochains*. This collection of possible quantities, which can be measured, can then be called a section of a fiber bundle, which permits the modeling of these measurements as a function that can be integrated on arbitrary n -dimensional (sub)domains or multivectors. This function can then be seen as the abstracted process of measurement of this quantity [55, 75]. The concept of cochains allows the association of numbers not only to single cells, as chains do, but also to assemblies of cells. Briefly, the necessary requirements are that this mapping is not only orientation dependent but also linear with respect to the assembly of cells. A cochain representation is now the global quantity association with subdomains of a cell complex, which can be arbitrarily built to discretize a domain.

A linear transformation σ of the n -chains into the field \mathbb{R} of real numbers forms a vector space $c_n \rightarrow \wedge\{\sigma\}\mathbb{R}$ and is called a vector-valued m -dimensional cochain or short m -cochain. The coboundary δ of an m -cochain is an $(m + 1)$ -cochain defined as

$$\delta c^m = \sum_i v_i \tau_i, \quad \text{where} \quad v_i = \sum_{b \in \text{faces}(\tau_i)} \sigma(b, \tau_i) c_m(b) \quad (34)$$

Thus, the coboundary operator assigns nonzero coefficients only to those $(m + 1)$ cells that have c_m as a face. As can be seen, δc_m depends not only on c_m but on how c_m lies in the complex \mathcal{K} . This is a fundamental difference between the two operators ∂ and δ . An example is given in Fig. 10 where the coboundary operator is used on a one-cell. The right part $\delta \circ \delta \mathcal{K}$ of Fig. 10 is also depicted for the continuous differential forms in Fig. 7. The coboundary of an m -cochain is an $(m + 1)$ -cochain which assigns to each $(m + 1)$ cell the sum of the values that the $m + 1$ -cochain assign to the m -cells which form the boundary of the $(m + 1)$ cell. Each quantity appears in the sum multiplied by the corresponding incidence number. Cochain complices [33, 35] are similar to chain complices except that the arrows are reversed, so a cochain complex $C^* = \{C^m, \delta^m\}$ is a sequence of modules C^m and homomorphisms:

$$\delta^m : C^m \rightarrow C^{m+1} \quad (35)$$

such that

$$\delta^{m+1} \delta^m = 0 \quad (36)$$

$\mathcal{K}^1 \xrightarrow{\delta} \delta \mathcal{K}^1 \xrightarrow{\delta} \delta \circ \delta \mathcal{K}^1 = 0$. Proceeding from left to right, a one-cochain represented by a line segment, a two-cochain generated by the product of two one-forms, and a three-cochain depicted by volume objects are illustrated.

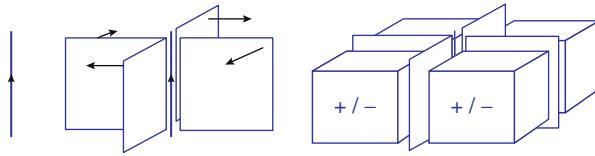

Fig. 10 Cochain complex with the corresponding coboundary operator

Then, the following sequence with $\delta \circ \delta = 0$ is generated:

$$0 - \xrightarrow{\delta} C^0 - \xrightarrow{\delta} C^1 - \xrightarrow{\delta} C^2 - \xrightarrow{\delta} C^3 - \xrightarrow{\delta} 0 \quad (37)$$

Cochains are the algebraic equivalent of alternating differential forms, while the coboundary process is the algebraic equivalent of the external derivative and can therefore be considered as the discrete counterpart of the differential operators:

- grad.
- curl.
- div.

It indeed satisfies the property $\delta \circ \delta \equiv 0$ corresponding to

- curlgrad. $\equiv 0$
- divcurl. $\equiv 0$

Duality Between Chains and Cochains

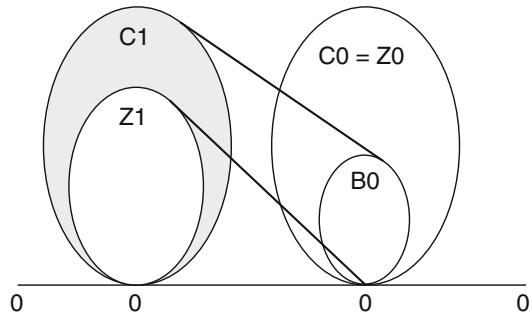

Furthermore, a definition of the adjoint nature of $\partial, \delta : C^p \rightarrow C^{p+1}$ can be given:

$$\langle c^p, \partial c_{p+1} \rangle = \langle \delta c^p, c_{p+1} \rangle \quad (38)$$

The concepts of chains and cochains coincide on finite complices [45]. Geometrically, however, C_p and C^p are distinct [12] despite an isomorphism. An element of C_p is a formal sum of p -cells, whereas an element of C^p is a linear function that maps elements of C_p into a field. Chains are dimensionless multiplicities of aggregated cells, whereas those associated with cochains may be interpreted as physical quantities [65]. The extension of cochains from single cell weights to quantities associated with assemblies of cells is not trivial and makes cochains very different from chains, even on finite cell complices. Nevertheless, there is an important duality between p -chains and p -cochains. The first part of the de Rham (cohomology group) complex, depicted in Fig. 11 on the left, is the set of closed one-forms modulo the set of exact one-forms denoted by

$$H^1 = Z^1 / B^1 \quad (39)$$

Fig. 11 A graphical representation of closed and exact forms. The forms Z_1 , B_1 , Z_0 , and B_0 are closed forms, while only the forms B_0 and B_1 are exact forms. The nilpotency of the operation d forces the exact forms to vanish

This group is therefore trivial (only the zero element) if all closed one-forms are exact. If the corresponding space is multiply connected, then there are closed one-chains that are not themselves boundaries, and there are closed one-forms that are not themselves exact.

For a chain $c_p \in C_p(\mathcal{K}, \mathbb{R})$ and a cochain $c^p \in C^p(\mathcal{K}, \mathbb{R})$, the integral of c^p over c_p is denoted by $\int_{c_p} c^p$, and integration can be regarded as a mapping, where D represents the corresponding dimension:

$$\int : C_p(\mathcal{K}) \times C^p(\mathcal{K}) \rightarrow \mathbb{R}, \quad \text{for } 0 \leq p \leq D \quad (40)$$

Integration in the context of cochains is a linear operation: given $a_1, a_2 \in \mathbb{R}$, $c^{p,1}, c^{p,2} \in C^p(\mathcal{K})$ and $c_p \in C_p(\mathcal{K})$, reads

$$\int_{c_p} a_1 c^{p,1} + a_2 c^{p,2} = a_1 \int_{c_p} c^{p,1} + a_2 \int_{c_p} c^{p,2} \quad (41)$$

Reversing the orientation of a chain means that integrals over that chain acquire the opposite sign

$$\int_{-c_p} c^p = - \int_{c_p} c^p \quad (42)$$

using the set of p -chains with vector space properties $C_p(\mathcal{K}, \mathbb{R})$, e.g., linear combinations of p -chains with coefficients in the field \mathbb{R} . For coefficients in \mathbb{R} , the operation of integration can be regarded as a bilinear pairing between p -chains and p -cochains. Furthermore, for reasonable p -chains and p -cochains, this bilinear pairing for integration is nondegenerate,

$$\text{if } \int_{c_p} c^p = 0 \quad \forall c_p \in C_p(\mathcal{K}), \quad \text{then } c^p = 0 \quad (43)$$

and

$$\text{if } \int_{c_p} c^p = 0 \quad \forall c^p \in C^p(\mathcal{K}), \quad \text{then } c_p = 0 \quad (44)$$

The integration domain can be described by, using Geometric Algebra notation, the exterior product applied to multivectors. An example is then given by the generalized Stokes theorem:

$$\int_{c_p} df = \int_{\partial c_p} f \quad (45)$$

or

$$\langle df, c_p \rangle = \langle f, \partial c_p \rangle \quad (46)$$

The generalized Stokes theorem combines two important concepts, the integration domain and the form to be integrated.

Homology and Cohomology

The concepts of chains can also be used to characterize properties of spaces, the homology and cohomology, where it is only necessary to use $C_p(\mathcal{K}, \mathbb{Z})$. The algebraic structure of chains is an important concept, e.g., to detect a p -dimensional hole that is not the boundary of a $p+1$ -chain, which is called a p -cycle. For short, a cycle is a chain whose boundary is $\partial_p c_p = 0$, a closed chain. The introduced boundary operator can also be related to homological terms. A boundary is a chain b_p for which there is a chain c_p such that $\partial_p c_p = b_p$. Since $\partial \circ \partial = 0$, $B_n \subset Z_n$ is obtained. The homology is then defined by $H_n = Z_n / B_n$. The homology of a space is a sequence of vector spaces. The topological classification of homology is defined by

$$\begin{aligned} B_p &= \text{im } \partial_{p+1} && \text{and} \\ Z_p &= \ker \partial_p \end{aligned}$$

so that $B_p \subset Z_p$ and

$$H_p = Z_p / B_p$$

where $\beta_p = \{\text{Rank}\} H_p$. Here $\{\text{im}\}$ is the image and $\{\ker\}$ is the kernel of the mapping. For cohomology

$$\begin{aligned} B^p &= \text{im } d^{p+1} && \text{and} \\ Z^p &= \ker d^p \end{aligned}$$

Fig. 12 Topologically a torus is the product of two circles. The partially shaded circle is spun around the fully drawn circle which can be interpreted as the closure of a cylinder onto itself

so that $B^p \subset Z^p$ and

$$H^p = Z^p / B^p$$

where $\beta^p = \{\text{Rank}\} H^p$. An important property of these vector spaces is given by β , which corresponds to the dimension of the vector spaces H and is called the Betti number [35, 86]. Betti numbers identify the number of nonhomologous cycles which are not boundaries:

- β_0 counts the number of connected components.
- β_1 counts the number of tunnels (topological holes).
- β_2 counts the number of enclosed cavities.

The number of connected components gives the number of distinct entities of a given object, whereas tunnels describe the number of separated parts of space. In contrast to a tunnel, the enclosed cavities are completely bounded by the object.

Examples for the Betti numbers of various geometrical objects are stated by:

- Cylinder: $\beta_0 = 1, \beta_1 = 1, \beta_n = 0 \forall n \geq 2$. The cylinder consists of one connected component, which forms a single separation of space. Therefore no enclosed cavity is present.
- Sphere: $\beta_0 = 1, \beta_1 = 0, \beta_2 = 1, \beta_n = 0 \forall n \geq 3$. If β_1 and β_2 are switched, a sphere is obtained by contracting the separation by generating an enclosed cavity from the tunnel.
- Torus: $\beta_0 = 1, \beta_1 = 2, \beta_2 = 1, \beta_n = 0 \forall n \geq 3$. Closing a cylinder onto itself results in a torus which not only generates an enclosed cavity but also maintains the cylinder's tunnel. An additional tunnel is introduced due to the closing procedure which is depicted in Fig. 12 as the central hole.

The Euler characteristics, which is an invariant, can be derived from the Betti numbers by: $\xi = \beta_0 - \beta_1 + \beta_2$.

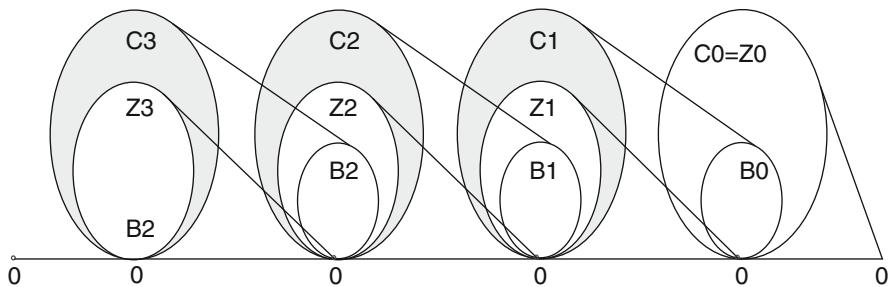

Fig. 13 A graphical representation of (co)homology for a three-dimensional cell complex

Fig. 14 Illustration of cycles
 A, B, C and a boundary C .
 A, B are not boundaries

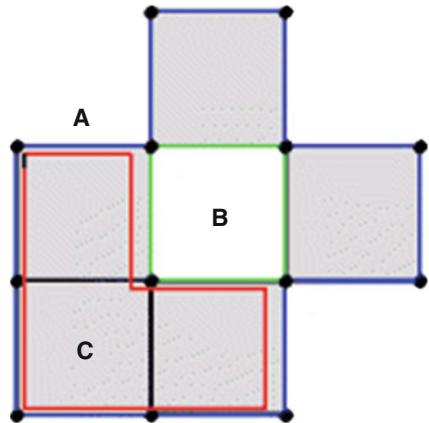

Figure 13 depicts the homology of a three-dimensional chain complex with the respective images and kernels, where the chain complex of \mathcal{K} is defined by $\{\text{im}\} \partial_{p+1} \subseteq \{\text{ker}\} \partial_p$. As can be seen, the boundary operator expression yields $\partial_p \circ \partial_{p+1} = 0$.

To give an example, the first homology group is the set of closed one-chains (curves) modulo the closed one-chains which are also boundaries. This group is denoted by $H_1 = Z_1/B_1$, where Z_1 are cycles or closed one-chains and B_1 are one-boundaries. Another example is given in Fig. 14, where A, B, C are cycles and a boundary C , but A, B are not boundaries.

Topology

Conceptual consistency in scientific visualization is provided by topology. Cell complices convey topology in a computationally treatable manner and can therefore be introduced by much simpler definitions. A topological space (X, \mathcal{T}) is the collection of sets \mathcal{T} that include:

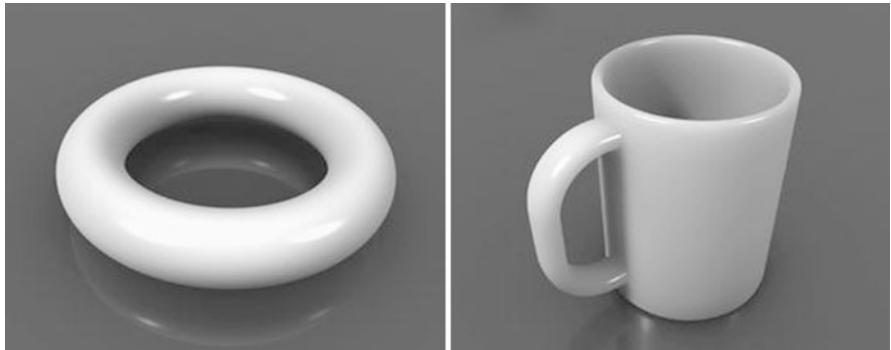

Fig. 15 Topologically a torus and a coffee mug are equivalent and so have the same Betti numbers

- The space itself X and the empty set \emptyset
- The union of any of these sets
- The finite intersection of any of the sets

The family \mathcal{T} is called a *topology* on X , and the members of \mathcal{T} are called *open sets*. As an example a basic set $X = \{a, b, c\}$ and a topology is given:

$$(X, \mathcal{T}) = \{ \quad \emptyset, \\ \{a\}, \{b\}, \{c\}, \\ \{a, b\}, \{a, c\}, \{b, c\}, \\ \{a, b, c\} \}$$

The general definition for a topological space is very abstract and allows several topological spaces which are not useful in scientific visualization, e.g., a topological space (X, \mathcal{T}) with a trivial topology $\mathcal{T} = \{\emptyset, X\}$. So basic mechanisms of separation within a topological space are required, e.g., the Hausdorff property. A topological space (X, \mathcal{T}) is said to be Hausdorff if, given $x, y \in X$ with $x \neq y$, there exist open sets U_1, U_2 such that $x \in U_1, y \in U_2$ and $U_1 \cap U_2 = \emptyset$. But the question remains on what “topology” actually is. A brief explanation is given by the study of properties of an object that do not change under *deformation*. To describe this deformation process, abstract rules can be stated and if they are true, then an object A can be transformed into an object B without change. The two objects A, B are then called homeomorphic:

- All points of $A \leftrightarrow$ all points of B
- 1 – 1 correspondence (no overlap)
- Bicontinuous (continuous both ways)
- Cannot tear, join, poke/seal holes

The deformation is $1 - 1$ if each point of A maps to a single point on B and there is no overlap. If this deformation is continuous, A cannot be torned, joined, disrupted, or sealed up. If two objects are homeomorphic, then they are topologically equivalent. Figure 15 illustrates an example of a torus and coffee mug which are a prominent example for topological equivalence. The torus can be continuously deformed, without tearing, joining, disrupting, or sealing up, into a cup. The hole in the torus becomes the handle of the cup. But why should anybody in visualization be concerned about how objects can be deformed? Topology is much more than the illustrated properties, it can be much better described by the study of connectedness:

- Understanding of space properties: how connectivity happens.
- Analysis of space properties: how connectivity can be determined.
- Articulation of space properties: how connectivity can be described.
- Control about space properties: how connectivity can be enforced.

Topology studies properties of sets that do not change under well-behaved transformations (homeomorphisms). These properties include completeness and compactness. In visualization, one property is of significance: connectedness. Especially, how many disjoint components can be distinguished and how many holes (or tunnels) are in these components. Geometric configuration is another interesting aspect in visualization because it is important to know which of these components have how many holes, and where the holes are relative to each other. Several operations in scientific visualization can be summarized:

- Simplification: reduction of data complexity. If objects are described with fewer properties, important properties such as components or holes should be retained or removed, if these properties become insignificant, unnecessary, or imperceptible.
- Compression: reduction of data storage. It is important that each operation does not alter important features (interaction of geometrical and topological features).
- Texturing: visualization context elements. How can a texture kept consistent if an object, e.g., a torus, is transformed into another object, e.g., a coffee cup.
- Morphing: transforming one object into another. If an object is morphed into another, topological features have to remain, e.g., the torus hole has to become the coffee cup handle hole.

4 Geometric Algebra Computing

Geometric Algebra as a general mathematical system unites many mathematical concepts such as vector algebra, quaternions, Plücker coordinates, and projective geometry, and it easily deals with geometric objects, operations, and transformations. A lot of applications in computer graphics, computer vision, and other engineering areas can benefit from these properties. In a ray-tracing application, for

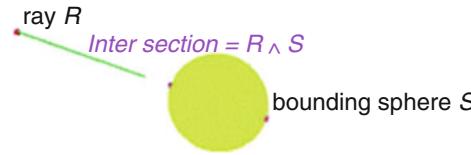

Fig. 16 Spheres and lines are basic entities of Geometric Algebra to compute with. Operations like the intersection of them are easily expressed with the help of their outer product. The result of the intersection of a ray and a (bounding) sphere is another geometric entity, the point pair of the two points of the line intersecting the sphere. The sign of the square of the point pair easily indicates whether there is a real intersection or not

instance, the intersection of a ray and a bounding sphere is needed. According to Fig. 16, this can be easily expressed with the help of the outer product of these two geometric entities.

Geometric Algebra is based on the work of Hermann Grassmann (see the conference [62] celebrating his 200th birthday in 2009) and William Clifford [20, 21]. Pioneering work has been done by David Hestenes, who first applied Geometric Algebra to problems in mechanics and physics [39, 40].

The first time Geometric Algebra was introduced to a wider computer graphics audience was through a couple of courses at the SIGGRAPH conferences in 2000 and 2001 (see [57]) and later at the Eurographics [41]. Researchers at the University of Cambridge, UK, have applied Geometric Algebra to a number of graphics-related projects. Geometrics [71] is a start-up company in Cambridge specializing in simulation software for physics and lighting, which presented its new technology allowing real-time radiosity in videogames utilizing commodity graphics-processing hardware. The technology is based on Geometric Algebra wavelet technology. Researchers at the University of Amsterdam, the Netherlands, are applying their fundamental research on Geometric Algebra to 3D computer vision and to ray tracing and on the efficient software implementation of Geometric Algebra. Researchers from Guadalajara, Mexico, are primarily dealing with the application of Geometric Algebra in the field of computer vision, robot vision, and kinematics. They are using Geometric Algebra, for instance, for tasks like visual-guided grasping, camera self-localization, and reconstruction of shape and motion. Their methods for geometric neural computing are used for tasks like pattern recognition [5]. Registration, the task of finding correspondences between two point sets, is solved based on Geometric Algebra methods in [65]. Some of their kinematics algorithms are dealing with inverse kinematics, fixation, and grasping as well as with kinematics and differential kinematics of binocular robot heads. At the University of Kiel, Germany, researchers are applying Geometric Algebra to robot vision and pose estimation [66]. They also do some interesting research dealing, for instance, with neural networks based on Geometric Algebra [14]. In addition to these examples, there are many other applications like Geometric Algebra Fourier transforms for the visualization and analysis of vector fields [24] or classification and clustering of spatial patterns with Geometric Algebra [63] showing the wide area

Table 1 Multiplication table of the 2D Geometric Algebra. This algebra consists of basic algebraic objects of grade (dimension) 0, the scalar; of grade 1, the two basis vectors e_1 and e_2 ; and of grade 2, the bi-vector $e_1 \wedge e_2$, which can be identified with the imaginary number i squaring to -1

| | 1 | e_1 | e_2 | $e_1 \wedge e_2$ |
|------------------|------------------|-------------------|------------------|------------------|
| 1 | 1 | e_1 | e_2 | $e_1 \wedge e_2$ |
| e_1 | e_1 | 1 | $e_1 \wedge e_2$ | e_2 |
| e_2 | e_2 | $-e_1 \wedge e_2$ | 1 | $-e_1$ |
| $e_1 \wedge e_2$ | $e_1 \wedge e_2$ | $-e_2$ | e_1 | -1 |

Table 2 List of the basic geometric primitives provided by the 5D conformal Geometric Algebra. The bold characters represent 3D entities (\mathbf{x} is a 3D point, \mathbf{n} is a 3D normal vector, and \mathbf{x}^2 is the scalar product of the 3D vector \mathbf{x}). The two additional basis vectors e_0 and e_∞ represent the origin and infinity. Based on the outer product, *circles* and *lines* can be described as intersections of two spheres, respectively two planes. The parameter r represents the radius of the sphere and the parameter d the distance of the plane to the origin

| Entity | Representation |
|--------|---|
| Point | $P = \mathbf{x} + \frac{1}{2}\mathbf{x}^2 e_\infty + e_0$ |
| Sphere | $S = P - \frac{1}{2}r^2 e_\infty$ |
| Plane | $\pi = \mathbf{n} + d e_\infty$ |
| Circle | $Z = S_1 \wedge S_2$ |
| Line | $L = \pi_1 \wedge \pi_2$ |

of possibilities of advantageously using this mathematical system in engineering applications.

Benefits of Geometric Algebra

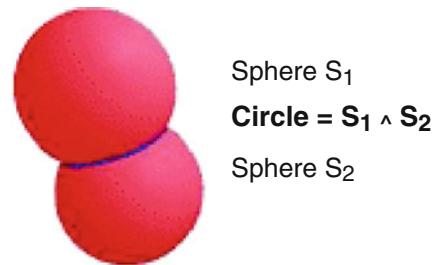

As follows, we highlight some of the properties of Geometric Algebra that make it advantageous for a lot of engineering applications.

Unification of Mathematical Systems

In the wide range of engineering applications, many different mathematical systems are currently used. One notable advantage of Geometric Algebra is that it subsumes mathematical systems like vector algebra, complex analysis, quaternions, or Plücker coordinates. Table 1, for instance, describes how complex numbers can be identified within the 2D Geometric Algebra. This algebra does not only contain the two basis vectors e_1 and e_2 but also basis elements of grade (dimension) 0 and 2 representing the scalar and imaginary part of complex numbers.

Other examples are Plücker coordinates based on the description of lines in conformal geometric algebra (see section “Conformal Geometric Algebra”) or quaternions as to be identified in Fig. 19 with their imaginary units.

Fig. 17 Spheres and circles are basic entities of Geometric Algebra. Operations like the intersection of two spheres are easily expressed

Uniform Handling of Different Geometric Primitives

Conformal Geometric Algebra, the Geometric Algebra of conformal space we focus on, is able to easily treat different geometric objects. Table 2 presents the representation of points, lines, circles, spheres, and planes as the same entities algebraically. Consider the spheres of Fig. 17, for instance. These spheres are simply represented by

$$S = P - \frac{1}{2}r^2 e_\infty \quad (47)$$

based on their center point P , their radius r , and the basis vector e_∞ which represents the point at infinity. The circle of intersection of the spheres is then easily computed using the outer product to operate on the spheres as simply as if they were vectors:

$$Z = S_1 \wedge S_2 \quad (48)$$

This way of computing with Geometric Algebra clearly benefits computer graphics applications.

Simplified Geometric Operations

Geometric operations like rotations, translations (see [41]), and reflections can be easily treated within the algebra. There is no need to change the way of describing them with other approaches (vector algebra, for instance, additionally needs matrices in order to describe transformations).

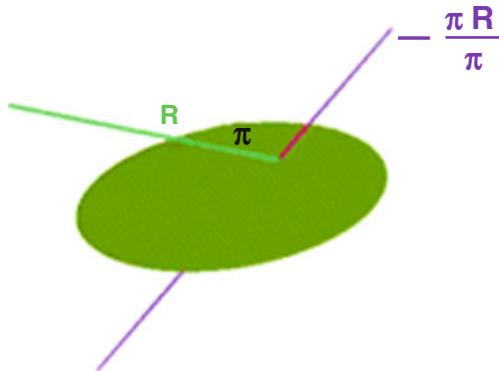

Figure 18 visualizes the reflection of the ray R from one plane

$$\pi = \mathbf{n} + d e_\infty \quad (49)$$

(see Table 2). The reflected line, drawn in magenta,

$$\mathbf{R}_{\text{reflected}} = -\frac{\pi \mathbf{R}}{\pi} \quad (50)$$

Fig. 18 The ray R is reflected from the plane π computing $-\frac{\pi R}{\pi}$

is computed with the help of the reflection operation including the reflection object as well as the object to be reflected.

More Efficient Implementations

Geometric Algebra as a mathematical language suggests a clearer structure and greater elegance in understanding methods and formulae. But, what about the runtime performance for derived algorithms? Geometric Algebra inherently has a large potential for creating optimizations leading to more highly efficient implementations especially for parallel platforms. Gaalop [44], as presented in section “Computational Efficiency of Geometric Algebra Using Gaalop,” is an approach offering dramatically improved optimizations.

Conformal Geometric Algebra

Conformal Geometric Algebra is a 5D Geometric Algebra based on the 3D basis vectors e_1 , e_2 , and e_3 as well as on the two additional base vectors e_0 representing the origin and e_∞ representing infinity.

Blades are the basic computational elements and the basic geometric entities of geometric algebras. The 5D conformal Geometric Algebra consists of blades with *grades* (dimension) 0, 1, 2, 3, 4, and 5, whereby a scalar is a *0-blade* (blade of grade 0). The element of grade five is called the pseudoscalar. A linear combination of blades is called a *k-vector*. So a bi-vector is a linear combination of blades with grade 2. Other *k*-vectors are vectors (grade 1), tri-vectors (grade 3), and quadvectors (grade 4). Furthermore, a linear combination of blades of different grades is called a *multivector*. Multivectors are the general elements of a Geometric Algebra. Table 3 lists all the 32 blades of conformal Geometric Algebra. The indices indicate 1, scalar; 2–6, vector; 7–16, bi-vector; 17–26, tri-vector; 27–31, quadvector; and 32, pseudoscalar.

A point $P = x_1 e_1 + x_2 e_2 + x_3 e_3 + \frac{1}{2} \mathbf{x}^2 e_\infty + e_0$ (see Table 2), for instance, can be written in terms of a multivector as the following linear combination of blades $b[i]$:

Table 3 The 32 blades of the 5D conformal Geometric Algebra

| Index | Blade | Grade |
|-------|--|-------|
| 1 | 1 | 0 |
| 2 | e_1 | 1 |
| 3 | e_2 | 1 |
| 4 | e_3 | 1 |
| 5 | e_∞ | 1 |
| 6 | e_0 | 1 |
| 7 | $e_1 \wedge e_2$ | 2 |
| 8 | $e_1 \wedge e_3$ | 2 |
| 9 | $e_1 \wedge e_\infty$ | 2 |
| 10 | $e_1 \wedge e_0$ | 2 |
| 11 | $e_2 \wedge e_3$ | 2 |
| 12 | $e_2 \wedge e_\infty$ | 2 |
| 13 | $e_2 \wedge e_0$ | 2 |
| 14 | $e_3 \wedge e_\infty$ | 2 |
| 15 | $e_3 \wedge e_0$ | 2 |
| 16 | $e_\infty \wedge e_0$ | 2 |
| 17 | $e_1 \wedge e_2 \wedge e_3$ | 3 |
| 18 | $e_1 \wedge e_2 \wedge e_\infty$ | 3 |
| 19 | $e_1 \wedge e_2 \wedge e_0$ | 3 |
| 20 | $e_1 \wedge e_3 \wedge e_\infty$ | 3 |
| 21 | $e_1 \wedge e_3 \wedge e_0$ | 3 |
| 22 | $e_1 \wedge e_\infty \wedge e_0$ | 3 |
| 23 | $e_2 \wedge e_3 \wedge e_\infty$ | 3 |
| 24 | $e_2 \wedge e_3 \wedge e_0$ | 3 |
| 25 | $e_2 \wedge e_\infty \wedge e_0$ | 3 |
| 26 | $e_3 \wedge e_\infty \wedge e_0$ | 3 |
| 27 | $e_1 \wedge e_2 \wedge e_3 \wedge e_\infty$ | 4 |
| 28 | $e_1 \wedge e_2 \wedge e_3 \wedge e_0$ | 4 |
| 29 | $e_1 \wedge e_2 \wedge e_\infty \wedge e_0$ | 4 |
| 30 | $e_1 \wedge e_3 \wedge e_\infty \wedge e_0$ | 4 |
| 31 | $e_2 \wedge e_3 \wedge e_\infty \wedge e_0$ | 4 |
| 32 | $e_1 \wedge e_2 \wedge e_3 \wedge e_\infty \wedge e_0$ | 5 |

$$P = x_{1*}b[2] + x_{2*}b[3] + x_{3*}b[4] + \frac{1}{2}\mathbf{x}_*^2b[5] + b[6] \quad (51)$$

with multivector indices according to Table 3.

Figure 19 describes some interpretations of the 32 basis blades of conformal Geometric Algebra. Scalars like the number π are grade 0 entities. They can be combined with the blade representing the imaginary unit i to complex numbers or with the blades representing the imaginary units i, j, k to quaternions. Since quaternions describe rotations, this kind of transformation can be handled within the

| Grade | Term | Blades | nr. |
|-------|--------------|--|-----|
| 0 | Scalar | 1 | 1 |
| 1 | Vector | $\theta_1, \theta_2, \theta_3, \theta_0, \theta_\infty$ | 5 |
| 2 | Bivector | $\theta_1 \wedge \theta_2, \theta_1 \wedge \theta_3, \theta_2 \wedge \theta_3$ $\theta_1 \wedge \theta_0, \theta_2 \wedge \theta_0, \theta_3 \wedge \theta_0$ $\theta_0 \wedge \theta_\infty$ | 10 |
| 3 | Trivector | ... | 10 |
| 4 | Quadvector | $\theta_1 \wedge \theta_2 \wedge \theta_3 \wedge \theta_\infty$ $\theta_1 \wedge \theta_2 \wedge \theta_3 \wedge \theta_0$ $\theta_1 \wedge \theta_2 \wedge \theta_0 \wedge \theta_\infty$ $\theta_1 \wedge \theta_3 \wedge \theta_0 \wedge \theta_\infty$ $\theta_2 \wedge \theta_3 \wedge \theta_0 \wedge \theta_\infty$ | 5 |
| 5 | Pseudoscalar | $\theta_1 \wedge \theta_2 \wedge \theta_3 \wedge \theta_0 \wedge \theta_\infty$ | 1 |

Fig. 19 The blades of conformal Geometric Algebra. *Spheres* and *planes*, for instance, are vectors. *Lines* and *circles* can be represented as bi-vectors. Other mathematical systems like complex numbers or quaternions can be identified based on their imaginary units i, j, k . This is why also transformations like rotations can be handled within the algebra

Table 4 The extended list of the two representations of the conformal geometric entities. The IPNS representations as described in Table 1 have also an OPNS representation, which are dual to each other (indicated by the star symbol). In the OPNS representation, the geometric objects are described with the help of the outer product of conformal points that are part of the objects, for instance, lines as the outer product of two points and the point at infinity

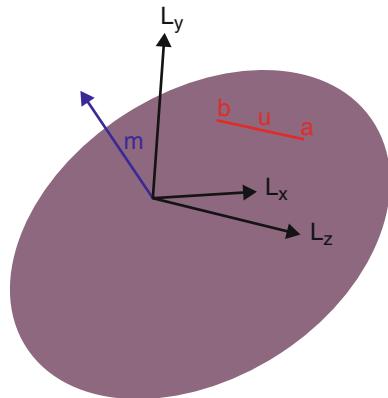

| Entity | IPNS representation | OPNS representation |
|------------|---|---|
| Point | $P = \mathbf{x} + \frac{1}{2}\mathbf{x}^2 e_\infty + e_0$ | |
| Sphere | $S = P - \frac{1}{2}r^2 e_\infty$ | $S^* = P_1 \wedge P_2 \wedge P_3 \wedge P_4$ |
| Plane | $\pi = \mathbf{n} + d e_\infty$ | $\pi^* = P_1 \wedge P_2 \wedge P_3 \wedge e_\infty$ |
| Circle | $Z = S_1 \wedge S_2$ | $Z^* = P_1 \wedge P_2 \wedge P_3$ |
| Line | $L = \pi_1 \wedge \pi_2$ | $L^* = P_1 \wedge P_2 \wedge e_\infty$ |
| Point pair | $Pp = S_1 \wedge S_2 \wedge S_3$ | $Pp^* = P_1 \wedge P_2$ |

algebra. Geometric objects like spheres, planes, circles, and lines can be represented as vectors and bi-vectors.

Table 4 lists the two representations of the conformal geometric entities. The inner product null space (IPNS) and the outer product null space (OPNS) [61] are dual to each other. While Table 2 already presented the IPNS representation of spheres and planes, they can be described also with the outer product of four points being part of them. In the case of a plane one of these four points is the point at infinity e_∞ . Circles can be described with the help of the outer product of three conformal points lying on the circle or as the intersection of two spheres.

Lines can be described with the help of the outer product of two points and the point at infinity e_∞ or with the help of the outer product of two planes (i.e., intersection in IPNS representation). An alternative expression is

Fig. 20 The line L through the 3D points \mathbf{a} , \mathbf{b} and the visualization of its 6D Plücker parameters based on the two 3D vectors \mathbf{u} and \mathbf{m} of Eq. (53)

$$L = \mathbf{u}e_{123} + \mathbf{m} \wedge e_{\infty} \quad (52)$$

with the 3D pseudoscalar $e_{123} = e_1 \wedge e_2 \wedge e_{\infty}$, the two 3D points \mathbf{a} , \mathbf{b} on the line, $\mathbf{u} = \mathbf{b} - \mathbf{a}$ as 3D direction vector, and $\mathbf{m} = \mathbf{a} \times \mathbf{b}$ as the 3D moment vector (relative to origin). The corresponding six Plücker coordinates (components of \mathbf{u} and \mathbf{m}) are (see Fig. 20)

$$(\mathbf{u} : \mathbf{m}) = (u_1 : u_2 : u_3 : m_1 : m_2 : m_3) \quad (53)$$

Computational Efficiency of Geometric Algebra Using Gaalop

Because of its generality, Geometric Algebra needs some optimizations for efficient implementations.

Gaigen [27] is a Geometric Algebra code generator developed at the University of Amsterdam (see [23, 26]). The philosophy behind Gaigen 2 is based on two ideas: generative programming and specializing for the structure of Geometric Algebra. Please find some benchmarks comparing Gaigen 2 with other pure software solutions as well as comparing five models of 3D Euclidean geometry for a ray-tracing application in [26, 28].

Gaalop [44] combines the advantages of software optimizations and the adaptability on different parallel platforms. As an example, an inverse kinematics algorithm of a computer animation application was investigated [42]. With the optimization approach of Gaalop, the software implementation became three times faster and with a hardware implementation about 300 times faster [43] (three times by software optimization and 100 times by additional hardware optimization) than the conventional software implementation. Figure 21 shows an overview over the architecture of Gaalop. Its input is a Geometric Algebra algorithm written in CLUCalc [60], a system for the visual development of Geometric Algebra

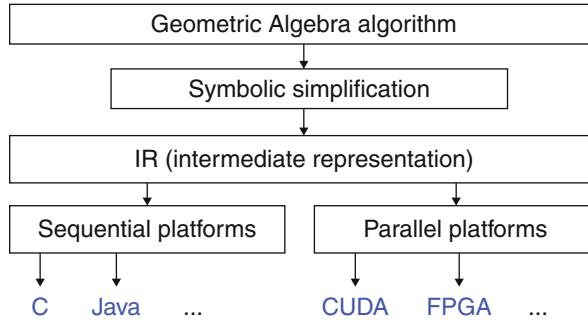

Fig. 21 Architecture of Gaalop

algorithms. Via symbolic simplification it is transformed into an intermediate representation (IR) that can be used for the generation of different output formats. Gaalop supports sequential platforms with the automatic generation of C and JAVA code while its main focus is on supporting parallel platforms like reconfigurable hardware as well as modern accelerating GPUs.

Gaalop uses the symbolic computation functionality of Maple (using the Open Maple interface and a library for Geometric Algebras [1]) in order to optimize a Geometric Algebra algorithm. It computes the coefficients of the desired multivector symbolically, returning an efficient implementation depending just on the input variables.

As an example, the following CLUCalc code computes the intersection circle C of two spheres $S1$ and $S2$ according to Fig. 17:

```

P1 = x1*e1 + x2*e2 + x3*e3 + 1/2*(x1*x1+x2*x2+x3*x3)*einf
      + e0; P2 = y1*e1 +
y2*e2 +y3*e3 + 1/2*(y1*y1+y2*y2+y3*y3)*einf + e0;
S1 =P1 - 1/2 * r1*r1 *
einf; S2 = P2 - 1/2 * r2*r2 * einf; ?C = S1 \$\wedge\$ S2;
  
```

See Table 2 for the computation of the conformal points $P1$ and $P2$, the spheres $S1$ and $S2$, as well as the resulting circle based on the outer product of the two spheres.

The resulting C code generated by Gaalop for the intersection circle C is as follows and depends only on the variables $x1$, $x2$, $x3$, $y1$, $y2$, $y3$, $r1$, and $r2$ for the 3D center points and radii:

```

float C [32] = {\{ }0.0{\}}; C[7] = x1*y2-x2*y1;
C[8] = x1*y3-x3*y1; C[9]
= -0.5*y1*x1-0.5*y1*x2*x2 -0.5*y1*x3*x3+0.5*y1*r1*r1 +
0.5*x1*y1*y1+0.5*x1*y2*y2 + 0.5*x1*y3*y3 - 0.5*x1*r2*r2;
C[10] = -y1 +
x1; C[11] = -x3*y2+x2*y3; C[12] = -0.5*y2*x1*x1-0.5*y2*x2*x2-
0.5*y2*x3*x3 + 0.5*y2*r1*r1 + 0.5*x2*y1*y1 + 0.5*x2*y2*y2 +
0.5*x2*y3*y3 -

In a nutshell, Gaalop always computes optimized 32-dimensional multivectors. Since a circle is described with the help of a bi-vector, only the blades 7–16 (see Table 3) are used. As you can see, all the corresponding coefficients of this multivector are very simple expressions with basic arithmetic operations.

5 Feature-Based Vector Field Visualization

We will identify derived quantities that describe flow features such as vortices (section “Derived Measures of Vector Fields”) and we discuss the topology of vector fields (section “Topology of Vector Fields”). However, not all feature-based visualization approaches can be covered here. The reader is referred to [84] for further information on this topic. We start with a description of integral curves in vector fields, which are the basis for most feature-based visualization approaches.

Characteristic Curves of Vector Fields

A curve $q : \mathbb{R} \rightarrow M$ (see section “Tangential Vectors”) is called a *tangent curve* of a vector field $\mathbf{v}(\mathbf{x})$, if for all points $\mathbf{x} \in q$ the tangent vector \dot{q} of q coincides with $\mathbf{v}(\mathbf{x})$. Tangent curves are the solutions of the autonomous ODE system

$$\frac{d}{d\tau} \mathbf{x}(\tau) = \mathbf{v}(\mathbf{x}(\tau)) \quad \text{with } \mathbf{x}(0) = \mathbf{x}_0 \quad (54)$$

For all points $\mathbf{x} \in M$ with $\mathbf{v}(\mathbf{x}) \neq \mathbf{0}$, there is one and only one tangent curve through it. Tangent curves do not intersect or join each other. Hence, tangent curves uniquely describe the directional information and are therefore an important tool for visualizing vector fields.

The tangent curves of a parameter-independent vector field $\mathbf{v}(\mathbf{x})$ are called *streamlines*. A streamline describes the path of a massless particle in \mathbf{v} .

In a one-parameter-dependent vector field $\mathbf{v}(\mathbf{x}, t)$, there are four types of characteristic curves: streamlines, path lines, streak lines, and time lines. To ease the explanation, we consider $\mathbf{v}(\mathbf{x}, t)$ as a time-dependent vector field in the following: in a space-time point (\mathbf{x}_0, t_0) we can start a *streamline* (staying in time slice $t = t_0$) by integrating

$$\frac{d}{d\tau} \mathbf{x}(\tau) = \mathbf{v}(\mathbf{x}(\tau), t_0) \quad \text{with } \mathbf{x}(0) = \mathbf{x}_0 \quad (55)$$

or a *path line* by integrating

$$\frac{d}{dt} \mathbf{x}(t) = \mathbf{v}(\mathbf{x}(t), t) \quad \text{with } \mathbf{x}(t_0) = \mathbf{x}_0 \quad (56)$$

Path lines describe the trajectories of massless particles in time-dependent vector fields. The ODE system (56) can be rewritten as an autonomous system at the expense of an increase in dimension by one, if time is included as an explicit state variable:

$$\frac{d}{dt} \begin{pmatrix} \mathbf{x} \\ t \end{pmatrix} = \begin{pmatrix} \mathbf{v}(\mathbf{x}(t), t) \\ 1 \end{pmatrix} \quad \text{with } \begin{pmatrix} \mathbf{x} \\ t \end{pmatrix}(0) = \begin{pmatrix} \mathbf{x}_0 \\ t_0 \end{pmatrix} \quad (57)$$

In this formulation space and time are dealt with on equal footing – facilitating the analysis of spatiotemporal features. Path lines of the original vector field \mathbf{v} in ordinary space now appear as tangent curves of the vector field

$$\mathbf{p}(\mathbf{x}, t) = \begin{pmatrix} \mathbf{v}(\mathbf{x}, t) \\ 1 \end{pmatrix} \quad (58)$$

in space-time. To treat streamlines of \mathbf{v} , one may simply use

$$\mathbf{s}(\mathbf{x}, t) = \begin{pmatrix} \mathbf{v}(\mathbf{x}, t) \\ 0 \end{pmatrix} \quad (59)$$

Figure 22 illustrates \mathbf{s} and \mathbf{p} for a simple example vector field \mathbf{v} . It is obtained by a linear interpolation over time of two bilinear vector fields. Figure 22a depicts streamlines, Fig. 22b depicts pathlines.

A *streak line* is the connection of all particles set out at different times but the same point location. In an experiment, one can observe these structures by constantly releasing dye into the flow from a fixed position. The resulting streak line consists of all particles which have been at this fixed position sometime in the past. Considering the vector field \mathbf{p} introduced above, streak lines can be obtained in the following way: apply a stream surface integration in \mathbf{p} where the seeding curve is a straight line segment parallel to the t -axis; a streak line is the intersection of this stream surface with a hyperplane perpendicular to the t -axis (Fig. 22c).

A *time line* is the connection of all particles set out at the same time but different locations, i.e., a line which gets advected by the flow. An analogon in the real world is a yarn or wire thrown into a river, which gets transported and deformed by the flow. However, in contrast to the yarn, a time line can get shorter and longer. It can be obtained by applying a stream surface integration in \mathbf{p} starting at a line with $t = \{\text{const.}\}$ and intersecting it with a hyperplane perpendicular to the t -axis (Fig. 22d).

Streak lines and time lines cannot be described as tangent curves in the spatiotemporal domain. Both types of lines fail to have a property of stream and path lines: they are not locally unique, i.e., for a particular location and time there

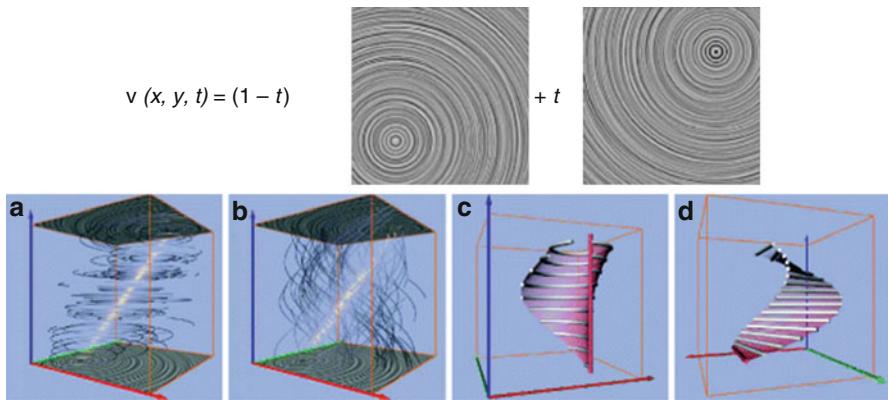

Fig. 22 Characteristic curves of a simple 2D time-dependent vector field. Streamlines and path lines are shown as illuminated field lines. Streak and time lines are shown as thick cylindrical lines, while their seeding curves and resulting stream surfaces are colored red. The red/green coordinate axes denote the (x, y) -domain; the blue axis shows time

is more than one streak and time line passing through. However, stream, path, and streak lines coincide for steady vector fields $\mathbf{v}(\mathbf{x}, t) = \mathbf{v}(\mathbf{x}, t_0)$ and are described by (54) in this setting. Time lines do not fit into this.

Derived Measures of Vector Fields

A number of measures can be derived from a vector field \mathbf{v} and its derivatives. These measures indicate certain properties or features and can be helpful when visualizing flows. The following text assumes the underlying manifold M where the vector field is given to be Euclidean space, i.e., the manifold is three-dimensional and Cartesian coordinates are used where the metric (see section “Tensors”) is representable as the unit matrix.

The *magnitude* of \mathbf{v} is then given as

$$|\mathbf{v}| = \sqrt{u^2 + v^2 + w^2} \quad (60)$$

The *divergence* of a flow field is given as

$$\text{div}(\mathbf{v}) = \nabla \cdot \mathbf{v} = \text{trace}(\mathbf{J}) = u_x + v_y + w_z \quad (61)$$

and denotes the gain or loss of mass density at a certain point of the vector field: given a volume element in a flow, a certain amount of mass is entering and exiting it. Divergence is the net flux of this at the limit of a point. A flow field with $\{\text{div}\}(\mathbf{v}) = 0$ is called *divergence-free*, which is a common case in fluid dynamics since a number of fluids are *incompressible*.

The *vorticity* or *curl* of a flow field is given as

$$\omega = \begin{pmatrix} \omega_1 \\ \omega_2 \\ \omega_3 \end{pmatrix} = \nabla \times \mathbf{v} = \begin{pmatrix} w_y - v_z \\ u_z - w_x \\ v_x - u_y \end{pmatrix} \quad (62)$$

This vector is the axis of locally strongest rotation, i.e., it is perpendicular to the plane in which the locally highest amount of circulation takes place. The vorticity magnitude $|\omega|$ gives the strength of rotation and is often used to identify regions of high vortical activity. A vector field with $\omega = \mathbf{0}$ is called *irrotational* or *curl-free*, with the important subclass of *conservative* vector fields, i.e., vector fields which are the gradient of a scalar field. Note that Geometric Algebra (see section “Geometric Algebra” and Sect. 4) treats Eqs. (61) and (62) as an entity, called the geometric derivative. The identification of vortices is a major subject in fluid dynamics. The most widely used quantities for detecting vortices are based on a decomposition of the Jacobian matrix $\mathbf{J} = \mathbf{S} + \boldsymbol{\Omega}$ into its symmetric part, the strain tensor

$$\mathbf{S} = \frac{1}{2}(\mathbf{J} + \mathbf{J}^T) \quad (63)$$

and its antisymmetric part, the vorticity tensor

$$\boldsymbol{\Omega} = \frac{1}{2}(\mathbf{J} - \mathbf{J}^T) = \begin{pmatrix} 0 & -\omega_3 & \omega_2 \\ \omega_3 & 0 & -\omega_1 \\ -\omega_2 & \omega_1 & 0 \end{pmatrix} \quad (64)$$

with ω_i being the components of vorticity (62). While $\boldsymbol{\Omega}$ assesses vortical activity, the strain tensor \mathbf{S} measures the amount of stretching and folding which drives mixing to occur.

Inherent to the decomposition of the flow field gradient \mathbf{J} into \mathbf{S} and $\boldsymbol{\Omega}$ is the following duality: vortical activity is high in regions where $\boldsymbol{\Omega}$ dominates \mathbf{S} , whereas strain is characterized by \mathbf{S} dominating $\boldsymbol{\Omega}$.

In order to identify vortical activity, Jeong et al. used this decomposition in [47] to derive the vortex region quantity λ_2 as the second largest eigenvalue of the symmetric tensor $\mathbf{S}^2 + \boldsymbol{\Omega}^2$. Vortex regions are identified by $\lambda_2 < 0$, whereas $\lambda_2 > 0$ lacks physical interpretation. λ_2 does not capture stretching and folding of fluid particles and hence does not capture the vorticity-strain duality.

The Q -criterion of Hunt [46], also known as the Okubo-Weiss criterion, is defined by

$$Q = \frac{1}{2}(\|\boldsymbol{\Omega}\|^2 - \|\mathbf{S}\|^2) = \|\omega\|^2 - \frac{1}{2}\|\mathbf{S}\|^2 \quad (65)$$

where Q is positive and the vorticity magnitude dominates the rate of strain. Hence it is natural to define vortex regions as regions where $Q > 0$. Unlike λ_2 , Q has a

physical meaning also where $Q < 0$. Here the rate of strain dominates the vorticity magnitude.

Topology of Vector Fields

In this section we collect the first-order topological properties of steady 2D and 3D vector fields. The extraction of these topological structures has become a standard tool in visualization for the feature-based analysis of vector fields.

Critical Points

Considering a steady vector field $\mathbf{v}(\mathbf{x})$, an isolated *critical point* \mathbf{x}_0 is given by

$$\mathbf{v}(\mathbf{x}_0) = \mathbf{0} \quad \text{with} \quad \mathbf{v}(\mathbf{x}_0 \pm \epsilon) \neq \mathbf{0} \quad (66)$$

This means that \mathbf{v} is zero at the critical point but nonzero in a certain neighborhood.

Every critical point can be assigned an *index*. For a 2D vector field it denotes the number of counterclockwise revolutions of the vectors of \mathbf{v} while traveling counterclockwise on a closed curve around the critical point (for 2D vector fields, it is therefore often called the *winding number*). Similarly, the index of a 3D critical point measures the number of times the vectors of \mathbf{v} cover the area of an enclosing sphere. The index is always an integer and it may be positive or negative. For a curve/sphere enclosing an arbitrary part of a vector field, the index of the enclosed area/volume is the sum of the indices of the enclosed critical points. Mann et al. show in [54] how to compute the index of a region using Geometric Algebra. A detailed discussion of index theory can be found in [25, 31, 32].

Critical points are characterized and classified by the behavior of the tangent curves around it. Here we concentrate on first-order critical points, i.e., critical points with $\det(\mathbf{J}(\mathbf{x}_0)) \neq 0$. As shown in [37, 38], a first-order Taylor expansion of the flow around \mathbf{x}_0 suffices to completely classify it. This is done by an eigenvalue/eigenvector analysis of $\mathbf{J}(\mathbf{x}_0)$. Let λ_i be the eigenvalues of $\mathbf{J}(\mathbf{x}_0)$ ordered according to their real parts, i.e., $\operatorname{Re}(\lambda_{i-1}) \leq \operatorname{Re}(\lambda_i)$. Furthermore, let \mathbf{e}_i be the corresponding eigenvectors, and let \mathbf{f}_i be the corresponding eigenvectors of the transposed Jacobian $(\mathbf{J}(\mathbf{x}_0))^T$ (note that \mathbf{J} and \mathbf{J}^T have the same eigenvalues but not necessarily the same eigenvectors). The sign of the real part of an eigenvalue λ_i denotes – together with the corresponding eigenvector \mathbf{e}_i – the flow direction: positive values represent an *outflow* and negative values an *inflow* behavior. Based on this we give the classification of 2D and 3D first-order critical points in the following.

2D Vector Fields Based on the flow direction, first-order critical points in 2D vector fields are classified into:

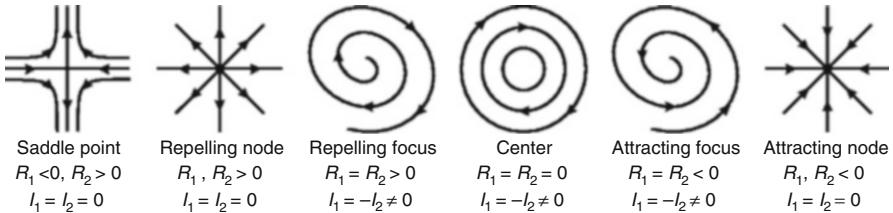

Fig. 23 Classification of first-order critical points. R_1, R_2 denote the real parts of the eigenvalues of the Jacobian matrix, while I_1, I_2 denote their imaginary parts (From [37])

$$\begin{array}{ll}
 \text{Sources :} & 0 < \text{Re}(\lambda_1) \leq \text{Re}(\lambda_2) \\
 \text{Saddles :} & \text{Re}(\lambda_1) < 0 < \text{Re}(\lambda_2) \\
 \text{Sinks :} & \text{Re}(\lambda_1) \leq \text{Re}(\lambda_2) < 0
 \end{array}$$

Thus, sources and sinks consist of complete outflow/inflow, while saddles have a mixture of both.

Sources and sinks can be further divided into two stable subclasses by deciding whether or not imaginary parts are present, i.e., whether or not λ_1, λ_2 is a pair of conjugate complex eigenvalues:

$$\begin{array}{ll}
 \text{Foci :} & \text{Im}(\lambda_1) = -\text{Im}(\lambda_2) \neq 0 \\
 \text{Nodes :} & \text{Im}(\lambda_1) = \text{Im}(\lambda_2) = 0
 \end{array}$$

There is another important class of critical points in 2D: a *center*. Here, we have a pair of conjugate complex eigenvalues with $\text{Re}(\lambda_1) = \text{Re}(\lambda_2) = 0$. This type is common in incompressible (divergence-free) flows but unstable in general vector fields since a small perturbation of \mathbf{v} changes the center to either a sink or a source. Figure 23 shows the phase portraits of the different types of first-order critical points following [37].

The index of a saddle point is -1 , while the index of a source, sink, or center is $+1$. It turns out that this coincides with the sign of $\det(\mathbf{J}(\mathbf{x}_0))$: a negative determinant denotes a saddle, a positive determinant a source, sink, or center. This already shows that the index of a critical point cannot be used to distinguish or classify them completely, since different types like sources and sinks have assigned the same index.

An iconic representation is an appropriate visualization for critical points, since vector fields usually contain a finite number of them. We will display them as spheres colored according to their classification: sources will be colored in red, sinks in blue, saddles in yellow, and centers in green.

3D Vector Fields Depending on the sign of $\text{Re}(\lambda_i)$ we get the following classification of first-order critical points in 3D vector fields:

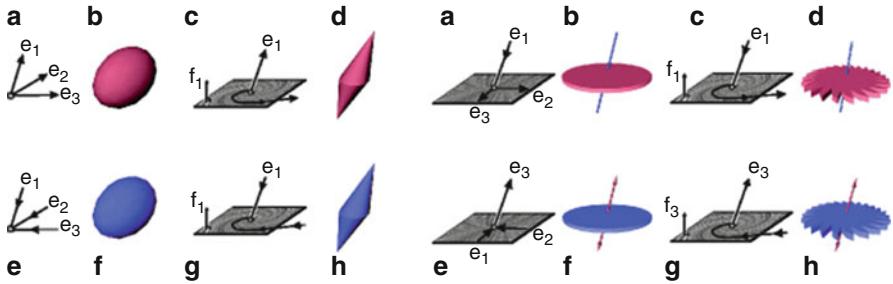

Fig. 24 Flow behavior around critical points of 3D vector fields and corresponding iconic representation

$$\begin{array}{ll}
 \text{Sources :} & 0 < \\
 \text{Repelling saddles : } & \text{Re}(\lambda_1) < 0 < \text{Re}(\lambda_2) \leq \text{Re}(\lambda_3) \\
 \text{Attracting saddles : } & \text{Re}(\lambda_1) \leq \text{Re}(\lambda_2) < 0 < \text{Re}(\lambda_3) \\
 \text{Sinks :} & \text{Re}(\lambda_1) \leq \text{Re}(\lambda_2) \leq
 \end{array}$$

Again, sources and sinks consist of complete outflow/inflow, while saddles have a mixture of both. A repelling saddle has one direction of inflow behavior (called *inflow direction*) and a plane in which a 2D outflow behavior occurs (called *outflow plane*). Similar to this, an attracting saddle consists of an *outflow direction* and an *inflow plane*.

Each of the four classes above can be further divided into two stable subclasses by deciding whether or not imaginary parts in two of the eigenvalues are present ($\lambda_1, \lambda_2, \lambda_3$ are not ordered):

$$\begin{array}{ll}
 \text{Foci :} & \text{Im}(\lambda_1) = 0 \text{ and } \text{Im}(\lambda_2) = -\text{Im}(\lambda_3) \neq 0 \\
 \text{Nodes :} & \text{Im}(\lambda_1) = \text{Im}(\lambda_2) = \text{Im}(\lambda_3) = 0
 \end{array}$$

As argued in [29], the index of a first-order critical point is given as the sign of the product of the eigenvalues of $\mathbf{J}(\mathbf{x}_0)$. This yields an index of +1 for sources and attracting saddles and an index of -1 for sinks and repelling saddles.

In order to depict 3D critical points, several icons have been proposed in the literature; see [30, 36, 37, 53]. Basically, we follow the design approach of [72, 85] and color the icons depending on the flow behavior: attracting parts (inflow) are colored blue, while repelling parts (outflow) are colored red (Fig. 24).

Separatrices

Separatrices are streamlines or stream surfaces which separate regions of different flow behavior. Here we concentrate on separatrices that emanate from critical points. Due to the homogeneous flow behavior around sources and sinks (either a complete outflow or inflow), they do not contribute to separatrices. Each saddle point creates two separatrices: one in forward and one in backward integration into the directions

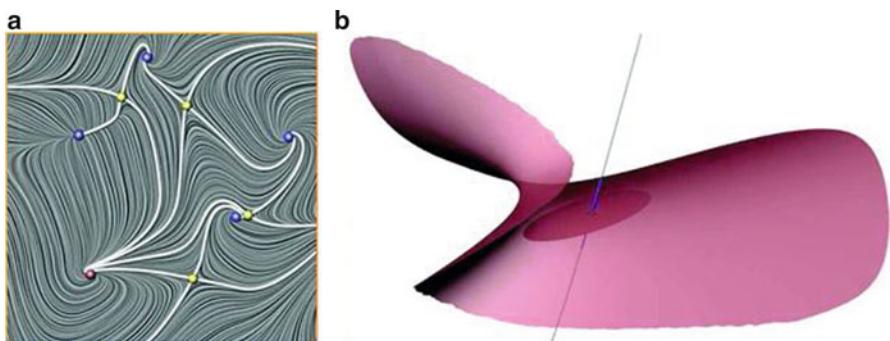

Fig. 25 Separatrices are streamlines or surfaces starting from saddle points into the direction of the eigenvectors

of the eigenvectors. For a 2D saddle point, this gives two separation lines (Fig. 25a). Considering a repelling saddle \mathbf{x}_R of a 3D vector field, it creates one separation curve (which is a streamline starting in \mathbf{x}_R in the inflow direction by backward integration) and a separation surface (which is a stream surface starting in the outflow plane by forward integration). Figure 25b gives an illustration. A similar statement holds for attracting saddles.

Other kinds of separatrices are possible as well: they can emanate from boundary switch curves [85] and attachment and detachment lines [48], or they are closed separatrices without a specific emanating structure [73].

Application

In the following, we exemplify the topological concepts described above by applying them to a 3D vector field. First, we extract the critical points by searching for zeros in the vector field. Based on an eigenvalue/eigenvector analysis, we identify the different types of the critical points. Starting from the saddles, we integrate the separatrices into the directions of the eigenvectors.

Figure 26 visualizes the electrostatic field around a benzene molecule. This data set was calculated on a 101^3 regular grid using the fractional charges method described in [70]. It consists of 184 first-order critical points depicted in Fig. 26a. The separation surfaces shown in Fig. 26b emanate from 78 attracting and 43 repelling saddles. Note how they hide each other as well as the critical points. Even rendering the surfaces in a semitransparent style does not reduce the visual clutter to an acceptable degree. This is one of the major challenges for the topological visualization of 3D vector fields.

Figure 26c shows a possible solution to this problem by showing the 129 *saddle connectors* that we found in this data set. Saddle connectors are the intersection curves of repelling and attracting separation surfaces and have been introduced to the visualization community in [72]. Despite the fact that saddle connectors can only indicate the approximate run of the separation surfaces, the resulting visualization gives more insight into the symmetry and three-dimensionality of the

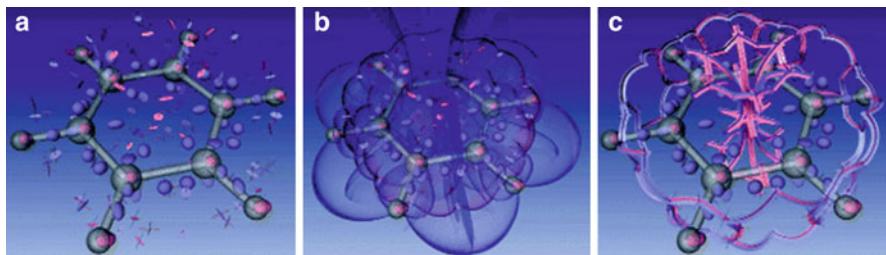

Fig. 26 Topological representations of the benzene data set with 184 critical points. (a) Iconic representation. (b) Due to the shown separation surfaces, the topological skeleton of the vector field looks visually cluttered. (c) Visualization of the topological skeleton using saddle connectors

data set. Saddle connectors are a useful compromise between the amount of coded information and the expressiveness of the visualization for complex topological skeletons.

6 Anisotropic Diffusion PDEs for Image Regularization and Visualization

Regularization PDEs: A Review

We consider a 2D multivalued image $\mathbf{I} : \Omega \rightarrow \mathbb{R}^n$ ($n = 3$ for color images) defined on a domain $\Omega \subset \mathbb{R}^2$ and denote by $I_i : \Omega \rightarrow \mathbb{R}$ the scalar channel i of \mathbf{I} :

$$\forall \mathbf{X} = (x, y) \in \Omega, \mathbf{I}_{(\mathbf{X})} = (I_{1(\mathbf{X})} \ I_{2(\mathbf{X})} \ \dots \ I_{n(\mathbf{X})})^T.$$

Local Multivalued Geometry and Diffusion Tensors

PDE-based regularization can be often seen as the local smoothing of an image \mathbf{I} along defined directions depending themselves on the local configuration of the pixel intensities, i.e., one wants basically to smooth \mathbf{I} in parallel to the image discontinuities. Naturally, this means that one has first to retrieve the *local geometry* of the image \mathbf{I} . It consists in the definition of these important features at each image point $\mathbf{X} = (x, y) \in \Omega$:

- Two orthogonal directions $\theta_{(\mathbf{X})}^+, \theta_{(\mathbf{X})}^- \in S^1$ along the local maximum and minimum variations of image intensities at \mathbf{X} . θ^- is then considered to be parallel to the local edge, when there is one.
- Two corresponding positive values $\lambda_{(\mathbf{X})}^+, \lambda_{(\mathbf{X})}^-$ measuring the effective variations of the image intensities along $\theta_{(\mathbf{X})}^+$ and $\theta_{(\mathbf{X})}^-$, respectively. λ^-, λ^+ are related to the local *contrast* of an edge.

For scalar images $I : \Omega \rightarrow \mathbb{R}$, this local geometry $\{\lambda^{+/-}, \theta^{+/-} | \mathbf{X} \in \Omega\}$ is usually retrieved by the computation of the smoothed gradient field $\nabla I_\sigma =$

$\nabla I * G_\sigma$ where G_σ is a 2D Gaussian kernel with standard deviation σ . Then, $\lambda^+ = \|\nabla I_\sigma\|^2$ is a possible measure of the local contrast of the contours, while $\theta^- = \nabla I_\sigma^\perp / \|\nabla I_\sigma\|$ gives the contours direction. Such a local geometry $\{\lambda^{+/-}, \theta^{+/-} | \mathbf{X} \in \Omega\}$ can be represented in a more convenient form by a field $\mathbf{G}: \Omega \rightarrow P(2)$ of second-order tensors (2×2 symmetric and semi-positive matrices):

$$\forall \mathbf{X} \in \Omega, \quad \mathbf{G}_{(\mathbf{X})} = \lambda^- \theta^- \theta^{-T} + \lambda^+ \theta^+ \theta^{+T}.$$

Eigenvalues of \mathbf{G} are indeed λ^- and λ^+ and corresponding eigenvectors are θ^- and θ^+ . The local geometry of scalar-valued images I can be then modeled by the tensor field $\mathbf{G}_{(\mathbf{x})} = \nabla I_{\sigma(\mathbf{x})} \nabla I_{\sigma(\mathbf{x})}^T$.

For multivalued images $\mathbf{I}: \Omega \rightarrow \mathbb{R}^n$, the local geometry can be retrieved in a similar way, by the computation of the field \mathbf{G} of the smoothed *structure tensors*. As explained in [22, 82], this is a nice extension of the gradient for multivalued images:

$$\forall \mathbf{X} \in \Omega, \quad \mathbf{G}_{\sigma(\mathbf{X})} = \left(\sum_{i=1}^n \nabla I_{i\alpha(\mathbf{X})} \nabla I_{i\alpha(\mathbf{X})}^T \right)_* G_\sigma \quad \text{where} \quad \nabla I_{i\alpha} = \begin{pmatrix} \frac{\partial I_i}{\partial x} \\ \frac{\partial I_i}{\partial y} \end{pmatrix} * G_\alpha \quad (67)$$

$\mathbf{G}_{\sigma(\mathbf{x})}$ is a very good estimator of the local multivalued geometry of \mathbf{I} at \mathbf{X} : its spectral elements give at the same time the vector-valued variations (by the eigenvalues λ^-, λ^+ of \mathbf{G}_σ) and the orientations (edges) of the local image structures (by the eigenvectors $\theta^- \perp \theta^+$ of \mathbf{G}_σ), σ being proportional to the so-called noise scale.

Once the local geometry \mathbf{G}_σ of \mathbf{I} has been determined, the way the regularization process is achieved is defined by another field $\mathbf{T}: \Omega \rightarrow P(2)$ of *diffusion tensors*, which specifies the local smoothing geometry that should drive the PDE flow. Of course, \mathbf{T} depends on the targeted application, and most of the time it is constructed from the local geometry \mathbf{G}_σ of \mathbf{I} . It is thus defined from the spectral elements λ^-, λ^+ and θ^-, θ^+ of \mathbf{G}_σ . In [19, 78], the following expression is proposed for image regularization:

$$\forall \mathbf{X} \in \Omega, \quad \mathbf{T}_{(\mathbf{X})} = f_{(\lambda^+, \lambda^-)}^- \theta^- \theta^{-T} + f_{(\lambda^+, \lambda^-)}^+ \theta^+ \theta^{+T} \quad (68)$$

where

$$f_{(\lambda^+, \lambda^-)}^- = \frac{1}{(1 + \lambda^+ + \lambda^-)^{p_1}} \quad \text{and} \quad f_{(\lambda^+, \lambda^-)}^+ = \frac{1}{(1 + \lambda^+ + \lambda^-)^{p_2}} \quad \text{with } p_1 < p_2$$

are the two functions which set the strengths of the desired smoothing along the respective directions θ^-, θ^+ . This latest choice basically says that if a pixel \mathbf{X} is located on an image contour ($\lambda_{(\mathbf{x})}^+$ is high), the smoothing on \mathbf{X} would be performed mostly along the contour direction $\theta_{(\mathbf{x})}^-$ (since $f_{(\dots)}^+ \ll f_{(\dots)}^-$). Conversely, if a pixel \mathbf{X} is located on a homogeneous region ($\lambda_{(\mathbf{x})}^+$ is low), the smoothing on \mathbf{X} would be

performed in all possible directions (isotropic smoothing), since $f_{(\dots)}^+ \simeq f_{(\dots)}^-$ (and then $\mathbf{T} \simeq \mathbb{I}_d$). Predefining the smoothing geometry \mathbf{T} of each applied PDE iteration is the first stage of most of the PDE-based regularization algorithms. Most of the differences between existing regularization methods (as in [2,3,10,18,19,49,52,58,59,67–69]) lie first on the definition of \mathbf{T} , but also on the kind of the diffusion PDE that will be used indeed to perform the desired smoothing.

Divergence-Based PDEs

One of the common choices to smooth a corrupted multivalued image $\mathbf{I}: \Omega \rightarrow \mathbb{R}^n$ following a local smoothing geometry $\mathbf{T}: \Omega \rightarrow \mathcal{P}(2)$ is to use the divergence PDE:

$$\forall i = 1, \dots, n, \quad \frac{\partial I_i}{\partial t} = \operatorname{div}(\mathbf{T} \nabla I_i) \quad (69)$$

The general form of this now classical PDE for image regularization has been introduced by Weickert in [82] and adapted for color/multivalued images in [83]. In this latter case, the tensor field \mathbf{T} is chosen the same for all image channels I_i , ensuring that channels are smoothed with a *coherent multivalued geometry* which takes the correlation between channels into account (since \mathbf{T} depends on \mathbf{G}). Equation (69) unifies a lot of existing scalar or multivalued regularization approaches and proposes at the same time two interpretation levels of the regularization process:

- *Local interpretation:* Equation (69) may be seen as the physical law describing local diffusion processes of the pixels individually regarded as temperatures or chemical concentrations in an anisotropic environment which is locally described by \mathbf{T} .
- *Global interpretation:* The problem of image regularization can be regarded as the minimization of the energy functional $E(\mathbf{I})$ by a gradient descent (i.e., a PDE), coming from the Euler-Lagrange equations of $E(\mathbf{I})$ [3, 19, 49, 51, 78]:

$$E(\mathbf{I}) = \int_{\Omega} \psi(\lambda^+, \lambda^-) d\Omega \quad \text{where } \psi : \mathbb{R}^2 \rightarrow \mathbb{R} \quad (70)$$

- It results in a particular case of the PDE (69), with $\mathbf{T} = \frac{\partial \Psi}{\partial \lambda} \theta^- \theta^{-T} + \frac{\partial \Psi}{\partial \lambda^+} \theta^+ \theta^{+T}$, where λ_+, λ_- are the two positive eigenvalues of the *non-smoothed* structure tensor field $\mathbf{G} = \sum_i \nabla I_i \nabla I_i^T$ and θ_+, θ_- are the corresponding eigenvectors.

Unfortunately, there are local configurations where the PDE (69) *does not fully respect the geometry* \mathbf{T} and where the smoothing is performed in unexpected directions. For instance, considering (69) with tensor fields $\mathbf{T}_{1(x)} = \left(\frac{\nabla I}{\|\nabla I\|} \right) \left(\frac{\nabla I}{\|\nabla I\|} \right)^T$ (purely anisotropic) and $\mathbf{T}_{2(x)} = \mathbb{I}_d$ (purely isotropic) lead both to the heat equation $\frac{\partial I}{\partial t} = \Delta I$ which has obviously an isotropic smoothing behavior. Different tensors fields \mathbf{T} with different shapes (isotropic or anisotropic) may define the same regularization behavior. This is due to the fact that the divergence implicitly

introduces a dependance on the *spatial variations* of the tensor field \mathbf{T} , so it hampers the design of a pointwise smoothing behavior.

Trace-Based PDEs

Alternative PDE-based regularization approaches have been proposed in [3, 51, 68, 69, 78] in order to smooth an image directed by a local smoothing geometry. They are insipit very similar to the divergence equation (69), but based on a *trace* operator:

$$\forall i = 1, \dots, n, \quad \frac{\partial I_i}{\partial t} = \text{trace}(\mathbf{T}\mathbf{H}_i) \quad \text{with } \mathbf{H}_i = \begin{pmatrix} \frac{\partial^2 I_i}{\partial x^2} & \frac{\partial^2 I_i}{\partial x \partial y} \\ \frac{\partial^2 I_i}{\partial x \partial y} & \frac{\partial^2 I_i}{\partial y^2} \end{pmatrix} \quad (71)$$

\mathbf{H}_i stands for the Hessian of I_i . Equation (71) is in fact nothing more than a tensor-based expression of the PDE $\frac{\partial \mathbf{I}}{\partial t} = f_{(\lambda^-, \lambda^+)}^- \mathbf{I}_{\theta^- \theta^-} + f_{(\lambda^-, \lambda^+)}^+ \mathbf{I}_{\theta^+ \theta^+}$ where $\mathbf{I}_{\theta^- \theta^-} = \frac{\partial^2 \mathbf{I}}{\partial \theta^- \partial \theta^-}$. This PDE can be viewed as a simultaneous combination of two orthogonally oriented and weighted 1D Laplacians. In case of multivalued images, each channel I_i of \mathbf{I} is here also coherently smoothed with the same tensor field \mathbf{T} . As demonstrated in [78], the evolution of Eq.(71) has a geometric meaning in terms of local linear filtering: it may be seen locally as the application of very small convolutions around each point \mathbf{X} with a Gaussian mask $G_t^\mathbf{T}$ oriented by the tensor $\mathbf{T}_{(x)}$:

$$G_{t(\mathbf{X})}^\mathbf{T} = \frac{1}{4\pi t} \exp\left(-\frac{\mathbf{X}^T \mathbf{T}^{-1} \mathbf{X}}{4t}\right)$$

This ensures that the smoothing performed by (71) is indeed oriented along the predefined smoothing geometry \mathbf{T} . As the trace is not a differential operator, the spatial variation of \mathbf{T} does not trouble the diffusion directions here and two different tensor fields will necessarily lead to different smoothing behaviors. Under certain conditions, the divergence PDE (69) may be also developed as a trace formulation (71). But in this case, the tensors inside the trace and the divergence *are not the same* [78]. Note that trace-based equations (71) are rather directly connected to functional minimizations, especially when considering the multivalued case. For scalar-valued images ($n = 1$), some correspondences are known anyway [3, 19, 51].

Curvature-Preserving PDEs

Basically, the divergence and trace Eqs. (69) and (71) locally behave as oriented Gaussian smoothing whose strengths and orientations are directly related to the tensors $\mathbf{T}_{(x)}$. But on curved structures (like corners), this behavior is not desirable: in case of high variations of the edge orientation θ^- , such a smoothing will tend to *round* corners, even by conducting it only along θ^- (an oriented Gaussian is not curved by itself). To avoid this over-smoothing effect, regularization PDEs may try to stop their action on corners (by vanishing tensors $\mathbf{T}_{(x)}$ there, i.e., $f^- = f^+ = 0$),

but this implies the detection of curved structures on images that are themselves noisy or corrupted. This is generally a hard task.

To overcome this problem, curvature-preserving regularization PDEs have been introduced in [77]. We illustrate the general idea of these equations by considering the simplest case of image smoothing along a single direction, i.e., a *vector field* $\mathbf{w} : \Omega \rightarrow \mathbb{R}^2$ instead of a tensor-valued one \mathbf{T} . The two spatial components of \mathbf{w} are denoted $\mathbf{w}_{(x)} = (u_{(x)} v_{(x)})^T$.

The curvature-preserving regularization PDE that smoothes \mathbf{I} along \mathbf{w} is defined as

$$\forall i = 1, \dots, n, \quad \frac{\partial I_i}{\partial t} = \text{trace}(\mathbf{w}\mathbf{w}^T \mathbf{H}_i) + \nabla I_i^T \mathbf{J}_w \mathbf{w} \quad \text{with } \mathbf{J}_w = \begin{pmatrix} \frac{\partial u}{\partial x} & \frac{\partial u}{\partial y} \\ \frac{\partial v}{\partial x} & \frac{\partial v}{\partial y} \end{pmatrix} \quad (72)$$

where \mathbf{J}_w stands for the Jacobian of \mathbf{w} . Equation (72) simply adds a term $\nabla I_i^T \mathbf{J}_w \mathbf{w}$ to the corresponding trace-based PDE (71) that would smooth \mathbf{I} along \mathbf{w} . This term naturally depends on the variation of the vector field \mathbf{w} . Actually, it has been demonstrated in [77] that Eq.(72) is equivalent to the application of this one-dimensional PDE flow:

$$\frac{\partial I_i(\mathcal{C}_{(a)})}{\partial t} = \frac{\partial^2 I_i(\mathcal{C}_{(a)})}{\partial a^2} \quad \text{with} \quad \begin{cases} \mathcal{C}_{(0)}^X = \mathbf{X} \\ \frac{\partial \mathcal{C}_{(a)}^X}{\partial a} = \mathbf{w}(\mathcal{C}_{(a)}^X) \end{cases} \quad (73)$$

where $\mathcal{C}_{(a)}^X$ is the streamline curve of \mathbf{w} , starting from \mathbf{X} and parameterized by $a \in \mathbb{R}$. Thus, Eq.(73) is nothing more than the *one-dimensional heat flow constrained on the streamline curve \mathcal{C}* . This is indeed very different from a heat flow *oriented* by \mathbf{w} , as in the formulation $\frac{\partial I_i}{\partial t} = \frac{\partial^2 I_i}{\partial \mathbf{w}^2}$ since the curvatures of the streamline of \mathbf{w} are now implicitly taken into account. In particular, Eq.(73) has the interesting property to vanish when the image intensities are constant on the streamline \mathcal{C}^X , whatever the curvature of \mathcal{C}^X is. So, defining a field \mathbf{w} that is tangent everywhere to the image structures allows the preservation of these structures during the regularization process, even if they are curved (such as corners).

Moreover, as Eq.(73) is a 1D heat flow on a streamline \mathcal{C}^X , its solution at time dt can be estimated by convolving the image signal lying on the streamline \mathcal{C}^X by a 1D Gaussian kernel [50]:

$$\forall \mathbf{X} \in \Omega, \quad \mathbf{I}_{(\mathbf{X})}^{[dt]} = \int_{-\infty}^{+\infty} \mathbf{I}^{[t=0]} \left(\mathcal{C}_{(p)}^X \right) G^{dt}(p) dp \quad (74)$$

This formulation is very close to the line integral convolution (LIC) framework [17], which has been introduced as a visualization technique to render a textured image representing a 2D vector field \mathbf{w} . As we are considering diffusion equations here, the weighting function in Eq.(74) is naturally Gaussian. This geometric interpretation particularly allows to implement curvature-preserving PDEs (74) using Runge-

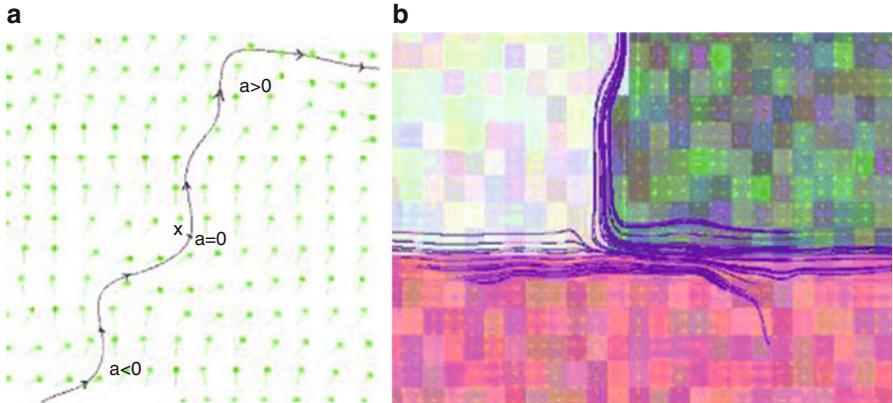

Fig. 27 Streamline C^X of various vector fields $w: \Omega \rightarrow \mathbb{R}^2$. (a) Streamline of a general field w . (b) Example of streamlines when w is the lowest eigenvector of the smoothed structure tensor \mathbf{G}_σ (one block is one color pixel)

Kutta estimations of the streamline geometries, leading to sub-pixel precision of the smoothing process.

This single-direction smoothing PDE (72) can be easily extended to deal with a tensor-valued geometry $\mathbf{T}: \Omega \rightarrow \text{P}(2)$, in order to be able to represent both *anisotropic* or *isotropic* regularization behaviors. This is done by decomposing the tensor field \mathbf{T} as the sum of several single-directional tensors, i.e., $\mathbf{T} = \frac{2}{\pi} \int_{\alpha=0}^{\pi} (\sqrt{\mathbf{T}} a_\alpha) (\sqrt{\mathbf{T}} a_\alpha)^T d\alpha$, where $a_\alpha = \cos\alpha \sin\alpha^T$. This naturally suggests to decompose a tensor-driven regularization process into a sum of single-direction smoothing processes, each of them being expressed as a curvature-preserving PDE. As a result, the corresponding curvature-preserving PDE directed by a tensor field \mathbf{T} is

$$\forall i = 1, \dots, n, \quad \frac{\partial I_i}{\partial t} = \text{trace}(\mathbf{T} \mathbf{H}_i) + \frac{2}{\pi} \nabla I_i^T \int_{\alpha=0}^{\pi} \mathbf{J}_{\sqrt{\mathbf{T}} a_\alpha} \sqrt{\mathbf{T}} a_\alpha d\alpha \quad (75)$$

When \mathbf{T} is locally isotropic (on homogeneous region), Eq. (75) is similar to a 2D heat flow, while when \mathbf{T} is locally anisotropic (on an image contour), it behaves as a 1D heat flow on the streamline curve following the contour path, thus taking care of its curvature (Fig. 27).

Applications

Some application results are presented here, mainly based on the use of the curvature-preserving PDEs (75). A specific diffusion tensor field \mathbf{T} has been used to adapt the smoothing behavior to each targeted application.

(the in-painting mask covers the cage)

Fig. 29 Image inpainting using PDE-based regularization techniques

Color Image Denoising

Image denoising is a direct application of regularization methods. Sensor inaccuracies, digital quantifications, or compression artifacts are indeed some of the various noise sources that can affect a digital image, and suppressing them is a desirable goal. Figure 28 illustrates how curvature-preserving PDEs (75) can be successfully applied to remove such noise artifacts while preserving the thin structures of the processed images. The tensor field \mathbf{T} is chosen as in Eq. (68).

Color Image Inpainting

Image inpainting consists in filling in missing (user-defined) image regions by guessing pixel values such that the reconstructed image still looks natural. Basically, the user provides one color image $\mathbf{I}: \Omega \rightarrow \mathbb{R}^3$ and one *mask* image $M: \Omega \rightarrow \{0, 1\}$.

The inpainting algorithm must fill in the regions where $M(X) = 1$, by means of some intelligent interpolations. Image inpainting using diffusion PDEs has been proposed, for instance, in [10, 18, 78]. Inpainting is a direct application of our proposed curvature-preserving PDE (75), where the diffusion equation is applied only on the regions to inpaint, allowing the neighbor pixels to diffuse inside these regions in an anisotropic way (Fig. 29).

Visualization of Vector and Tensor Fields

Regularization PDEs such as (69), (71), and (75) can be also used to visualize a vector field $\mathbf{w} : \Omega \rightarrow \mathbb{R}^2$ or a tensor field $\mathbf{G} : \Omega \rightarrow \text{P}(2)$; see also Sect. 5. The idea is to smooth an originally pure noisy image using a diffusion tensor field \mathbf{T} which is chosen to be $\mathbf{T} = \mathbf{w}\mathbf{w}^T$ or $\mathbf{T} = \mathbf{G}$ or other variations as long as the smoothing geometry is indeed directed by the field we want to visualize. Whereas the PDE evolution time t goes by, more global structures of the considered fields appear, i.e., a visualization *scale-space* is constructed. The same PDE-based visualization technique allows to display interesting global rendering of DT-MRI volumes (medical imaging) displaying “stuffed” views of the fiber map (Fig. 30).

7 Conclusion

This chapter presented a selection of possible approaches for systematic treatment of multidimensional data sets and algorithms based on differential methods. Such data sets may be the result of some image processing, for instance, a three-dimensional stack of CT slices in medical imaging used to extract a triangular surface representing bones. Visual data analysis is particularly important for big data. Many such data sources originate in computational sciences, produced by algorithms based on differential methods. Utilizing the same concepts for image processing and multidimensional data in general allows generalization of methods and increased software reusability and applicability. Section 2 reviews a mathematically founded model to structure multidimensional data covering a wide category of data types. Since there is no commonly agreed standard in the scientific community on how to lay out multidimensional data for computational purposes, a multitude of alternative models exist. For a specific application, it is subject of investigation whether some specific model would fit all the respective requirements. Section 3 delves deeper into the modeling of mathematical operators using computational data structures. A mathematical algorithm must be cast into a discretized form in order to be applicable in a numerical code. Differential forms are a mathematical abstraction allowing coordinate-free formulations of partial differential equations, which are the basis of many physical and engineering methods, as well as image processing. Geometric Algebra, reviewed in Sect. 4, extends the notions of the commonly known vector algebra to form a full system of algebraic operations to include (among others) the notion of “dividing vectors.” While unfamiliar at first, the result is a visually intuitive way to phrase complex algebraic operations, enabling better insight and more efficient implementation as compared to “ad hoc” approaches. An important

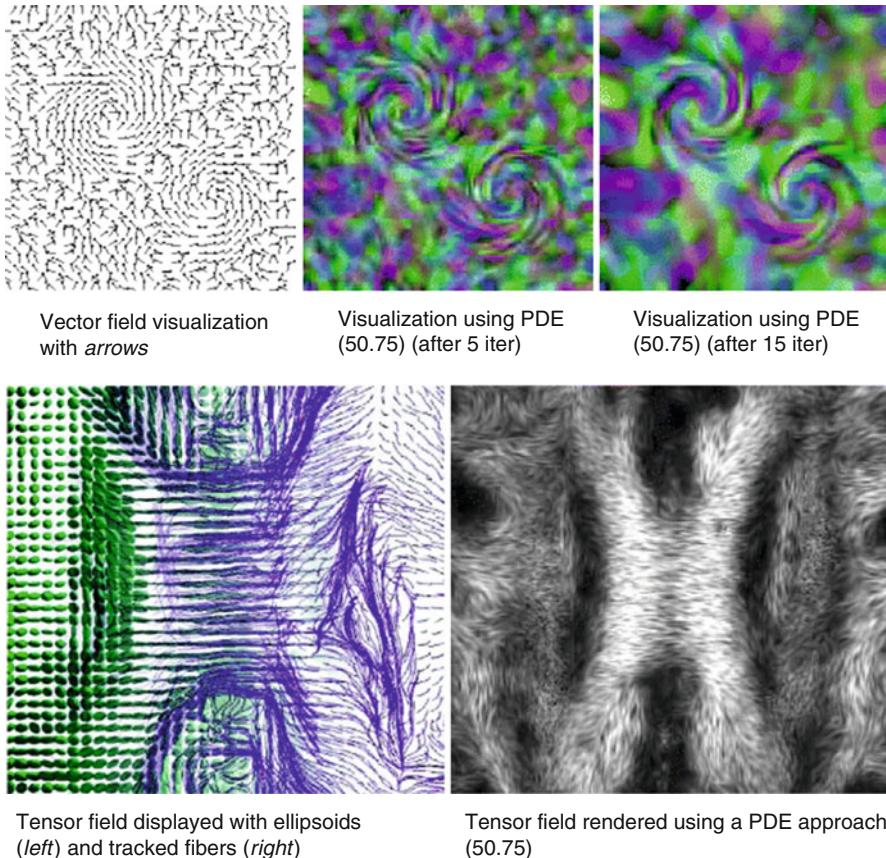

Fig. 30 Visualization of vector and tensor fields using PDEs

application of differential methods for multidimensional data is the investigation of features in vector fields. While primarily of interest to computational sciences such as computational fluid dynamics, identifying topological features in vector fields may well apply to color images with RGB channels and gradients of grayscale images or even more to stacks of images such as three-dimensional data and animation sequences. Section 5 presents some basics for feature detections in such data sets. While the application to animation sequences is beyond the scope of this chapter, utilizing the topological skeleton of some data set may well have potential for data compression or automatizing algorithms for motion pictures. Partial differential equations (PDEs) furthermore allow for direct improvement of image quality and feature reconstruction, as explained in the algorithms presented in Sect. 6. PDEs describing diffusion are particularly suitable for reducing noise in images, recovering lost features, as well as the direct visualization of vector and tensor fields. The set of presented algorithms in this chapter is still subject of active

research and neither a comprehensive nor the only reasonable approach; rather, the various aspects covered provide inspirations covering many scientific disciplines under one hood.
